CHAIRS' WELCOME

The 15th International Society of Scientometrics and Informetrics Conference took place at Boğaziçi University in Istanbul, from June 29 to July 4, 2015. The Conference was jointly organised by Boğaziçi University, Hacettepe University, and the TÜBİTAK ULAKBIM (Turkish Academic Network and Information Center – The Scientific and Technological Research Council of Turkey) under the auspices of ISSI – the International Society for Scientometrics and Informetrics.

The ISSI biennial conference is the premier international forum for scientists, research managers, authorities and information professionals to discuss the current status and progress in informetric and scientometric theories, concepts, tools, platforms, and indicators. In addition to theoretical and quantitative focus of the conference, the participants had the opportunity to discuss practical, cross-cultural, and multi-disciplinary aspects of information and library science, R&D-management, and science ethics, among other related topics.

The focus theme of ISSI2015 was "**the future of scientometrics**". Scientometrics and informetrics together represent a broad field with a rich history. Scientometrics has been responsible for creating tools for research assessment and evaluation, as well as for use in charting the flow of scientific ideas and people. Today, with the advancements of computing power, technology, and database management systems, the impact of scientometrics has become ubiquitous for scientists and science policy makers. However, the high diffusion of scientometric and informetric research has also brought a new wave of criticism and concern, as people grapple with issues of goal displacement and inappropriate use of indicators. The question facing the field is how best to move forward given the computational opportunities and the sociological concerns. Therefore, the goal of ISSI2015 was to highlight the best research in this field and to bring together scholars and practitioners in the area to discuss new research directions, methods, and theories, and to reflect upon the history of scientometrics and its implications.

The keynote given by Loet Leydesdorff demonstrated the potential of thinking of science as a complex institution. By building on the Triple Helix Model of University-Industry-Government relations, Dr. Leydesdorff showed that innovation systems can provide institutional mediation between knowledge production, wealth generation, and governance.

The second keynote, by Kevin Boyack, directly answered the challenge of the focus theme of ISSI2015, and proposed several opportunities to expand the field of scientometrics. Dr. Boyack called for increasing attention to funding, workforce, data and instrumentation, research objects, and innovation.

The conference included four special sessions on a range of topics, including performance indicators, algorithms for topic detection, empirical evaluation of education, research and innovation, and how scientometrics can be used to improve and inform university rankings. These special sessions included poster presentations, panel discussions, invited speakers, and public debates.

The increasing number of open-source software for scientometrics presents great opportunities for researchers. Four tutorials, organized on the first day of the conference, aimed to introduce a number of tools in depth: open source data analysis and visualization tools, citation exploration software, measurement of scholarly impact, and on social network analysis with the popular R software.

The Doctoral Forum, organized by Andrea Scharnhorst and Judit Bar-Ilan, is a meeting of senior researchers and selected doctoral students for presenting and discussing research projects and an

excellent way for students of getting valuable feedback, along with strong networking opportunities. This is the sixth ISSI Doctoral Forum and we are extremely happy about the interest it continues to receive from the community. Additionally, the prestigious Eugene Garfield Doctoral Dissertation Scholarship is given by the Eugene Garfield Foundation.

During the Conference, the Derek de Solla Price Award of the International Journal Scientometrics was given to Mike Thelwall, Professor of Information Science at the University of Wolverhampton (UK), in a special session organized for this purpose. This award recognizes excellence through outstanding, sustained career achievements in the field of quantitative studies of science and their applications.

The satellite workshops of the conference reflected the diversity of the field. In "**Mining Scientific Papers: Computational Linguistics and Bibliometrics",** researchers in bibliometrics and computational linguistics were brought together to study the ways bibliometrics can benefit from large-scale text analytics and sense mining of scientific papers, thus exploring the interdisciplinarity of Bibliometrics and Natural Language Processing. The workshop on "**Grand challenges in data integration for research and innovation policy**" dealt with problems of big, open and linked data. The "**Forecasting science: Models of science and technology dynamics for innovation policy"** workshop discussed methodology for predicting the circumstances leading to scientific or technological innovation. "**Workshop on Bibliometrics Education**" brought together educational institutions, employers, professional societies, and Bibliometrics researchers and professionals to tackle this problem. Finally, "**Google Scholar and related products"** was a highly interactive workshop on the benefits and limitations of some of the most important citation tools.

All contributions for the conference were evaluated by at least two reviewers of the Scientific Program Committee. The papers that required additional reviews were discussed by the Program Chairs before a decision was reached. From 228 full and research in progress paper submissions, 123 papers were accepted for publication (54 percent acceptance rate). 82 of these papers were full papers, and 41 were research in progress. There was a large number of paper submissions on social media, technology transfer, science policy and research assessment. From 123 poster and ignite talk submissions, 68 posters and 13 ignite talks were accepted (66 percent). The ignite talks were to increase discussion of underrepresented topics and novel ideas. Because of the large number of papers, and to allow proper discussion for each paper, four parallel sessions were implemented. Several poster sessions were organized, each containing a relatively manageable number of posters. The conference brought together researchers from 42 countries and the works of 458 researchers were presented.

We thank all our contributors for their submissions, the members of the Organizing Committee for their work, the Scientific Program Committee for their reviewing effort, the ISSI board for their trust and guidance, the Rectorate and the Faculty of Engineering of Boğaziçi University for their constant assistance and support, as well as the sponsors for their generous financial contributions. We particularly thank Metin Tunç (Thomson Reuters), Elif Gürses (formerly of TÜBİTAK ULAKBİM), Juan Gorraiz (Universitat Wien), Figen Atalan (Boğaziçi University), Orçun Madran (Hacettepe University) and Büşra Şahin (DEKON Congress & Tourism) for their help in organizing ISSI2015.

KEYNOTES

Increasing the Relevance of the ISSI Community in Today's Changing Scientific Landscape

Kevin W. Boyack

kboyack@mapofscience.com
SciTech Strategies, Inc., 8421 Manuel Cia Pl NE, Albuquerque, NM 87122 (USA)

The call for papers for the ISSI 2015 conference set forth a bold agenda by specifically asking for papers related to the "Future of Scientometrics". Many fields in science are what one might call primary fields in the same sense that there are primary colors. These are fields with a self-contained base and upon which other fields build. Scientometrics is not one of these primary fields, but rather operates on theories and data about the processes and outputs of science. We are, in essence, a service industry, and as a service industry we have the potential to exercise great influence on science as a whole. We also have the potential to flounder and die a slow death, or to be overtaken and replaced by another industry. In my opinion, our best opportunity to flourish as a field and community is to truly understand the structure, dynamics, and interactions of science as a whole and in parts, at multiple levels of detail, and to not only measure things but to develop predictive capacities. Opportunities exist for us to expand our view beyond traditional roles, if we can but see what they are.

In this talk I will propose that our opportunities to expand and flourish as a community can be enhanced in several ways. First, it is time for most of us to become far more acquainted with the work done by the pioneers in our field, and in related fields, than we currently are. Scientometrics is a melting pot in many ways, populated to a large degree by those trained in other fields – physics, chemistry, engineering, etc. Many of us are lacking in historical knowledge. We hear the names of Kuhn, Price, Merton, Crane, Latour, and many others, but how many of us are really familiar with not only their popular contributions, but also their smaller experiments that are less well known? There is much to be learned from the work started (and often abandoned due to lack of resources) by these giants that is perhaps even more relevant today than before.

Second, as a community we are highly focused on measuring the "arguments" (documentation) of science, whether using citation data or altmetrics. The science system, however, is comprised of far more than "arguments". Some of us do, to a lesser degree, address other parts of the science system – funding, workforce, data and instrumentation, research objects, and innovation. However, it is rare to see analyses that integrate multiple parts of the science system and explore their interactions. Our influence as a community can certainly be increased if we focus more on these interactions.

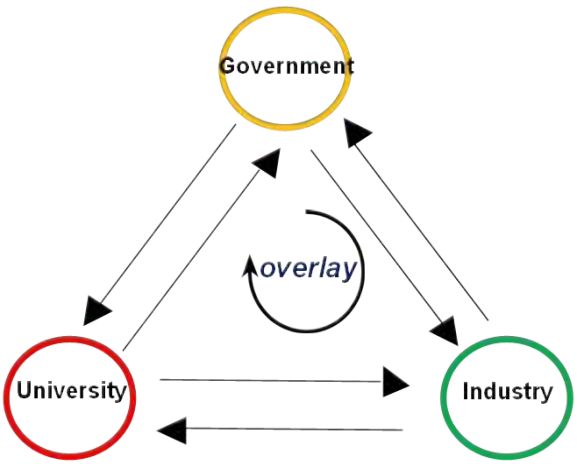
Third, and perhaps most controversially, I suggest that we seek to understand the effect of motivations on science. Perhaps the best way to do this is to start with ourselves, and reflect on "Why do we do what we do?" Are our motives aligned with the purest motives of society? Are we seeking, as individuals and as a community, to serve science and society, or are we seeking for self-aggrandizement? Each of us is many things in life, among which being a researcher or policy maker or scientometrician is only one facet. Often our choice of a career, and of the particular topics we research and for which we advocate are directly tied to these motives. Each of us has a story. Once we understand how our stories drive us to do what we do, then perhaps we can extend that knowledge to better understand science as a whole and how it is driven by the interacting motivations of researchers and institutions. Dick Klavans and I recently created a map of altruism, and were amazed at how much the motives in that map reflect why we do what we do. The parts of the science system mentioned above are all motivated differently. Do we consider this in our models and analyses? How would our analyses change if we were to consider motivation?

Although this talk will use some examples from my current research, it will be largely philosophical, and will raise far more questions than it will give answers. I fully expect many to disagree with much of what will be presented. Nevertheless, I submit that raising these questions at this time has the potential to cause us all to think critically, and that such critical thinking is the first step toward increasing our relevance as a community in the scientific world of the future.

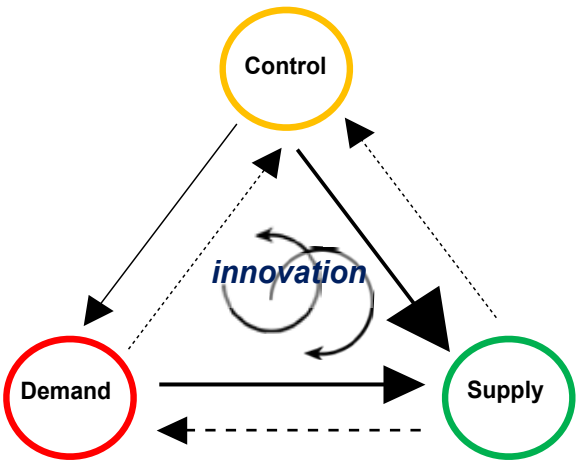
The Triple Helix of Knowledge Production, Wealth Generation, and Normative Control: A Neo-evolutionary Model of Innovation Ecosystems

Loet Leydesdorff

loet@leydesdorff.net
University of Amsterdam, Amsterdam School of Communication Research, Amsterdam, The Netherlands



The neo-institutional model of the Triple Helix of University-Industry-Government Relations (Etzkowitz & Leydesdorff, 1995).



The neo-evolutionary model of innovation in three dimensions (Leydesdorff & Zawdie, 2010; Lawton-Smith & Leydesdorff, 2014).

When three sub-dynamics can operate as selection environments on the variations among one another, a communication field can be generated that proliferates auto-catalytically using each third actor as a feedback or feed forward operating on mutual relations in clockwise or counter-clockwise rotations. This model improves on the neo-Schumpeterian models of innovation systems in evolutionary economics and technology studies, while these models assume a dialectics or co-evolution, for example, between trajectories and selection environments. By extending the Lotka-Volterra equations from two to three dimensions, Ivanova & Leydesdorff (2014) proved the possible emergence of a communication field ("overlay") as an emerging (fourth) subdynamic. In the communication field new options can be generated by sharing meaning provided to the events (Leydesdorff & Ivanova, 2014). This extension of innovative options can be measured as redundancy in terms of bits of information. Petersen, Rotolo & Leydesdorff (in preparation) analyzed Medicals Subject Headings (MEDLINE/PubMed) of approximately 100,000 articles in three research areas including technological breakthroughs in medical innovation (honored with Nobel Prizes in Physiology and Medicine) in terms of "Diseases" (demand), "Drugs and Chemicals" (supply), and "Techniques" (control). Periods of synergy (operationalized as redundancy) can be distinguished from periods in which outward exploration prevails. Innovation systems (e.g., at national or regional levels, but also sectorial ones such as in medicine) provide institutional mediation between wealth generation, knowledge

production, and governance as different perspectives. In the case of China, Leydesdorff & Zhou (2014) found, for example, that the four municipalities play a mediating role above expectation between knowledge production and wealth generation. Note that the three dimensions can differently be operationalized depending on the research design (e.g., as "university," "industry," and "government"); but the dimensions have to be specified as analytically independent so that the three co-variations can be measured (Leydesdorff, Park, & Lengyel, 2014).

Abstract
The research field of altmetrics has gathered increased attention within scientometrics. Here, we pay particular attention to the connection between countries of readers of papers (at Mendeley) and countries of authors as well as citers of papers (from Web of Science). This study uses the Mendeley application programming interface to gather Mendeley reader statistics for the comprehensive F1000Prime publication set (n_r=149,227 records, n_p = 114,582 papers). F1000Prime is a post-publication peer-review system for papers of the biomedical research. The F1000 papers are rated by experts as good, very good, or exceptional. We find no significant differences between authorship, readership, and authorship of citing papers broken down into countries across quality levels. Most authors, citers, and readers are located in the USA followed by UK and Germany. Except for a few cases, we find that percentages of readers, citers, and authors are rather well balanced. Although Russia and China host many large research groups with a large publication output, both countries are below the top 10 countries ordered according to readership percentages.

Conference Topic
Altmetrics

Introduction
Online reference managers can be seen as the scientific variant of social bookmarking platforms, in which users can save and tag web resources (e.g. blogs or web sites). The best known online reference managers with a social networking component are Mendeley (www.mendeley.com) and CiteULike (www.citeulike.org), which were launched in 2004 (CiteULike) and 2008 (Mendeley), and can be used free of charge (Li et al., 2012). Mendeley – in 2013 acquired by Elsevier (Rodgers and Barbrow 2013) – has developed since then into the most popular product among the reference managers (Haustein 2014), and most empirical studies involving reference managers have used data from Mendeley. Mendeley has obtained a rather unique position as an online reference manager with desktop and mobile app versions. Furthermore, Mendeley offers social networking services, which go beyond the capability of most reference managers.

The platforms allow users to save or organize literature, to share literature with other users, as well as to save keywords and comments on a publication (or to assign tags to them) (Bar-Ilan, et al., 2014, Haustein et al., 2014). Even if it is literature that is mainly saved by the users, they can also add to a library other products of scientific work (such as data sets, software and presentations). The providers of online reference managers make available a range of data for the use of publication by the users: The most important numbers are the user counts, which provide the number of readers of publications via the saves of publications (Li et al., 2012). The readers

can be differentiated into different status and country groups as well as scientific sub-disciplines. The readers' data from Mendeley is also evaluated to make suggestions to the users for new papers and potential collaborators (Priem & Hemminger, 2010, Galloway et al., 2013). Although it is not quite known what Mendeley reader counts mean exactly, they can be viewed as citations to be. Many Mendeley users bookmark a paper in Mendeley with the intend to cite this paper in a forthcoming manuscript. As this is not the only reason to bookmark a publication in Mendeley, it is clear that Mendeley reader counts measure also something different than citations. This additional part of a publication's impact is another means to measure its usage.

In this study, the country information of Mendeley readers is used to compare the readers of papers with their authors as well as those authors who have cited the papers. We are interested in differences and similarities between the countries worldwide: Which are the countries in which the scientists read (or cite) more than publish and vice versa? In which countries are the numbers of authors, readers, and citers similar? As publication set, we used papers from the post-publication peer review system of F1000. It is an advantage of this dataset that each paper is classified according to its quality (based on expert scores). Thus, we are able to investigate the distribution of authors, readers, and citers for papers with different quality.

Literature review

Mendeley is used chiefly by science, technology, engineering and mathematics researchers (Neylon et al., 2014). According to a questionnaire in the bibliometric community (Haustein et al., 2014), 77% of those questioned know Mendeley. But Mendeley is actually used by only 26% of those questioned. However, with respect to the number of saved papers there are large differences between disciplines: Thus, for example, only about a third of the humanities articles indexed in the Web of Science (WoS) can also be found in Mendeley; however, in the social sciences, it is more than half (Mohammadi & Thelwall, 2013). Among the reference managers, Mendeley seems to have the best coverage of globally published literature (Haustein et al., 2014, Zahedi et al., 2014). The large user population and coverage result in Mendeley being seen as the most promising new source for evaluation purposes (among the online reference managers) (Haustein, 2014). Priem (2014) sees Mendeley already as a rival to commercial databases (such as Scopus and WoS).

With a view to the use of the data from online reference managers in research evaluation, bookmarks to publications (i.e. the saving of bibliographic data about publications in libraries) express the interest of a user in a publication (Weller & Peters 2012). But this interest is very variable; the spectrum extends from simple saving of the bibliographic data of a publication up to painstaking reading, annotation and use of a publication (Shema et al., 2014, Thelwall & Maflahi, in press). According to Taylor (2013), the following motives could play a role in the saving of a publication: "Other people might be interested in this paper … I want other people to think I have read this paper … It is my paper, and I maintain my own library … It is my paper, and I want people to read it … It is my paper, and I want people to see that I wrote it" (p. 20). The problem of the unclear meaning of the saving (or naming) of a publication is common to bookmarks in reference managers and also many other traditional and alternative metrics: Thus, for example, traditional citations can mean either simple naming citations in the introduction to a paper, as well as extensive discussions in the results or discussion sections (Bornmann & Daniel, 2008). Traditional citations can also be self-citations.

The data from online reference managers is seen as one of the most attractive sources for the use of altmetrics in research evaluation (Sud & Thelwall, in press). The following reasons are chiefly given for this:

- The collection of literature in reference managers is – similar to the way this is the case with citations and downloads of publications – a by-product of existing workflows (Haustein 2014). This is why saves are appropriate as an alternative metric chiefly for the measurement of impact in areas of work where literature is collected and evaluated (such as with researchers in academic and industrial research, students and journalists).
- Whereas the impact of classical papers can be measured very well via citations in databases (such as the WoS), this is hardly possible with other types of publication such as books or reports.
- According to Mohammadi and Thelwall (2014), usage data of literature may be partially available (i.e. from publishers); but there is a shortage of global and publisher-independent usage data.
- Data sets of online reference managing platforms are highly accessible. The data may be available via API or database dumps (Priem & Hemminger, 2010).

However, the use of data from online reference managers is not only seen as advantageous, but also as problematic:

- Since not everybody who reads and uses scientific literature works with an online reference manager (and Mendeley, particularly), there is the problem that the evaluation of saved data only takes into account a part of the actual readership. Among researchers this part is probably younger, more sociable and more technologically-oriented than average for researchers (Sud & Thelwall, in press).
- The data which are entered by users into the online reference managers are erroneous or incomplete. This can lead to saves not being able to be associated unambiguously with a publication (Haustein, 2014).

Similar to Twitter citations, readership counts can also be manipulated relatively simply (for example with artificially generated spam) (Bar-Ilan et al., 2014).

Many of the empirical-statistical studies into social bookmarking – according to Priem and Hemminger (2010) – deal with tags and tagging. Seen overall, the studies come to the conclusion that exact overlaps of tags and professionally created metadata are rare; most matches are found when comparing tags and title terms (Haustein & Peters, 2012). A large part of the studies into online reference managers has evaluated the correlation between traditional citations (from Scopus, Google Scholar and the WoS) and bookmarks in Mendeley and/or CiteULike. The meta-analysis of (Bornmann, 2015) shows that the correlation is medium to large (CiteULike pooled r=0.23; Mendeley pooled r=0.51).

Two studies have already investigated country information from Mendeley: (1) Haustein and Larivière (2014) analyzed the journal *Aslib Proceedings* (AP) with a set of indicators from several perspectives. The results show that the largest share of AP papers in the last eight years were written by authors affiliated to UK (58 %), Iran (6 %), South Africa and USA (both 5 %). In contrast, Mendeley readers of AP articles were mainly from the USA (14 %), UK (12 %), Spain (6 %), India (4 %), Canada (3 %), South Africa (3 %) and Malaysia (2 %). (2) For some WoS categories, Thelwall and Maflahi (in press) downloaded all article (article meta data) that were written in English from 2011. The country affiliation of the authors was extracted from the WoS affiliation field; each article was searched for in Mendeley to receive the number of readers from each country. The results of the study show that there is a tendency for articles to be more read in

countries with a higher share of their authorship. Possible reasons for the tendency are that authors are often readers of their own articles and that the readers often know or have heard of the authors.

Methods

Peer ratings provided by F1000Prime

F1000Prime is a post-publication peer review system of the biomedical literature (papers from medical and biological journals). F1000 Biology was launched in 2002 and F1000 Medicine in 2006. The two services were merged in 2009 and today form the F1000 database. Papers for F1000Prime are selected by a peer-nominated global Faculty of leading scientists and clinicians who then rate them and explain their importance (F1000, 2012). This means that only a restricted set of papers from the medical and biological journals covered is reviewed, and most of the papers are actually not (Kreiman & Maunsell, 2011, Wouters & Costas, 2012).

The Faculty nowadays numbers more than 5,000 experts worldwide, assisted by 5,000 associates, which are organized into more than 40 subjects (which are further subdivided into over 300 sections). On average, 1,500 new recommendations are contributed by the Faculty each month (F1000, 2012). Faculty members can choose and evaluate any paper that interests them; however, the great majority pick papers published within the past month, including advance online papers, meaning that users can be made aware of important papers rapidly (Wets et al., 2003). Although many papers published in popular and high-profile journals (e.g. *Nature*, *New England Journal of Medicine*, *Science*) are evaluated, 85% of the papers selected come from specialized or less well-known journals (Wouters & Costas, 2012). Less than 18 months since Faculty of 1000 was launched, the reaction from scientists has been such that two-thirds of top institutions worldwide already subscribe, and it was the recipient of the Association of Learned and Professional Society Publishers (ALPSP) award for Publishing Innovation in 2002 (http://www.alpsp.org/about.htm) (Wets et al., 2003).

The papers selected for F1000Prime are rated by the members as good, very good, or exceptional, which is equivalent to recommendation scores (rs) of 1, 2, or 3, respectively. Since many papers are not rated by one member alone, but by several, we calculated a mean rs for every paper. In order to categorize the F1000 papers into three quality levels, papers with mean rs < 2 have been categorized as Q1 and papers with mean rs > 2.5 as Q3. Papers with rs in-between are categorized as Q2, then. This is not a categorization of low and high quality because all F1000Prime papers have a very high quality compared to other papers in their field. This is merely a further distinction between high quality papers, as papers with low quality do not get recommended into F1000Prime.

Data sets used from Mendeley and WoS

In January 2014, F1000 provided one of the authors with data on all recommendations (and classifications) made and the bibliographic information for the corresponding papers in their system (n_r=149,227 records, n_p = 114,582 papers). Each of these records with either a PubMed-ID or a DOI was used to retrieve the Mendeley usage statistics via the R (http://www.r-project.org, accessed October 14, 2014) API of Mendeley (https://github.com/Mendeley/mendeley-api-r-example, http://dev.mendeley.com/methods/, both accessed October 14, 2014). An example R script is available at http://dx.doi.org/10.6084/m9.figshare.1335688. In the summer of 2014, a new version of the API was released which we used for this study (Bonasio,

2014). The previous API had some limitations, such as providing only the information of the demographics for the top three categories as a percentage. Another problem (which has not been solved yet) is that most users do not record their country and so only some readership country location information is available (Thelwall & Maflahi, in press). We requested the actual numbers of Mendeley users for each F1000 record (and the result was not truncated after the top three categories). We observed several (probably random) connection problems. Overall, about 99% of the F1000 paper set was found on Mendeley, which implies a rather good coverage of scientific papers on Mendeley (Bornmann & Haunschild, 2015). We recorded a total of 5,885,534 Mendeley reader counts.

For bibliometric analysis in the current study, country information of the authors who published a F1000 paper or published a paper citing a F1000 paper were sought in an in-house database of the Max Planck Society (MPG) based on the WoS and administered by the Max Planck Digital Library (MPDL). Despite different meanings of (citing) authors' and readers' countries, we talk about countries of readers and (citing) authors in the same way in the following sections.

Technical limitations

Only about 17.6% of 5,885,534 Mendeley reader counts (n=1,038,449) provided were available with their country association. For only 1,064 records of the F1000 data set, we found that the sum over all reader's countries was equal to the total number of reader counts. Thus, in the majority of cases (99.3%) some Mendeley readers are missing in our statistic because many readers did not share their location.

In contrast to the Mendeley data (in which the country information is reader-specific), the country information for the (citing) authors is address-specific. If two authors have different addresses, the country information is counted twice. However, if the addresses are identical, they are counted once. This limitation is unavoidable using our current WoS data. A second limitation of the data is that papers with different publication years have been considered without time-normalization in the study. For different publication years, one can expect different numbers of readers and citers: The longer the reader and citation window, the more counts are expectable. Since the counts have not been time-normalized in the study, papers with longer windows will have a greater effect on the results than papers with smaller windows. However, the papers with longer and smaller windows are unsystematically distributed across the different quality levels of the papers. Thus, the missing time-normalization of the data won't influence the investigation of the relationship between the distribution of readers and (citing) authors across countries and quality levels.

Processing and visualization of the data

The Mendeley reader data, as well as the WoS author and citer data, were processed by Perl (http://www.perl.org/) and Gawk (http://awk.info/) scripts. Visualization of the data was carried out using Tableau (http://www.tableausoftware.com/). Plots of country and world maps use the Mercator projection.

Results

The results of the study including all F1000 papers with data from WoS and Mendeley are shown in Figures 1 and 2, as well as Table 1 (all papers). For each country, we calculated the percentage of authors, readers, and citers. In Figure 1, the percentage of authors (red colour), citers (blue colour), and readers (green colour) are visualized for all countries worldwide. Figure 2 shows a

more detailed analysis of Europe as very many circles are overlapping in this region in Figure 1. The left panel of Figure 2 compares readers (green colour) and authors (blue colour) while the right panel compares citers (red colour) and authors (blue colour). The bigger the circle on the maps, the higher the percentage for a country is.

As the results in Figure 1 show most authors, readers, and citers are located in the USA. The results in Table 1 (all papers) point out that 29.2% of all readers, 38.3% of all authors, and 39.9% of all citers come from the USA. The USA is the country with the most readers, authors, and citers – significantly more than any other country. The high percentages of authors and citers point to a high level of research activity in the USA. The population and number of research groups in the USA are significantly higher compared to most other countries. In Table 1 (all papers), the USA is followed by the UK (all papers: readers=10.7%, citers=6.6%, and authors=9.3%). Further countries in the table (Germany, France, Japan, and Canada) show small differences in the percentages compared to the UK (less than 10 percentage points). Despite the rather large number of research groups in Russia and China, it is quite surprising that both do not appear in the top 10 list ordered by the number of Mendeley readers. In fact, we find China on rank 13 and Russia on rank 25, close to Poland and the Czech Republic.

As the results in Table 1 further show, many countries have different percentages of authors, readers, and citers. The US has a similar percentage of authors and citers (see e.g. the numbers for all papers), but the percentage of readers is lower than both other percentages. This result seems to reflect the fact that Mendeley is only one reference manager software among others in the USA. For other countries it is the other way around. For example, while 4.7% of all readers come from Brazil (all papers), less than 1% of all authors and citing authors are working in this country.

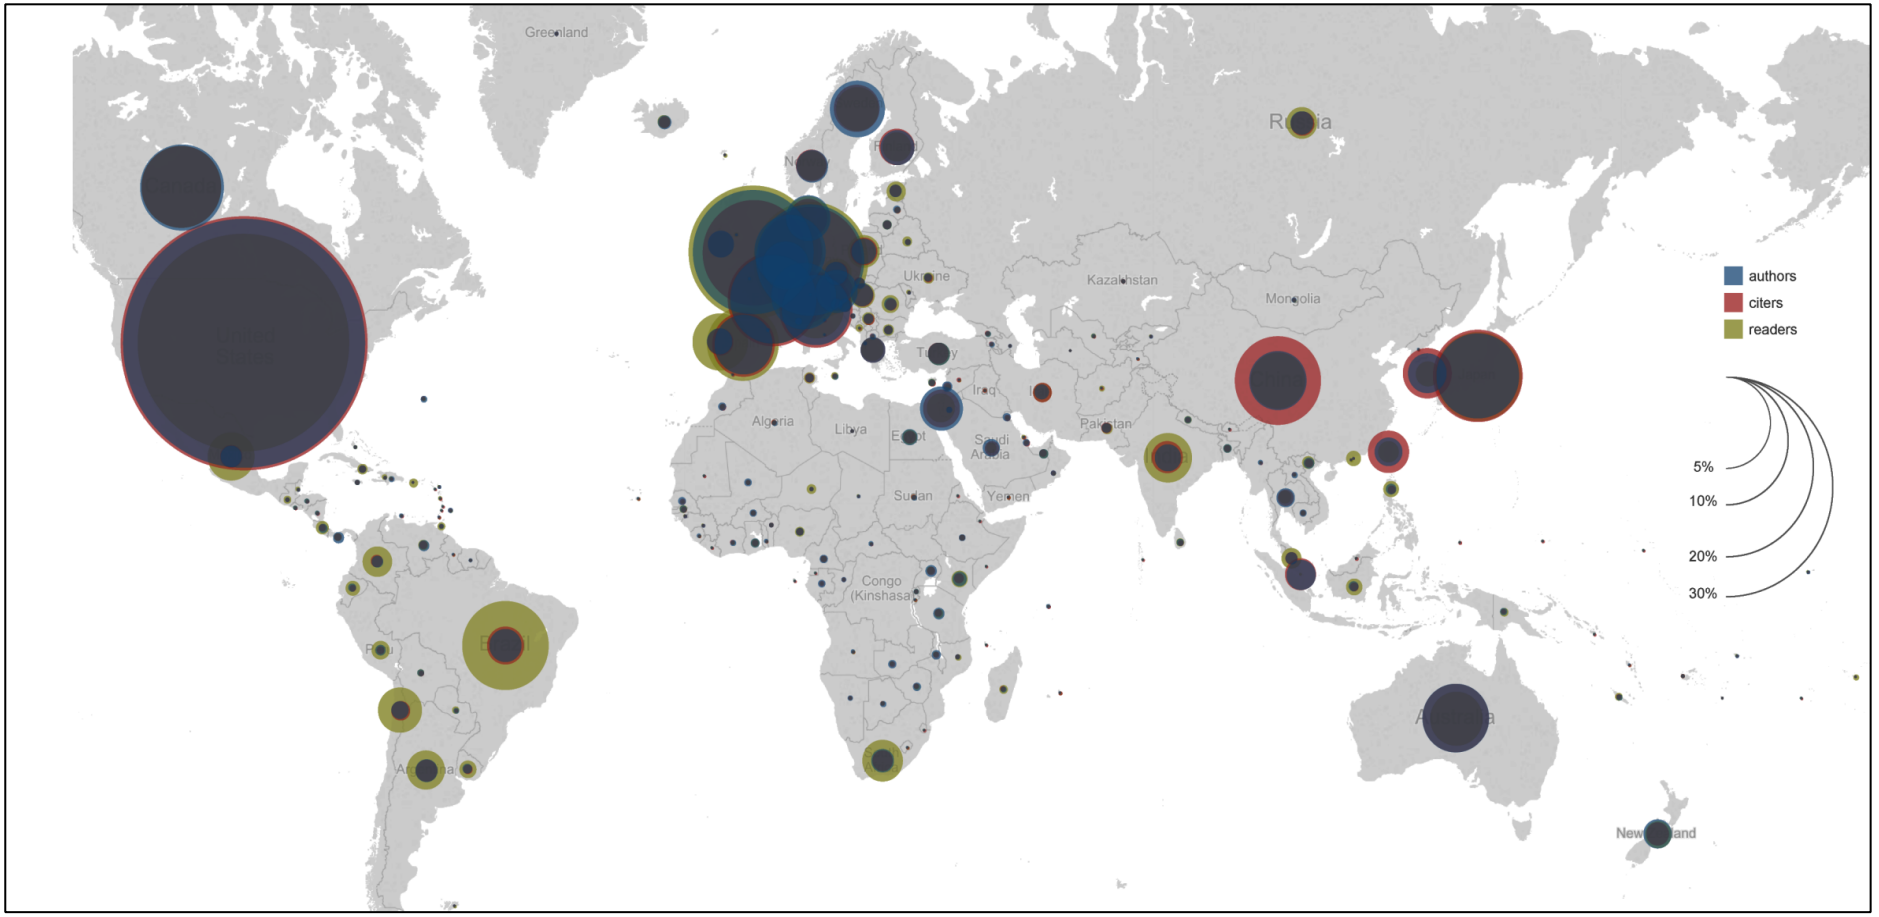

Figure 1. Percentage of authors (blue colour), citers (red colour), and readers (green colour). The circle sizes indicate the share of the country in the amount of readers, citers and authors, respectively. The map is based on all F1000 papers.

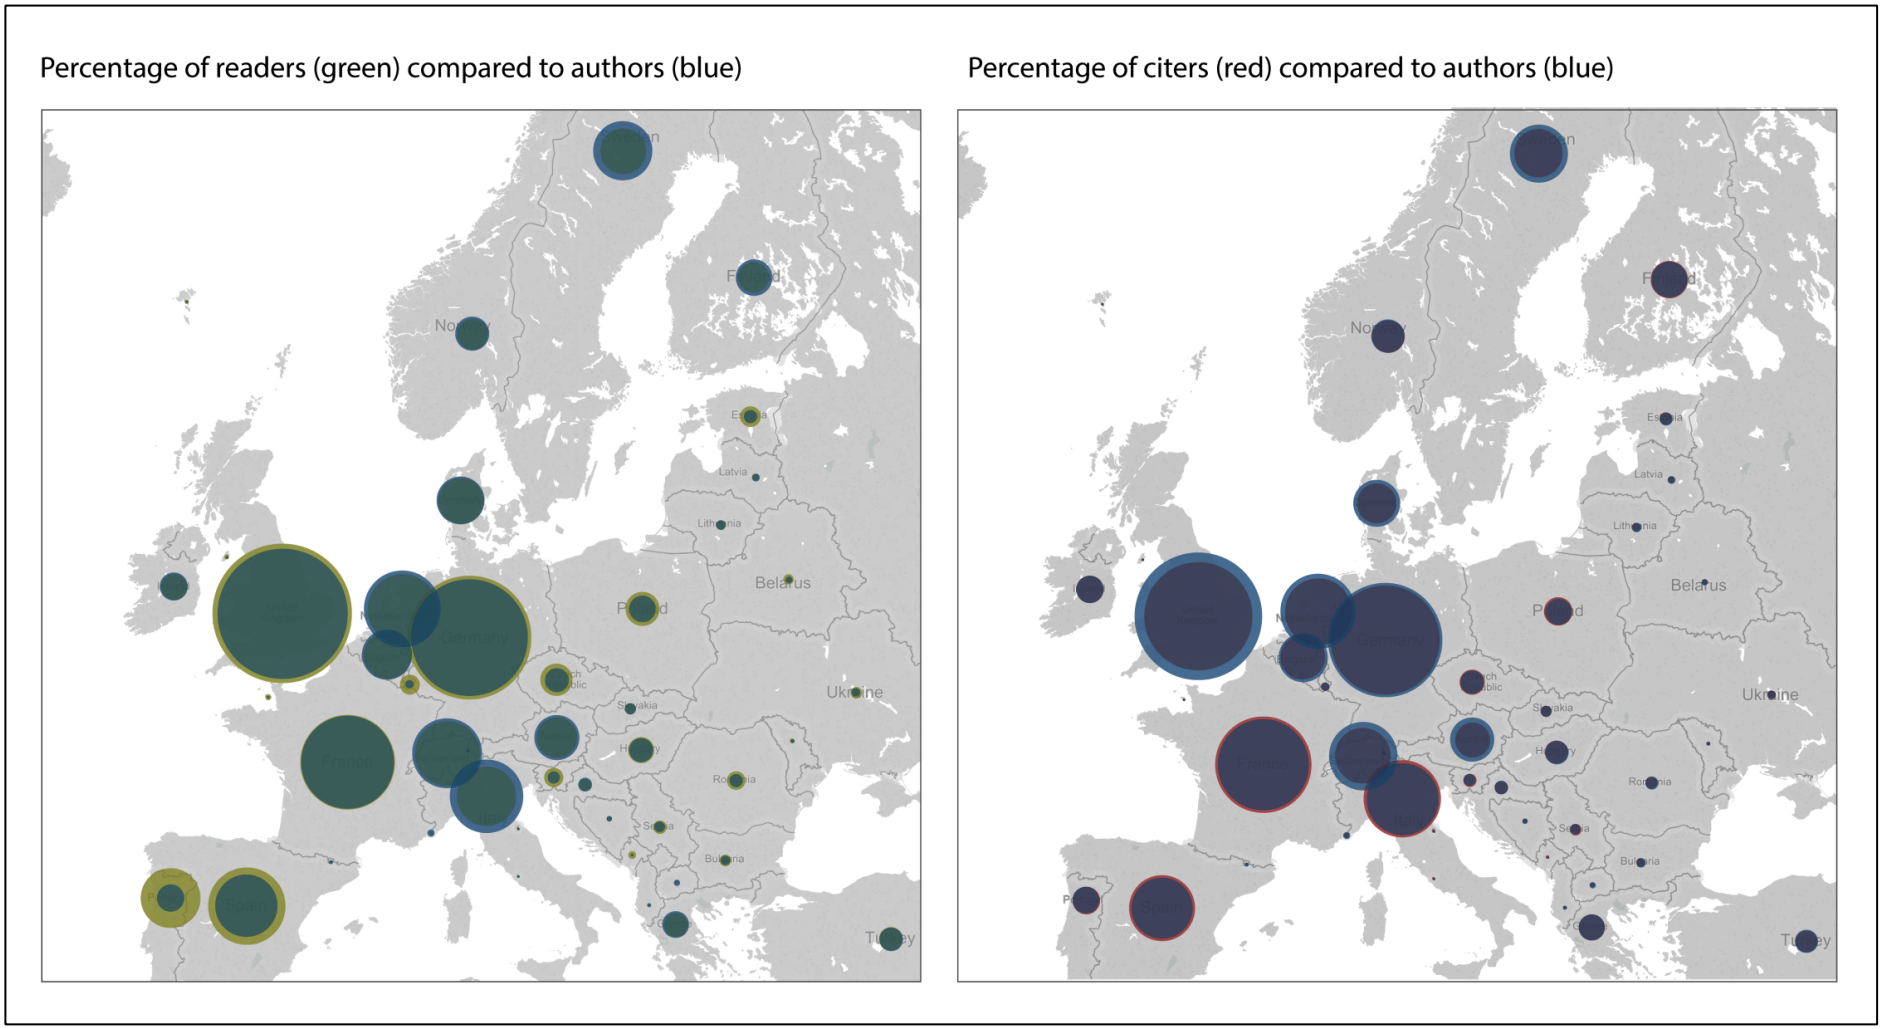

Figure 2. Percentage of readers (green colour) and authors (blue colour) on the left panel, as well as percentages of citers (red colour) and authors (blue colour) visualized on the right panel for European countries. The circle sizes indicate the share of the country in the amount of readers, citers and authors, respectively. The map is based on all F1000 papers.

Table 1. Percentage of authors, citers, and readers from different countries. The percentages are presented for all papers, as well as for papers with Q1 (rs<2), Q2 (rs>=2 and rs<=2.5), and Q3 (rs>2.5) quality. The ten countries are listed with the highest percentage of readers.

All papers	Authors	Citers	Readers	Q1	Authors	Citers	Readers
USA	38.3	39.9	29.2	USA	37.7	39.4	28.7
UK	9.3	6.6	10.7	UK	9.2	6.6	10.7
Germany	7.4	6.8	8.4	Germany	7.4	6.7	8.3
France	4.7	5.2	4.9	Brazil	0.6	0.8	5.0
Japan	4.3	5.1	4.7	France	4.7	5.3	4.9
Brazil	0.6	0.8	4.7	Japan	4.3	5.0	4.5
Canada	4.4	4.0	4.0	Canada	4.5	4.0	4.0
Spain	2.0	2.4	3.2	Spain	2.1	2.5	3.3
Netherlands	3.1	2.5	2.6	Netherlands	3.2	2.5	2.6
Switzerland	2.6	1.7	2.2	Switzerland	2.4	1.6	2.2
Q2	Authors	Citers	Readers	Q3	Authors	Citers	Readers
USA	39.0	40.4	29.4	USA	40.7	41.2	30.6
UK	9.5	6.7	10.7	UK	9.3	6.6	10.7

Brazil	0.5	0.7	4.4	Canada	4.2	3.7	4.0
Canada	4.3	3.9	3.9	Brazil	0.6	0.8	4.0
Spain	2.0	2.3	3.1	Spain	1.5	2.2	3.0
Netherlands	3.1	2.4	2.6	Netherlands	2.9	2.3	2.7
Switzerland	2.8	1.7	2.2	Switzerland	2.9	1.7	2.1

This result points out that Brazil rather receives than produces scientific results in the field of biomedical research: Since a low percentage of citing authors reflects a low number of subsequent published papers (following and basing on the F1000Prime papers), this percentage is not only an indicator of reception but also of productivity. Similar results as for Brazil are not only visible on the map in Figure 1 for other south-American countries (such as Argentina or Chile), but also for India and African countries.

From the European countries, Spain and Portugal receive more F1000 papers than they produce (c.f. left panel of Figure 2). Spain is located on rank 8 (see Table 1), and Portugal is located on rank 11. The northern European countries produce more F1000 papers than they cite (c.f. right panel of Figure 2). This is vice versa for most southern European countries.

Table 1 shows the percentage of authors, citers, and readers from different countries not only for all papers, but also for papers with different rs: Q1 (rs < 2), Q2 (2 <= rs <= 2.5), and Q3 (rs > 2.5) section. Comparing the numbers of authors, citers, and readers for different paper quality levels, we see only minor differences for most countries: Brazil shows a somewhat higher amount of readers in the Q1 section (5%) than in the Q3 section (4%), while the percentage of authors and citers does not differ at all between Q3 and Q1 section papers. The USA shows a somewhat higher amount of authors, citers, and readers in the Q3 section (40.7%, 41.2%, and 30.6%, respectively) than in the Q1 section (37.7%, 39.4%, and 28.7%, respectively). The UK shows a nearly constant percentage across quality levels for authors, citers and readers: 9.2%, 6.6%, and 10.7%, respectively for Q1, 9.5%, 6.7%, and 10.7%, respectively for Q2, and 9.3%, 6.6%, and 10.7%, respectively for Q3.

Discussion

By far the highest number of authors, citers, and readers are located in the USA. More F1000 papers are authored, cited, and read in western European countries than in eastern European countries. The amount of F1000 papers authored, cited, and read in China and Russia is small compared to the large number of research groups located there (rank 13 and 25, respectively, according to Mendeley readers). Other reference softwares might be more popular in these countries (or this kind of software is scarcely in use). Traffic data from Alexa.com can be used as an estimate for the Mendeley distribution. The top 5 countries where Mendeley is used seem to be USA (30.4%), India (20.7%), UK (4.3%), Pakistan (3.9%), and Malaysia (3.0%) (http://www.alexa.com/siteinfo/www.mendeley.com, visited on 19 December 2014). Roughly a year earlier, the top 5 countries were somewhat different: USA (16.1%), India (13.2%), Belgium (9.9%), Germany (6.2%), and UK (5.9%) (Thelwall and Maflahi, in press). This relative gain of Mendeley traffic from India, Pakistan, and Malaysia is different from our results, as they do not appear on our top 10 list of Mendeley readers. Within the F1000 readership on Mendeley, India is on rank 15, Malaysia on rank 38, and Pakistan on rank 59. Probably, scientists who use Mendeley in these countries are not that active in the bio-medical research. Belgium, which was in the top 5 list of Mendeley traffic a year ago, is on rank 17 according to our Mendeley readership results of the F1000 paper set.

We find only minor differences in the readership of papers with different quality levels Q1-Q3. The similarities of the results across paper quality levels can be explained with the very high standard of all publications in the F1000Prime set. Also, papers within the Q1 quality section in the F1000 publication set gather a rather high amount of citations (Bornmann 2014). Considering that all papers in the F1000 publication set are of a higher than average quality in the biomedical area, one probably cannot expect a clear difference between quality levels in the Mendeley readership.

Most countries show a quite good balance between consumption and production of F1000 papers. See for example in Table 1, the percentages of Germany are 7.4% authors, 6.8% citers, and 8.4% readers. Although scientists in Germany seem to consume somewhat more of

the literature of the F1000 paper set, the difference between authors (citers) and readers can be neglected, considering the limitations of our study and the (necessary) counting of authors (citers) and readers on unequal footing. In contrast to Germany, the number of readers is significantly higher than the number of authors and citers in some south-American countries (e.g. Brazil, Mexico, Chile, and Argentina) and some European and Asian countries (e.g. Portugal and India).

It is important to keep in mind that we measure authors and citers based on their institutional affiliation and readers on a personal level.

Another problem in the interpretation of the results is that the distribution of the Mendeley software is probably different for each country. Mendeley is free of charge. Thus, one could expect a higher number of Mendeley users in countries with tight research budgets. However, scientists in countries with tight research budgets might not author, cite, or read many publications which got recommended into F1000Prime, as many F1000Prime papers were published in journals with rather high subscription fees.

A third problem in the interpretation of the results is that a rather small number of readers provide their country, as it is not mandatory information. While we found approximately 99% of the F1000 papers at Mendeley, country information were available only for nearly 18% of the reader counts. This is significantly less than the value reported in a previous study done using a much smaller amount of papers (Haustein and Larivière 2014). However, it is reasonable to expect that Mendeley users who do not provide their location are evenly distributed over the world and are reading all quality classes of the F1000 papers.

Abstract
In this study, the 'academic status' of users of scientific publications in Mendeley is explored in order to analyse the usage pattern of Mendeley users in terms of subject fields, citation and readership impact. The main focus of this study is on studying the filtering capacity of Mendeley readership counts compared to journal citation scores in detecting highly cited WoS publications. Main finding suggests a faster reception of Mendeley readerships as compared to citations across 5 major field of science. The higher correlations of scientific users with citations indicate the similarity between reading and citation behaviour among these users. It is confirmed that Mendeley readership counts filter highly cited publications (PPtop 10%) better than journal citation scores in all subject fields and by most of user types. This result reinforces the potential role that Mendeley readerships could play for informing scientific and alternative impacts.

Conference Topic
Altmetrics

Introduction
Mendeley is a popular reference management tool and a rich source of readership metrics for scholarly outputs, used by more than 2.5 million users[1]. This platform collects a wide variety of different metadata[2] for each publication saved by the different types of users in their individual library. Among these metadata, statistics about 'academic status', 'discipline' and 'country' provide useful information on the typologies of users of scientific publications in Mendeley.

Mendeley has different coverage and presence across different fields of science (Zahedi, Costas & Wouters, 2014). A moderate correlation between Mendeley readership and citation counts has been observed for different sets of publications from different fields showing that Mendeley readership counts reflect similar but (perhaps) also other types of impact (Thelwall et al., 2013; Haustein et al., 2013; Zahedi, Costas & Wouters, 2014; Mohammadi & Thelwall, 2014). Also, a weak correlation among number of authors, departments, institutions and countries and readership and citation counts for WoS publications has been observed (Sud & Thelwall, in press; Thelwall & Maflahi, in press). Research on users showed that the majority of Mendeley users per publication are PhDs and students. However, one important limitation with Mendeley data on the analysis of users was the data restriction caused by the reporting of only the three most common user types per publication. Full data on users are necessary in order to properly determine the readership patterns among types of users (Zahedi, Costas & Wouters, 2013 & 2014; Haustein & Larivière, 2014; Mohammadi et al., 2014).

The new Mendeley API provides data on all typologies of readers per publication. This means that 100% of all the users per publication are now fully reported[3]. This study represents one of

[1] http://blog.mendeley.com/start-up-life/mendeley-has-2-5-million-users/
[2] See: http://apidocs.mendeley.com/home/user-specific-methods/user-library-document-details
[3] according to William Gunn in the 1:Am altmetrics conference in London (September 2014) www.altmetricsconference.com/

the first approaches to the analysis of Mendeley readerships based on statistics per publication from all users. We overcome the main limitation of previous studies which were limited to restricted Mendeley users statistics.

In this paper, the usage patterns of the different Mendeley users based on their 'academic status'[4] by fields, citation and readership impact are studied. Also, we analyse the extent to which Mendeley readerships correlate with the number of citations and across 5 major fields of science in the Leiden Ranking (LR). An important focus of this study is on studying the filtering capacity of Mendeley readerships compared to journal citation scores in detecting highly cited publications. Therefore, particular attention will be paid to the extent to which highly cited outputs can be distinguished by these different impact indicators. Similarly, potential differences among Mendeley users in detecting highly cited publications will be also explored. The concrete objectives and research questions of the paper are the following:

O1: To study the general distribution of Mendeley readerships over WoS publications

Q2. What is the distribution of Mendeley readerships across LR fields and by different users?

O3: To study the relationship of Mendeley readerships with bibliometric indicators

Q4. Are there any differences in correlation by different Mendeley users and across LR fields?

O5: To investigate the ability to identify highly cited publications by Mendeley readerships in contrast to journal citation impact indicators

Q6. Which one of these impact indicators can better filter the WoS highly cited publications across LR fields and by different users?

Data and Methodology

For this study, we used a dataset of 1,196,421 Web of Science (WoS) publications from the year 2011 with Digital Object Identifiers (DOI). DOIs were used as the basis to extract readership metrics through the Mendeley REST API in mid-October 2014. The data from Mendeley has been matched with the CWTS in house WoS to add citation data. Citations have been calculated up to 2014.

Although Mendeley has released the full statistics for all the typologies of the users per publications through its API, some Mendeley user statistics are still missing from some publications[5]. These publications were excluded from the analysis due to their unclear reader counts and types. Limiting the dataset to articles and reviews, a final set of 977,067 publications received 12,418,426 total readerships[6] and 6,882,632 total citations. Comparing the ratios of mean citation score per publication (MCS) and mean readerships per publication (MRS), we also find higher MRS (12.7) than MCS (7.04). The actual number of the different types of Mendeley users per publication has been calculated as well as several bibliometrics

[4] These are the different types of users in Mendeley (i.e. PhD students, Professors, Post doc, researchers, Students (under graduates and post graduates), Librarians, Lecturers, Other Professionals and Academic and non-Academic researchers) who have saved publications in their individual libraries. This information allows us to identify users of scientific publications but this information is not free of limitations. For example, it is not clear whether the academic status of the users is updated regularly or how to distinguish users who could belong to more than one category (e.g. a librarian who is also a PhD student).

[5] There are 144,8495 publications with missing readership statistics. These publications have been saved in Mendeley but since their readership counts are missing, they are excluded from the analysis.

[6] We have found some inconsistencies in the counts of readerships. There is a difference between the sum of total readership counts reported by Mendeley (i.e. as they come directly from the readership count provided by Mendeley) and the sum of the individual Mendeley readerships by the different users (calculated by ourselves). (12,418,426 - 12,412,305=6121 differences)

indicators. Precision-recall analysis (Waltman & Costas, 2014) has also been performed, considering 5 major fields of science as represented in the Leiden Ranking (LR)[7].

Analysis and Results

General distribution of Mendeley readerships by major fields of Science and by Mendeley users

Table 1 shows that Biomedical & health sciences (37%) have the highest share of publications with readerships while Mathematics and computer science (8%) have the lowest share. In terms of readership density (i.e. MRS scores) the Life & earth sciences have the highest values (17.5) followed by the Social science & humanities (17), Biomedical & health sciences (14.4) and Natural sciences & engineering (9.7). Mathematics and computer science (9.4) exhibit the lowest readerships density. Also, on average, all fields show higher MRS scores than MCS scores. This could be explained by the relative early publication year (2011) of publications, which could still need some time to get their optimum levels of citations, while in terms of social media, the uptake is normally faster (Haustein et al, 2013), although we still lack information on the obsolescence and time patters of readerships for publications.

Table 1. Mendeley readerships distribution across 5 major fields of science in LR.

LR Main fields of all Publications	P	%	TCS	%	MCS	TRS	%	MRS
Biomedical & health sciences	419,693	37	3617563	44	8,6	6051206	39	14,4
Natural sciences & engineering	322,009	28	2362700	29	7,3	3119704	20	9,7

Total Citation Score (TCS); Total Readership Score (TRS); Mean Citation Score (MCS); Mean Readership Score (MRS)

Figure 1 shows the proportion of readerships by the different types of Mendeley users across the LR fields. Although there are some differences across the fields, in general we find that PhD and students are the most common types of users while Lecturers and Librarian are the least common types of users across all LR fields.

[7] http://www.leidenranking.com/ranking/2013

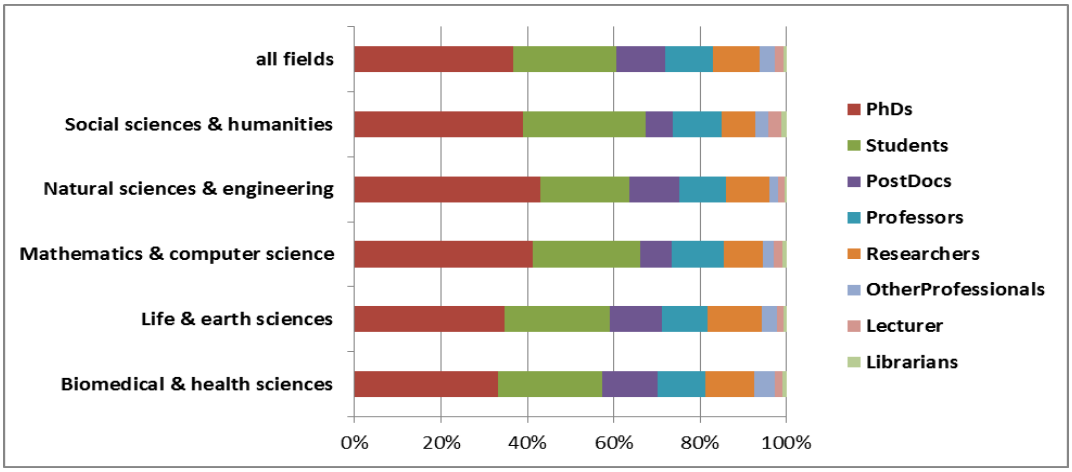

Figure 1. Distribution of Mendeley readerships by the different types of users across LR fields.

Relationship of Mendeley readerships with bibliometric indicators

Spearman correlation analysis among readerships and bibliometric indicators and by the different types of users and across LR Fields has been calculated. The focus here is to explore the extent to which the readerships for the publications saved by the different users in Mendeley are related to their citations and journal indicators. Overall correlation scores among total readerships and bibliometrics indicators are positive and moderate ranging from p=.41 to p=.52 (Table 2).

Table 2. Spearman Correlation analysis of bibliometrics and altmetrics variables.

n=977,067	CS	NCS	JCS	NJCS	RS
CS	1	.93	.57	.43	.52

NJCS				1	.41
RS					1

Citation Score (CS); Normalized Citation Score (NCS); Journal Citation Score (JCS); Normalized Journal Citation Score (NJCS); Readership Score (RS)

Regarding the different types of users, citations have a higher correlation with PhD followed by Students, PostDocs, Researchers, Professors and Other Professionals; however, Librarians and Lecturers exhibit the lowest correlations with citations. These different patterns in terms of correlations among the different types of users might suggest that they have different readership patterns and potentially different readership interests. For example, readership scores for Students, PostDocs, Professors and Researchers correlate most with PhD readership as 'Scientific users', which may indicate their similar scholarly and research usage behaviour. On the other hand, scientific users correlate less with 'other professionals' and Librarians (i.e. suggesting a kind of 'Professional users') and Lecturers as the 'Educational users' (Zahedi, Costas & Wouters, 2013). The latter also correlate most among themselves which may suggest both their similar use of scientific outputs and usage for other purposes than citation such as for self-awareness, teaching and educational or practical and professional purposes (Table3).

Table 3. Spearman Correlation analysis of citation and readerships variables by types of Mendeley users.

n=977,067	CS	PhDs	Students	Post Docs	Professors	Researchers	Other Professionals	Lecturers	Librarians
CS	1	.46	.40	.41	.36	.37	.24	.18	.06

Students			1	.41	.44	.44	.31	.29	.12
PostDocs				1	.42	.43	.26	.21	.06
Professors					1	.39	.27	.26	.09
Researchers						1	.32	.23	.11
Other Professionals							1	.20	.12
Lecturers								1	.09
Librarians									1

In terms of LR fields, the correlation of citations and readerships is the highest for Social sciences and humanities (p=.61) followed by Natural sciecnes and engineering (p=.59), Life and earth sciences (p=.57), Biomedical and health sciences (p=.55) and the least for Mathematics and computer sciences (p=.45). Regarding the readership by user types and across fields, for most users the highest correlations are in Social sciences and humanities. The lowest correlation with citations is in the field of Mathematics and computer sciences for PhD, Students, PostDocs, Professors and Researchers while for Other Professionals, Lecturers and Librarians the field Natural sciences and engineering displays the lowest correlation with citations (Table 4). This may indicate a relatively stronger use of social media platforms such as Mendeley by scholars in Social science and humanities in their research process than other fields (Rowlands et al., 2011; Tenopir, Volentine & King, 2013).

Table 4. Spearman Correlation analysis of citation and readership by types of Mendeley users across 5 LR Fields.

LR Fields	Total CS and RS	PhD	Student	Post Doc	Professor	Researcher	Other Professional	Lecturer	Librarian
Biomedical & health sciences	.55	.47	.42	.42	.40	.39	.26	.19	.05
Natural sciences &engineering	.59	.51	.43	.39	.35	.33	.17	.18	.04

CS (Citation Score); RS (Readership Score)

Analyzing the filtering capacity of highly cited publications by Mendeley readerships

The focus here is to explore the potential use of Mendeley users for filtering highly cited publications compared to journal citation scores. For this purpose, the proportion of top 10% highly cited publications (PPtop 10%)[8] in the sample have been detected. The precision-recall analysis[9] has been performed for all publications in the sample and the 5 LR fields and the different Mendeley users have been explored. Figure 2 shows the general precision-recall analysis of total readership scores and Journal Citation Scores (JCS) for all the publications in the dataset. This figure shows that readerships perform better than JCS in identifying the PPtop 10% most cited publications. The figure indicates that for example a recall of 0.5 (50%) corresponds with a precision of 0.45 (45%) for readership and 0.25 (25%) for journal citation scores in identifying highly cited publications, that is, publications belonging to the top 10% of their field in terms of citations. This means that in order to select half of all highly cited publications we have an error rate of 55% when the selection is made based on readership and an error rate of 75% when the selection is made based on journal citation scores. Since readership outperforms journal citation scores at all levels of recall, we conclude that readership scores identify highly cited publications much better than JCS.

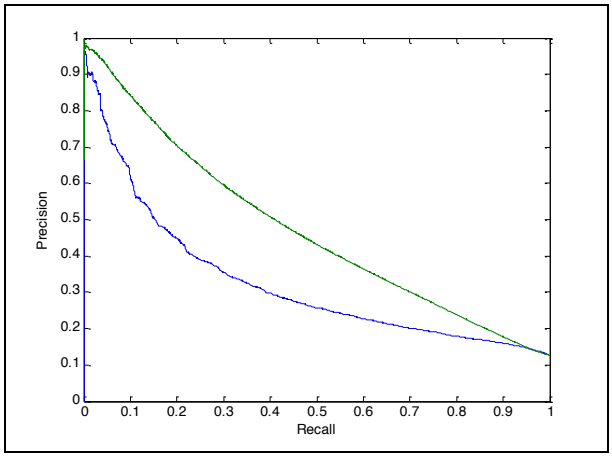

Figure 2. General Precision-recall curves for JCS (blue line) and total readerships (green line) for identifying PPtop10% most highly cited publications.

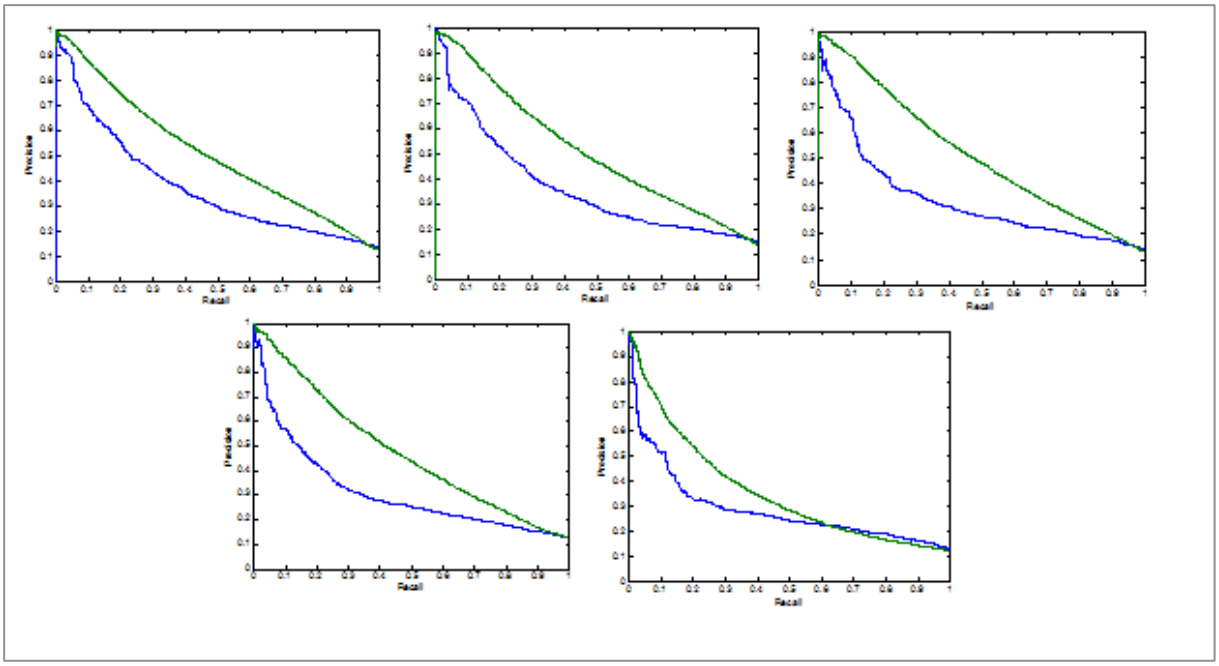
[8] PP(top 10%) (proportion of top 10% publications). Refers to the proportion of the publications that compared with other publications in the same field and in the same year, belong to the top 10% most frequently cited.

[9] following Waltman & Costas (2014), For a given selection of publications, "precision is defined as the number of highly cited publications in the selection divided by the total number of publications in the selection. Recall is defined as the number of highly cited publications in the selection divided by the total number of highly cited publications".



From left to right: Biomedical & health sciences, Life & earth sciences, Natural Sciences & engineering, Social sciences & humanities, Mathematics & computer science

Figure 3.Precision-recall curves for JCS (blue line) and LR Fields (green line) for identifying PPtop10% most highly cited publications.

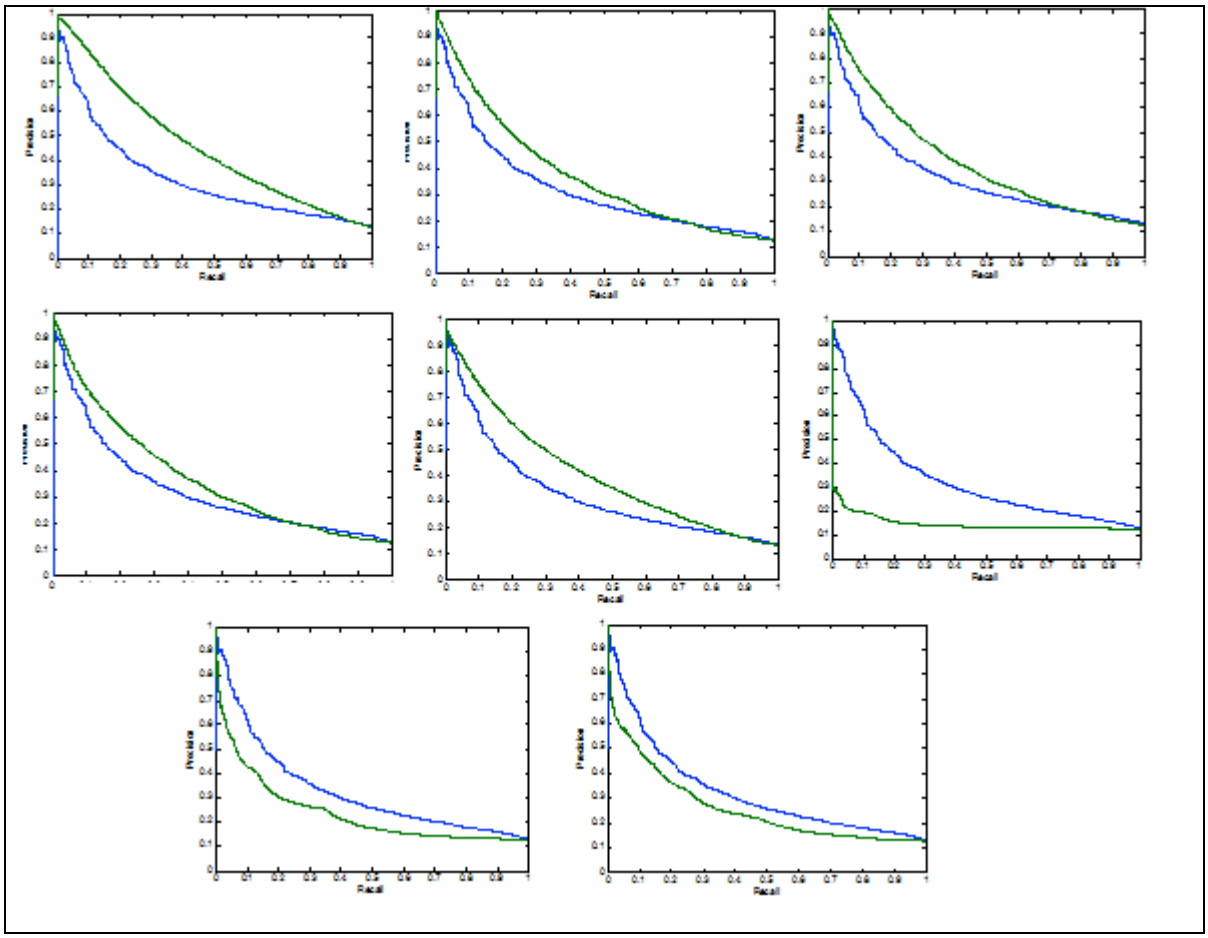
Precision-recall analysis of the different fields of science

The results of the precision-recall analysis for all fields of science again show that readership outperforms JCS scores in filtering highly cited publications. This result supports the idea that Mendeley readership counts filter highly cited publications better than average citation impact of journals (JCS) for all LR fields within our sample. All the figures are similar resembling the general pattern in figure 2 except the figure for Mathematics & computer science, which shows that from recall of 0.6 (60%), the two lines intersect each other and from that point onwards there is a small improvement of JCS over readership scores.

Precision-recall analysis of different types of Mendeley users

The same approach has been done based on the different Mendeley users. Figure 4 shows the results of the precision-recall analysis of readerships scores by the different types of users in Mendeley and Journal Citation Score (JCS). Again, readerships perform better than JCS for most types of users (PhDs, PostDocs, Professors, Researchers and Students vs. Other Professionals, Librarians and Lecturers) in identifying the PPtop10% most highly cited publications within our dataset thus resembling the general pattern in Figure 2. The only exceptions are observed for Librarians, Lecturers and other Professionals where JCS overlaps or outperforms Mendeley readerships. This is in line with the result of the correlation analyse in which these Mendeley user types exhibit less correlations with citations than other types.

Also, regarding the figures for PostDocs, Professors, Researchers and Students, from recall of 0.8 onwards two lines intersect each other and there is a slight improvement of JCS over readerships in the highest level of recall. However, in general, considering readership scores by most types of Mendeley users can help to detect highly cited publications.



From left to right: PhDs, PostDocs, Professors, Researchers, Students, Librarians, Lecturers and Other professionals

Figure 4. Precision-recall curves for JCS (blue line) and type of users readerships (green line) for identifying PPtop10% most highly cited publications.

Main results and discussion

Mendeley is a major multidisciplinary source of readership counts for scholarly publications (Zahedi, Costas & Wouters, 2014) and also it is one of the most promising tools for 'altmetrics' research (Li, Thelwall & Giustini, 2012; Wouters & Costas, 2012). The statistics about the 'Academic Status' of Mendeley users is a valuable source of information to learn more about the academic and non-academic positions of readers of scientific outputs, thus opening the possibility of studying the different types of impact that these different users may entail. Although Mendeley is now reporting the full data per publication, yet more clarity on how Mendeley users are defined is very important, as well as on how the typologies are chosen and updated by the users. For example, the relatively strong correlation between PhDs and Students could suggest that (some) students that become PhD do not update their profiles and therefore they 'read' like PhD students but without updating their 'Academic status' in Mendeley.

The current study has analysed and compared the readership and citation impact of the scholarly publications saved in Mendeley in terms of their types of users and across different LR fields, particularly focusing on the filtering capacity of readership and journal citation impact indicators in identifying highly cited publications. The findings showed that in terms of readership density across the 5 major LR fields, on average, all fields show higher MRS scores than MCS values. This suggests a faster reception of Mendeley readerships as compared to citations and encourages the need to study the temporality and pace of readership

counts. Regarding the types of users, the most common types of users in Mendeley are PhDs and Students, for all LR fields. Correlation analysis shows relatively positive and moderate correlations among the different types of users and citations. The different correlations across users might support the idea that different users could be reading different publications, and thus justifying the use of 'Academic Status' to identify different reading behaviour and typologies of impact. For example, the higher correlations of scientific users with citations, supports their similar reading and citation behaviour vs. other more educational, teaching or professional patterns with lower correlations with citations. This may also be relevant in the analysis of the use of scientific publications in teaching or professional activities. Our results also suggest that readership counts really improve the filtering capacity of highly cited publications over JCS. This is one of the most promising results of this paper, showing the relevance of Mendeley readerships as a relevant filtering tool, something that has not been observed in the previous studies and for other altmetric sources (cf. Costas et al, 2014; Waltman & Costas, 2014). However, it should be taken into account that there are many scholars who don't use Mendeley or any other reference management tools in their scholarly process, so the act of using this type of tools may change in the future. Hence, the use of Mendeley readerships for evaluative purposes still needs careful consideration of its limitations and potential negative effects on the behaviour of individual scholars.

Acknowledgments

The authors are grateful to Erik van Wijk from CWTS for his support on the data collection of Mendeley information for this study. Also, special thanks to Ludo Waltman from CWTS for his fruitful comments on this paper.

Abstract
Twitter has been identified as one of the most popular and promising altmetrics data sources, as it possibly reflects a broader use of research articles by the general public. Several factors, such as document age, scientific discipline, number of authors and document type, have been shown to affect the number of tweets received by scientific documents. The particular meaning of tweets mentioning scholarly papers is, however, not entirely understood and their validity as impact indicators debatable. This study contributes to the understanding of factors influencing Twitter popularity of medical papers investigating differences between medical study types. 162,830 documents indexed in Embase to a medical study type have been analysed for the study type specific tweet frequency. Meta-analyses, systematic reviews and clinical trials were found to be tweeted substantially more frequently than other study types, while all basic research received less attention than the average. The findings correspond well with clinical evidence hierarchies. It is suggested that interest from laymen and patients may be a factor in the observed effects.

Conference Topic
Altmetrics

Introduction
In the context of altmetrics, defined as "the study and use of scholarly impact measures based on activity in online tools and environments" (Priem, 2014, p. 266), Twitter has been identified as one of the most interesting and widely-used data sources (Costas, Zahedi, & Wouters, 2014; Thelwall, Haustein, Larivière, & Sugimoto, 2013). Although restricted by brevity—a tweet is limited to 140 characters—Twitter is at the heart of the altmetrics idea to enable a broader scope for impact assessment beyond citation impact. As Twitter is used widely and particularly outside of academia by currently 284 million monthly active users[1], tweets mentioning scientific papers are hoped to capture use by the general public and thus societal impact. Initially suggested as predictors of future citations and thus early indicators of scientific impact (Eysenbach, 2011), more recent large-scale empirical studies suggest that tweets are more likely to reflect online visibility including some social and scientific impact but also self-promotion and buzz (Costas et al., 2014; Haustein, Larivière, Thelwall, Amyot, & Peters, 2014; Haustein, Peters, Sugimoto, Thelwall, & Larivière, 2014). The most tweeted documents seem to attract a lot of online attention rather due to humorous or curious topics than their scientific contributions, often fitting "the usual trilogy of sex, drugs, and rock and roll" (Neylon, 2014, para. 6).
Various, mostly quantitative, studies have shown, with respect to scientific papers, that—after the reference manager Mendeley—Twitter is the altmetrics data source with the second-largest prevalence and it is constantly increasing to currently more than one fifth of 2012 papers being tweeted (Haustein, Costas, & Larivière, 2015). Correlation studies provide evidence that tweets and citations measure different things (for example, Costas et al., 2014;

[1] https://about.twitter.com/company

Haustein, Larivière, et al., 2014; Haustein, Peters, et al., 2014; Priem, Piwowar, & Hemminger, 2012; Thelwall et al., 2013; Zahedi, Costas, & Wouters, 2014). The latest research shows that Spearman correlations with citations for 2012 papers in Web of Science are low at ρ=0.194 for all 1.3 million papers and ρ=0.148 excluding untweeted papers. Beyond the particular differences of Twitter coverage and density between scientific disciplines, research fields and journals reported by various studies (Costas et al., 2014; Haustein, Larivière, et al., 2014; Haustein, Peters, et al., 2014; Zahedi et al., 2014), Haustein et al. (2015) also identified large variations between document types deviating from patterns known for citations. For example, news items and editorial material, which are usually considered non-citable items (Martyn & Gilchrist, 1968), are the most popular types of journal publications on Twitter, showing a tendency of increasing Twitter impact for brief and condensed document types. A study based on a random sample of 270 tweets to scientific papers found that the majority of tweets contained either the paper title or a summary, did not attribute authorship and had a neutral sentiment, while 7% were self-citations (Thelwall, Tsou, Weingart, Holmberg, & Haustein, 2013). Other findings suggest that automated diffusion of article links on Twitter plays a role as well (Haustein, Bowman, et al., 2015).

Although these findings provide more evidence that the mechanisms behind tweeting a paper are different from those citing it, the meaning of tweets to scientific papers as well as the role of Twitter in scholarly communication are still unclear, not in the least due to the difficulty to identify 'tweeter motivations' based on 140 characters. This study aims to contribute to a better understanding of tweets as impact metrics by analysing the type of content that is distributed on Twitter. We propose that certain types of articles appeal more to the public than others, for example, because of their potential impact on health issues and everyday life or due to the fact that they are written in a certain way. Previous research has suggested that certain medical study types have a larger citation potential than others (Andersen & Schneider, 2011; Kjaergard & Gluud, 2002; Patsopoulos, Analatos, & Ioannidis, 2005), likely because they are more useful to the research community. In the context of Twitter, medical papers are of particular interest, because, on the one hand, these are particularly relevant to general Twitter users—as opposed to, for example, physics research—and practicing physicians belong to early adopters of social media in their work practice (Berger, 2009). In a survey asking researchers about social media use in research, the uptake by health scientists was, however, slightly below average (Rowlands, Nicholas, Russell, Canty, & Watkinson, 2011).

The aim of this paper is thus to investigate whether there is a connection between different medical study types and the frequency of tweets per article. We hypothesize that some study types are more popular on Twitter due to their attractiveness for a broader audience such as applied medical research relevant to patients as well as meta-analyses summarizing research and condensing results. We will approach this hypothesis by first investigating the potential differences in tweet frequency for a range of medical study types. We argue that logically there should be a connection between the clinical evidence hierarchy (further explained below) and the types of studies patients might consider interesting to discuss or spread on social media, as the highest evidence levels are those which are most likely to affect clinical practice. We therefore expect differences in tweet frequency to be related to evidence levels.

Materials and Methods

Comparing the impact of medical research study types on Twitter requires two pieces of information per research article: a classification of the study type as well as the number of tweets received by each particular paper. Currently no database contains both pieces of information, so that it was necessary to combine data from different sources. For this purpose, the medical study type classifications from the Embase bibliographical database was used,

enriched with metadata from PubMed and Web of Science and then matched to Twitter data from Altmetric.com. The datasets and the matching approach are described in further detail below. Following these descriptions is an account of the specific measurements and statistical tools employed as well as the limitations of this study.

Data collection and matching

Due to Twitter's 140 character limitation, mentions of a scientific paper in tweets are restricted to links to the publisher's homepage or unique document identifiers such as the Digital Object Identifier (DOI) or PubMed ID (PMID). As Twitter only provides access to the most recent tweets[2], it is necessary to constantly query various article identifiers to obtain a database of tweets to scientific papers. Altmetric LLP has been collecting tweets based on multiple document identifiers including the DOI, PMID and the publisher's URL since July 2011 and thus provides a valuable data source for the purposes of our study. To assure reliable and complete Twitter data, we focus our study on papers published 2012. In order to link all tweets to the bibliographic data and study type classification from Embase, the DOI and the PMID are needed.

The study type classifications (see below) for the analysis were retrieved from the Embase bibliographical database. Embase is a major database containing more bibliographical records than PubMed Medline; for example, 24%[3] more for documents published in 2012. It is unclear whether the study type classifications of either database outperforms the other, however, as the indexing of Embase is more exhaustive, we have chosen to use this database for our study. In order to identify relevant papers from Embase (and to be able to perform a citation analysis in the future), *Clinical Medicine* journals were selected from the Web of Science (WoS) based on the National Science Foundation (NSF) journal classification system. The Web of Science also provides bibliographic data and DOIs for the relevant papers, which were used to match Embase study types and tweets from Altmetric.

Embase was queried for the relevant journals using the journal name and various abbreviations as well as the ISSN. Limiting the results to papers published in 2012, the metadata of 593,974 records was retrieved from Embase. In order to obtain the PMID needed to match tweets, PubMed was queried in the same way resulting in 497,619 records. Embase, PubMed and Web of Science were matched using the DOI, PubMed as well as string matches of bibliographic information resulting in 238,560 documents in the final dataset, 94.9% of which with a PMID and 91.1% with a DOI.

The bibliographic metadata was matched to the Altmetric database using the DOI and PMID resulting in 80,116 records with at least one social media event as captured by Altmetric and 74,060 with at least one tweet at the time of data collection in August 2014. This amounts to 31% of the 238,560 being mentioned on Twitter at least once, which corresponds almost exactly to the Twitter coverage of biomedical & health sciences papers found by Haustein, Costas and Larivière (2015). To ensure comparability between tweets published in January and December 2012, we fixed the tweeting window to 18 months (546 days) for each of the tweeted documents, including tweets until 30 June 2013 for papers published on 1 January 2012 and until 30 June 2014 for papers published on 31 December 2012. The day of publication is based on the publication date provided by Altmetric. As this date is not available for all records and is sometimes incorrect, the dataset was further reduced to 52,911 documents, which had an Altmetric publication date in 2012 and not received a tweet before

[2] Twitter's REST API is limited to tweets from the previous week, while the Streaming API provides realtime data only.

[3] For the publication year 2012, Embase contains 1,334,356 records (search: "2012".yr) and PubMed Medline contains 1,072,384 (search: 2012[pdat]).

the publication date. Although these steps lead to an underestimate of the percentage of tweeted papers, they help to reduce biases induced by publication age when comparing the visibility of different medical study types on Twitter.

Medical study type classification

Embase indexes all articles using a controlled vocabulary (the Emtree thesaurus), which contains hierarchically ordered keywords in a classical thesaurus structure. Among these keywords are study type classifications, of which some are directly identifiable as such (e.g. randomised controlled trials), while others require some translation (e.g. "sensitivity and specificity" which is used for diagnostic accuracy studies). The Emtree thesaurus is designed for indexing and retrieval, and there is thus not a given connection between the hierarchical ordering of study type keywords and different levels of research methodology. This is particularly important, as one of the predominant approaches to Western medical research and practice is the so-called evidence based medicine (EBM). One of the cornerstones of EBM is the distinction between study types and their hierarchical ordering based on how much 'evidence' a study is assumed to contribute to the understanding of a given problem (Greenhalgh, 2010). Different hierarchies exist, e.g. the Oxford Centre for Evidence Based Medicine's "Levels of Evidence" (OCEBM Levels of Evidence Working Group, 2011).

Table 1. Medical study type classification system based on Röhrig et al (2009) and OECBM. Classifications with raised numerals have narrower terms, which are not shown here.

We have chosen to use a particular hierarchy, which allows a classification of study types on their level of research (Röhrig et al., 2009). We have added to the classification of Röhrig et al. (2009) by adding classification codes and the corresponding keywords in Emtree. The resulting system has been validated by two field-experts, and is displayed in Table 1. As can be seen, the classification system allows direct translation between specific Emtree keywords (we have added the broadest terms as well as their relevant narrower terms) and our classification codes on the third level (study_type). The system allows grouping of study

types into classes and research types (levels 2 and 1), thus allowing us to analyse the connection between tweets and the specific study types as well as the broader categories.

Of the entire population of 238,560 records, 162,830 records can be classified using our study type classification system. Of these, 36,595 (22.5%) receive at least one tweet within the fixed 18 months tweet window. Of the remaining 75,730 records without a classification, 16,316 (21.5%) receive at least one tweet. These data delimitations will be used to control for systematic errors in our main dataset (records with classifications). Among those that were classified, 55% had only one classification, 26% had two, 12% had three and the remaining 7% had four or more classifications. References with n classifications are treated as n observations, thus resulting in more than 162,830 observations on either classification level. Some classes in our classification system were not observed at all in the dataset. These classes are omitted in the results section.

Statistical methods and indicators

For each study type classification level we report several statistics for all documents (referred to by $*_A$, e.g. N_A) as well as the subset that has received at least one tweet ($*_T$). The included statistics are number of articles per classification (N), mean tweets per article (μ), the standard deviation from the mean (σ), percentage of articles with at least one tweet (N_T/N_A), and the mean normalised tweets ($\hat{\mu}$) defined as the ratio between μ for a specific classification and μ for the entire population.

As the distributions of tweets for any classification are extremely skewed (see results) similar to citations, the adequacy of the mean as an indicator of average activity is debatable (Calver & Bradley, 2009). However, while the median might be a methodologically more sound choice, the distributions are so extremely skewed that for study type level classification, medians are all 0 when all papers are included and either 1 or 2 if only tweeted papers are included. The corresponding means range from 0.35 to 1.74 and 2.02 to 5.01, providing considerably more information, especially as the scales for the mean are continuous. We therefore use the mean for comparisons, with due care and inclusion of standard deviations and percentage of tweeted articles to provide further information on differences in means. As we have large sample sizes, we expect any major differences in means to be real and not due to chance. However, to test this assumption, all classifications are tested pairwise and against the background population using the independent sample, unpaired Mann-Whitney test.

Limitations

The most obvious error source in this study is the proportion of papers included in the final analysis, compared to the overall population of papers published in 2012. Our background population of 162,830 classified papers only represents 27.4% of the 593,974 records downloaded from Embase. However, it still represents 68.3% of the 238,560 matchable records. This is a fairly high number of papers that could be classified, and if it is possible to improve the matching algorithms, it should also be possible to increase the total number of classified papers comparably. The only systematic error in this regard is the omission of particular documents based on lacking or erroneous DOI's. However, as missing DOI's are also an issue in collecting tweets, this error is not likely to affect the tweet counts with the limitations to tweet-collection that currently exist.

To test if there is a systematic error in the number of tweets per paper, with regard to whether a paper has been classified with a study type or not, we compare the percentage of papers with tweets for classified papers with unclassified papers. For the 162,830 papers with a classification, 36,595 (22.5%) received at least one tweet, while the 75,730 unclassified papers received tweets on 16,316 (21.5%) papers. These values also corroborate findings by Haustein, Costas & Larivière (2015). For the classified papers, mean tweets were 0.67, while

the mean was 0.71 for the unclassified papers. These differences are not random (p = 2.7e-14, using independent two-sample t-test), however, the effect size is also extremely small (Cohen's d = 0.018). We should therefore not consider the lack of study types as confounders for the number of tweets.

While the classification system we have used here was validated by two domain experts, it is only one possible system. Other classifications could have been created, in particular with regard to the translation from Emtree keywords to our classification system. The choices made in this regard will affect the results as presented here. However, when we compare the pairwise scores within a research class, we find high consistency between what could be considered "similar" research types. The only study type, which varies greatly from the other study types in their class is the non-systematic review. This is meaningful, as non-systematic reviews are regarded by medical researchers as much less evidential as their systematic counterparts.

Results

We analysed the classified papers on the three levels present in our classification system: research type, research class and study type. In Tables 2 to 4 we report summary statistics for the three levels, for all papers as well as limited to tweeted papers to determine differences between the share of tweeted papers as well as intensity of (re)use. Results are visualized in Figure 1. In Figures 2 to 4 we provide the results of the pairwise comparison to determine the statistical significance of differences between study types including binary and continuous statistical significance as well as Cohen's d to estimate effect size.

Summary statistics

As can be seen from Tables 2 to 4, there are large differences in the mean tweets per classification, regardless of classification level, although the largest differences are observable in the study types. The differences are clear from the means (μ_A and μ_T), but even more obvious when regarding the relative means ($\hat{\mu}_A$ and $\hat{\mu}_T$). This is also where we find the largest standard deviations, likely due to the smaller N per classification. Meta-analyses and systematic reviews receive considerably more tweets than other study types, which makes the synthesizing research type stand out as well. Overall, a generally increasing interest of the Twitter community can be observed from basic (A) over clinical (B) and epidemiological (C) to synthesizing research (D) papers. Larger variations per research type can be observed for clinical research, where clinical trials are much more tweeted than other study types. In fact, case studies (B2.1) have the lowest mean number of tweets per paper (μ_A), which also reflects in the low mean of observational clinical research (B2) on the research class level. Epidemiological research also performs above average of the entire sample, while basic research (A) consequently performs below, although with somewhat higher scores for genetic engineering (A2.4) than the papers classified as ex vivo (A2.1), in vivo (A2.2) and in vitro (A2.3) studies.

The distributions of tweets per classification are shown in Figure 1, illustrating the highly skewed nature of these distributions, but also the large differences between some categories. The results shown in these boxplots are directly comparable to the summary statistics, and the same classifications stand out as being particularly often tweeted.

From previous research we know that meta-analyses, systematic reviews and clinical trials are also the most highly cited study types (Andersen & Schneider, 2011). However, whether there is a connection between the citedness and tweetedness of medical study types is not obvious from the present data, and will require further research.

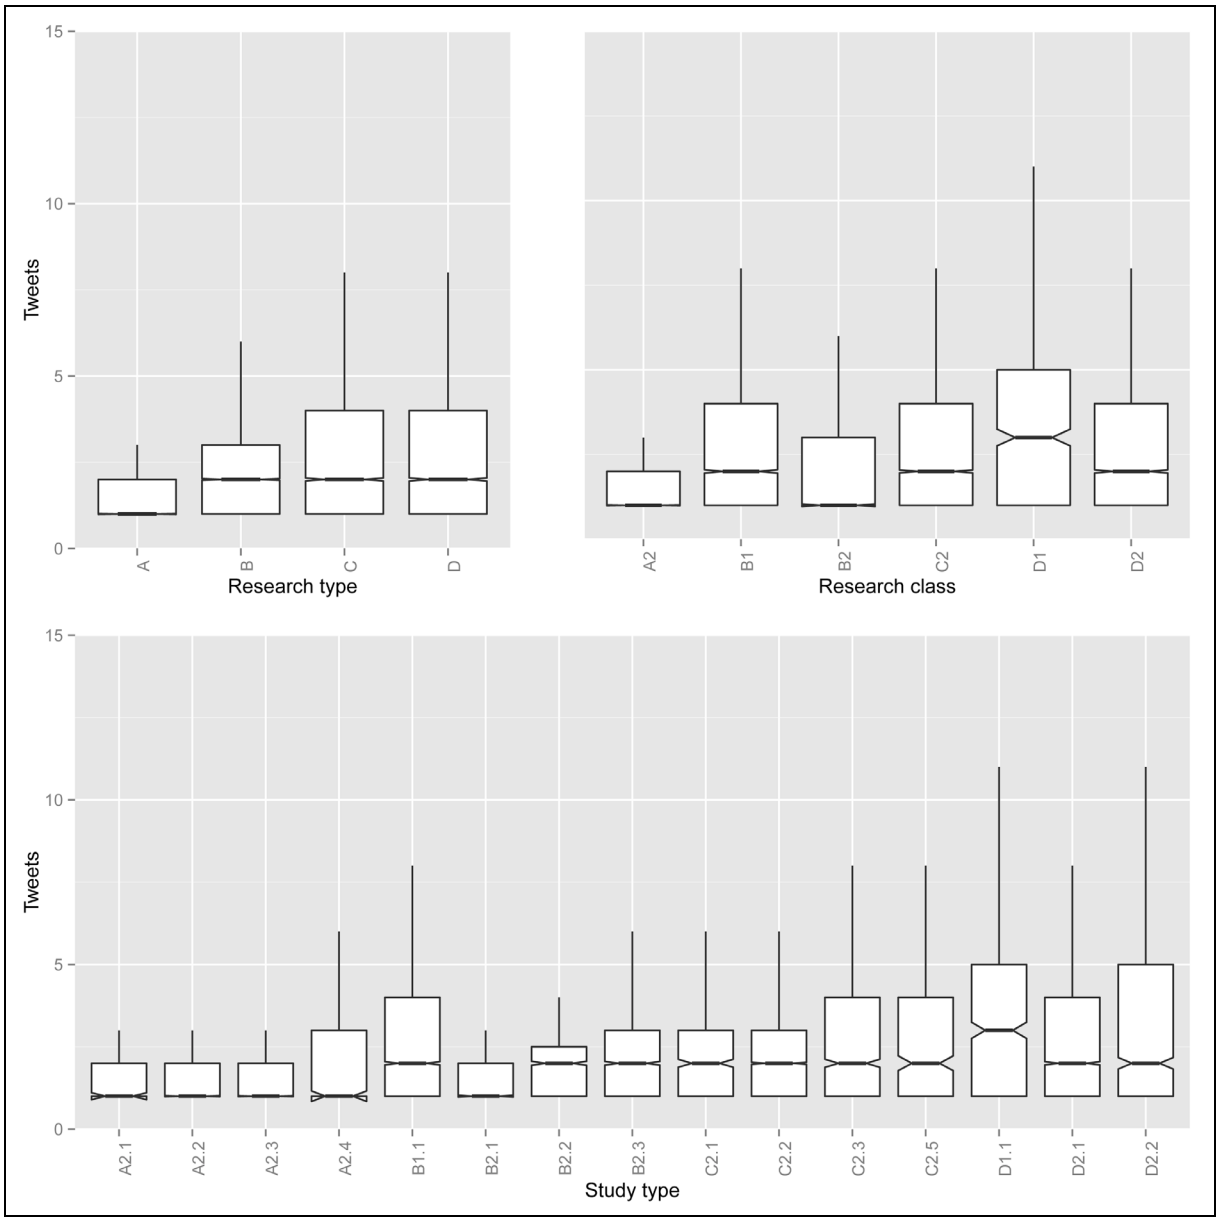

Figure 1. Notched boxplots showing tweet distributions for A) Research type, B) Research class and C) Study type.

Pairwise comparison

In order to analyse the magnitude of differences in classifications further, pairwise comparisons were made on each level. The independent two-sample Mann-Whitney test was used to test whether differences in sample means were due to random effects, and Cohen's *d* was used to estimate the effect size of varying means. There is of course a connection between the *p*-values of the Mann-Whitney tests and Cohen's *d*, to the extent that non-significant differences will also have very small effect sizes, as our sample sizes are quite large. In Figures 2 to 4 these pairwise comparisons are plotted as heatmaps, in which the diagonal and lower half have been omitted. The statistical significance of differences in mean are plotted as both binary maps (*p* below or above 0.05) and as continuous values. On the research type level, basic research stands out the most from the other types, with a lower mean of tweets per paper. For research classes, meta-analyses stand out with very large effect sizes, but overall the effect sizes are somewhat larger on this level than the broader research types. On the study type level, meta-analyses and systematic reviews stand out, but also

clinical trials and epidemiological study types have fairly large effect sizes, compared to other study types.

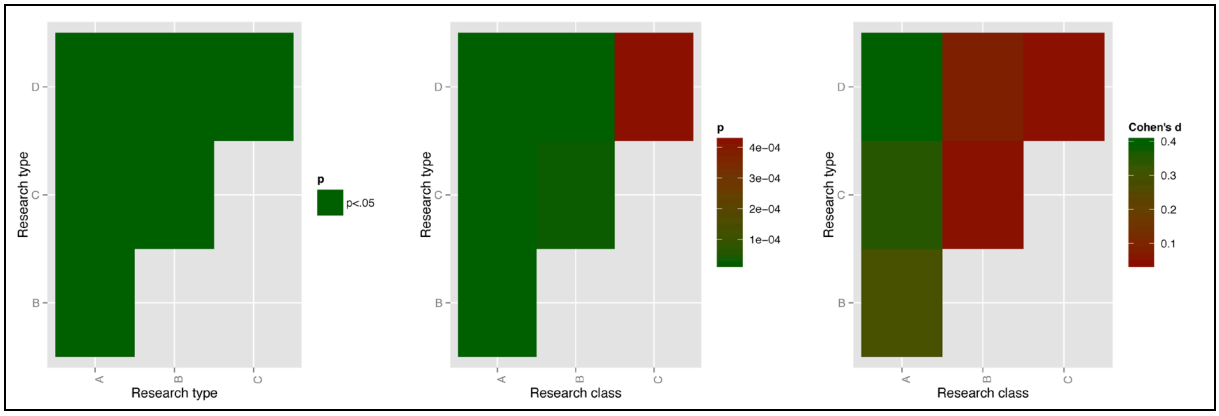

Figure 2. Heatmaps of pairwise comparisons showing A) binary statistical significance, B) continuous statistical significance and C) Cohen's *d* as effect size estimate. All figures are grouped on the research type level.

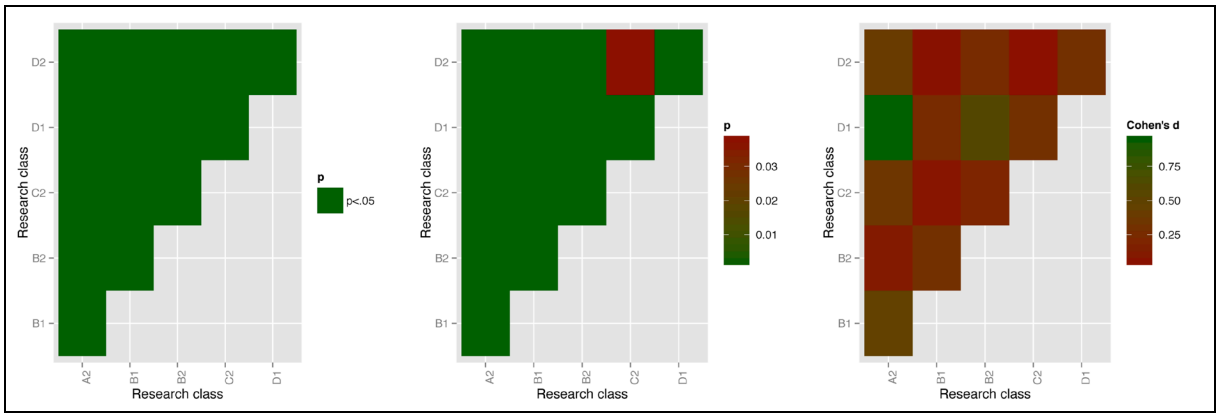

Figure 3. Heatmaps of pairwise comparisons grouped on the research class level. See figure 2 for legend.

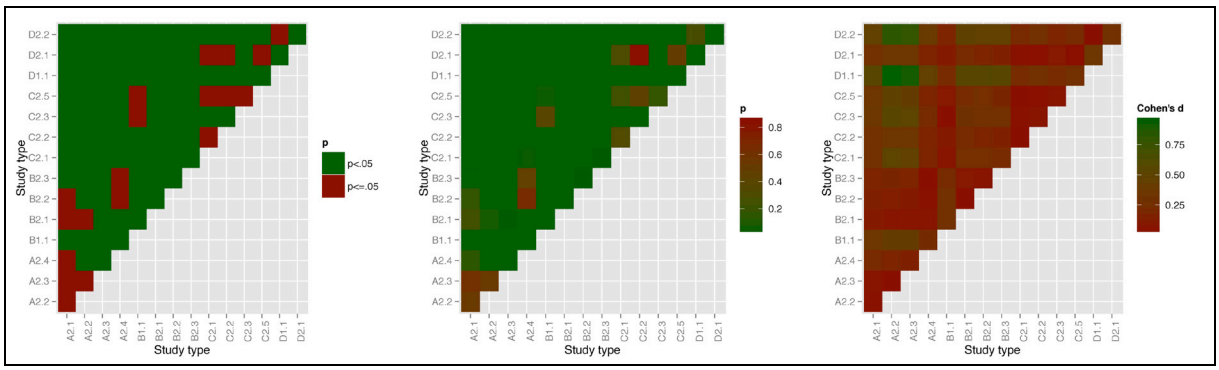

Figure 4. Heatmaps of pairwise comparisons grouped on the study type level. See figure 2 for legend.

Discussion and Outlook

We have analysed the frequency of tweets for medical research papers, distinguished by their specific study type. Our hypothesis was that some study types would be more frequently

tweeted, because they were interesting to a wider audience (e.g., patients and other laymen) than other types. It has not been possible to identify literature on which types of research are actually more useful to laymen, or even which types are most often used. We therefore assume that research, which is close to clinical practise and may contribute to changes in treatments would be more interesting to patients, as they might see a specific benefit to themselves. Based on findings by Haustein, Costas and Larivière (2015) that briefer and condensed document types received more tweets than research articles, we also assumed that synthesising research papers would be more popular on Twitter than basic research.

On the broadest classification level, the results fit well with this assumption, as basic research stands out as the least frequently tweeted research type on average. Basic medical research is also furthest removed from the actual treatment of diseases—so much that some physicians consider it irrelevant to their clinical practise (Andersen, 2013)—which makes them less interesting for the general public of medical laymen and patients active on Twitter. When fine-tuning the analysis to study types, meta-analyses and systematic reviews stand out particularly, followed by clinical trials and epidemiologic study types. This corresponds with typical evidence hierarchies and reflects similar patterns found for citations (Andersen & Schneider, 2011; Kjaergard & Gluud, 2002; Patsopoulos et al., 2005). While this might indicate a relationship between tweets and citations, other studies on a broader level have found this is not the case (Costas et al., 2014; Haustein et al., submitted; Haustein, Larivière, et al., 2014; Zahedi et al., 2014). Other explanations may be that physicians are more likely to tweet about high-evidence studies or that these are also the same types of studies which are most interesting to patients. The latter appears obvious, as high-evidence studies are also more likely to be included in clinical practice guidelines and thus have a greater potential for changing practice. Moreover, results indicating the uptake of social media to be lower among health researchers (Rowlands et al., 2011), while the frequency of tweets per paper in this area is high (Haustein, Peters, et al., 2014), provide some evidence, that the large effect size found for these study types cannot be explained purely by large Twitter-activity from medical researchers. Patients, patient groups and laymen interested in research or other factors may thus play an important role in this observation.

While factors such as entertaining topics may play a role (Neylon, 2014) when looking at the the top per mille most frequently tweeted papers, it is unlikely that all 1,883 meta-analyses, 3,713 systematic reviews and 28,343 clinical trials should have a higher tweet count than other study types due to entertainment value, especially as these are also the most highly regarded study types by the researchers as measured through citations. The mean may of course be affected by single high-scoring studies, however, as can be seen from Figure 1, it is the entire distribution rather than merely the mean, which is increased for these study types. In fact, the maximum tweets per study type is 46 for meta-analyses and 59 for systematic reviews, while it is 65 for two of the basic research study types and 62 for clinical trials. The lowest maximum tweet frequency of a study type is 25 (an in vivo study) and the highest is 67 (a cohort study). It can thus be concluded that medical study types are one of the factors determining popularity of scientific papers on Twitter but they are certainly not the only ones. Apart from factors explored by previous studies and known also from the citation context—such as discipline, publication age, number of authors etc.—Twitter-specific effects should also be investigated. This includes the effect of the number of followers and affordance use as well as the extent to which scientific papers receive tweets due to author and journal self-promotion as well as automated Twitter accounts (Haustein, Bowman, et al., 2015).

Abstract
The gender gap in science has been the focus of many analyses which have, for the most part, documented lower research productivity and citation impact for papers authored by female researchers. Given the rise of scholarly use of social media to disseminate scientific production and the healthy proportion of women on these sites, further investigation of potential gender disparities in social media metrics are warranted. Comparing event counts from Twitter, blogs, and news with citations, this study examines whether publications with male and female authors differ regarding their visibility on the social web and whether gender disparities can be observed in terms of social media metrics. Findings demonstrate increased gender parity using social media metrics than when considering scientific impact as measured by citations. It is acknowledged that this could be the results of the different impact communities, as the scientific community constituting the citing audience is more male-dominated than the social media environment. The implications for the use of social media metrics as measures of scientific quality are discussed.

Conference Topic
Altmetrics

Introduction
Early Internet use was heavily male-dominated—to the point of being considered a "boy toy" (Morahan-Martin, 1998; Weiser, 2000)—and promises of gender equity in computer-mediated communication were left unrealized (Herring & Stoerger, 2013). However, recent transformations in both the function and functionalities of the Internet have led to increased participation of women, particularly in the use of social networking sites (Kimborough et al., 2013). As of September 2014, slightly more women are using social networking sites than men (Duggan, Ellison, Lampe, Lenhart & Madden, 2015). However, although men and women now both employ social media, the ways in which they use them remain gendered (Correa, Hinsley, de Zuniga, 2010; Koenig, 2015; Muscanell & Guadagno, 2012; Piazza Technologies, 2015).

Twitter—an online social networking service for microblogging—is one of the top websites in the world (Alexa.com). However, despite equality in other social media sites, there appears to be a growing gender disparity in Twitter, with men using the platform at higher rates than women (24 vs 21%) (Duggan et al., 2015). Moreover, the gender gap in Twitter usage has been increasing in the last two years (Duggan & Brenner 2013; Duggan et al., 2015). Gender bias is also reflected by journalism's practices on Twitter, where reporters' tweets severely underrepresent women in quotes (Artwick, 2013). This speaks to women's underrepresentation as authorial voices—that is, voices that can speak as experts and

authority on matters of merit. Given the rise of scholarly use of Twitter (Costas, Zahedi & Wouters, 2014; Haustein, Costas & Larivière, 2015; Holmberg, Bowman, Haustein & Peters, 2014; Pscheida et al., 2013; Rowlands et al., 2011), further investigation of potential gender disparities in scholarly communication and measures of impact from this site are warranted.

Microblogging is not the only web space with demonstrated gender disparities. Given the underrepresentation of women in science (Larivière, Ni, Gingras, Cronin & Sugimoto, 2013; West, Jacquet, King, Correll & Bergstrom, 2013), many studies have sought to examine whether the web might provide a democratizing space for female academics. These studies have shown that men tend to have greater web presence than women (van der Weijden & Calero Medina, 2014) and blog at a greater rate (Puschmann & Mahrt, 2012; Shema, Bar-Ilan & Thelwall, 2012). Bar-Ilan and van der Weijden (2014) recently investigated whether gender specific differences could be found when considering Mendeley (a social bookmarking service) readership counts. Using the gender of one of the co-authors of astrophysics papers—a field where *hyperauthorship* is commonplace (Cronin, 2001), thus making it difficult to distinguish papers attributed to female researchers from male researchers—they showed that the share of papers, to which at least one male contributed were found more often on the platform that those to which at least one women contributed. On the other hand, women attract more profile view in Academia.edu (an academic social networking site) in certain disciplines (Thelwall & Kousha, 2014). Many of these social media sites are associated with less formal ways of discussing and sharing research results with a wider audience (Shema, Bar-Ilan & Thelwall, 2012; 2014). The degree to which this engagement is gender-neutral begs further investigation.

This study builds on these analyses and seeks to examine whether publications with male and female authors differ regarding their visibility on the social web, and whether gender disparities can be observed in terms of social media metrics. Comparing event counts from Twitter, blogs and news with citations, this study aims to answer the following research questions:

- Does the gender gap in scholarly communication observed for publications and citations extend to social media?
- Does the visibility of male and female authored papers differ among Twitter, blogs, and mainstream news media?
- Does the gender gap in social media visibility of scholarly journal articles differ by scientific discipline?

There has been a growing call for researchers to demonstrate social impact (e.g., Force 11, 2011; REF, 2014). Social media metrics have been promoted as a source of such impact measures (Priem, 2014). However, the degree to which gender inequalities exist on such platforms must be investigated prior to wide-scale adoption and use of social media metrics.

Methods

Data were drawn from Thomson Reuters' Web of Science (WoS), which includes the Science Citation Index Expanded, the Social Science Citation Index and the Arts and Humanities Citation Index. These databases index annually documents published in over 12,000 journals across all scholarly disciplines. To determine differences between scientific disciplines, the NSF field classification of journals (National Science Foundation, 2006) was used instead of WoS categories in order to avoid possible double counting of papers by classifying, as the NSF classification assigns each journal to only one specialty.

Only papers published in 2012 were considered, as this year provides the best compromise between the length of the citation window—citations to papers take time to accumulate—and the recent uptake of social media activity (Thelwall, Haustein, Larivière & Sugimoto, 2014). Citations to 2012 papers were counted until the end of 2013, which allows for a citation window of at least one complete year for all papers. Selecting 2012 publications also has the advantage of guaranteeing complete coverage of social media data for the whole year, as Altmetric.com started data collection mid-2011 (Costas, Zahedi & Wouters, 2014).

Altmetric.com was chosen as the data source for social media and mainstream media counts, as it is the most comprehensive source of social media data associated with scientific papers (Robinson-García, Torres-Salinas, Zahedi & Costas, 2014). News items, tweets and scientific blogs entries were selected for the analysis. Mainstream media and news sources captured by Altmetric.com include online mentions of scientific papers in more than 1,000 mainstream media and news outlets such as the Washington Post, Süddeutsche or CNN[1], giving insight on the visibility of a paper among the general public. The audience of Twitter and scientific blogs covered by Altmetric.com may reflect the overlap between the scientific community and the general public as both are widely used outside of academia but also by scholars. These metrics were selected because they represent three different types of social media events and levels of engagement from users, ranging from the one end of the spectrum with an engagement limited to 140 characters on Twitter, to the redaction of whole blog entries or newspaper articles, at the other end. Altmetric.com data includes counts collected up to August 2014. Given the quick uptake of social media-based indicators (excluding Mendeley) reported by Thelwall et al. (2014), we consider that the social media activity window of more than a full year considered in this study is long enough to cover the vast majority of social media activity around papers published in 2012.

The link between WoS papers and the Altmetric.com list of indicators was made using the Digital Object Identifier (DOI). Hence, papers that did not have DOIs were excluded from the analysis. As one might expect, the proportion of papers with DOIs is not distributed evenly across scientific disciplines. While, for most fields, the proportion of journals with publications with a DOI is very high (e.g., above than 70%), a substantial share of journals (30%), particularly in the Social Sciences and Humanities, do not use DOIs (Haustein, Costas & Larivière, 2015). Hence, for papers published in the latter group of journals, results from Altmetric.com are more likely to underestimate their actual online visibility, which represents a limitation of this study (as well as the great majority of social media metrics analyses). Arts and Humanities papers were thus excluded of the analysis because of the low number of papers and of citations. The gender of authors was attributed using the authors' given names, following the method developed in Larivière et al. (2013). The method allowed to assign a gender to the first author of 67.7% (N=696,186) of all 2012 papers that had a DOI (N=1,028,382). The analysis is, thus, based on this dataset of papers, and the gender of the first author is used to categorize the paper as female or male.

The prevalence of social media metrics is measured through intensity, which indicates the mean number of events for papers that show at least one of the particular events (non-zero counts) and coverage, percentage of papers with at least one event. While coverage reflects the probability of a document to be cited or mentioned on the particular platform, the intensity indicate rate aims to measure the frequency or popularity with which documents are (re)used once they are on the platform and remains independent of the coverage and zero values (Haustein, Costas & Larivière, 2015).

The scientific impact of male and female researchers is compared using the average of relative citations (ARC). The ARC provides a field-normalization and thus allows the

[1] http://www.altmetric.com/sources-news.php

comparison of citation impact between the different specialities that have otherwise different citation practices. More specifically, the number of citations received by a given paper is divided by the average number of citations received by articles in the same NSF research specialty published in the same year. An ARC greater than 1 indicates that an article is cited above the world average for the same field, and an ARC below 1 means that it is cited below the world average.

Results

Figure 1 compares the ARC of papers first authored by women and men, respectively, in order to assess whether a gender gap can be found in the dataset of papers used. Figure 1 confirms the widespread gender disparities observed in science (Larivière et al., 2013) in terms of scientific impact. More specifically, in each discipline, papers first authored by male researchers have higher citation impact, with the only exception of Engineering and Technology where papers first authored by female researchers have a slight advantage (ARC value of 1.18 for women and 1.17 for men). Biomedical Research (0.95 for women and 1.11 for men), Professional Fields (1.11 for women and 1.26 for men), Mathematics (1.03 for women and 1.19 for men) and Psychology (0.97 for women and 1.12 for men) show the greatest gender differences regarding citation impact.

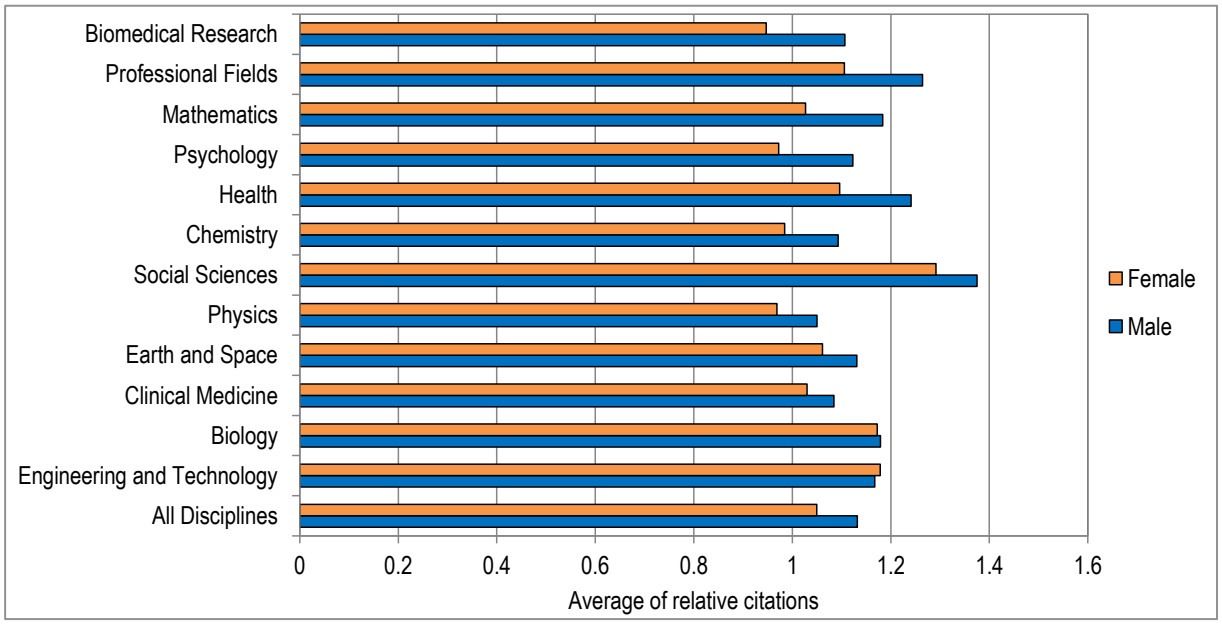

Figure 1. Average of relative citations of papers first authored by female and male researchers, by discipline and ordered by gender gap, 2012.

Figure 2 compares papers first authored by female and male researchers, in terms of intensity of news items (i.e., the mean number of events for all documents with at least one event) and coverage by news items (i.e., the percentage of papers with at least one event). All disciplines taken together, the intensity and the coverage of news items is gender-balanced, with an intensity difference of less than 0.07 event and a coverage difference of less than 1%. Physics (mean number of 1.04 for women and 1.34 for men) and Biomedical Research (1.63 for women, 1.87 for men) are the disciplines showing the strongest gender gap in terms of intensity of news items, in favour of papers first authored by men, corroborating the gender gap found in terms of citation impact (Figure 1). Coverage by news items of papers published in Biomedical Research (1.20% for women, 1.49% for men), Earth and Space (1.17% for women, 1.42% for men), Chemistry (0.59% for women, 0.84% for men) and Psychology

(1.26% for women, 1.50% for men) also confirm the gender gap found in terms of citation impact. However, papers first authored by female researchers in Health (1.32 for women, 1.26 for men), Clinical Medicine (1.39 for women, 1.33 for men) and Professional Fields (1.47 for women, 1.17 for men) have higher mean numbers of news items than that of male researchers while in Biology (0.73% for women, 0.62% for men), Engineering and Technology (0.60% for women, 0.55% for men) and Clinical Medicine (0.67% for women, 0.52% for men) they have a greater coverage.

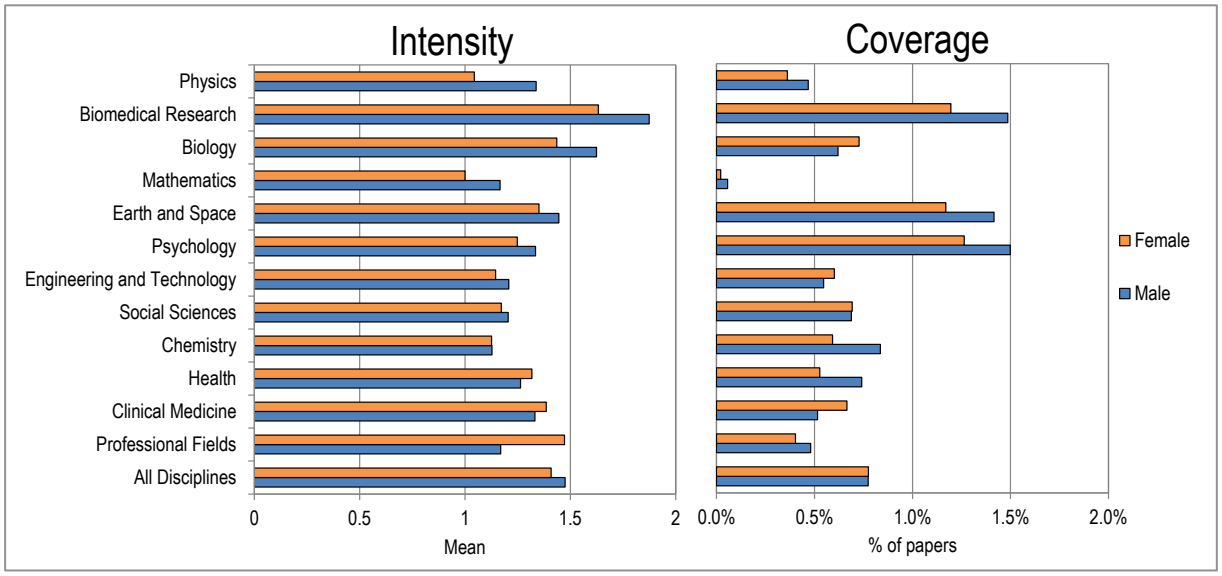

Figure 2. Intensity and coverage of news items of papers first authored by female and male researchers, by discipline, 2012.

Figure 3 provides the average numbers of tweets for all papers with at least one tweet (intensity for non-zero event items) and the percentage of papers with at least one tweet (coverage) by gender. It clearly shows that Twitter is the most popular platform among the three social media and mainstream media metrics analysed here, with an intensity of almost 3 tweets for papers tweeted at least once and coverage of almost 20% of papers (all genders and disciplines taken together). Gender analysis shows that, for all disciplines, papers first authored by female researchers are more intensely tweeted (2.98 tweets for women, 2.94 for men) and have a higher probability of being tweeted than papers first authored by male researchers (21% for women and 18% for men). Consistent with what has been found in terms of citations (Figure 1) and news items (Figure 2), Psychology and Biomedical Research show the highest gap in favour of men in terms of mean numbers of tweets.

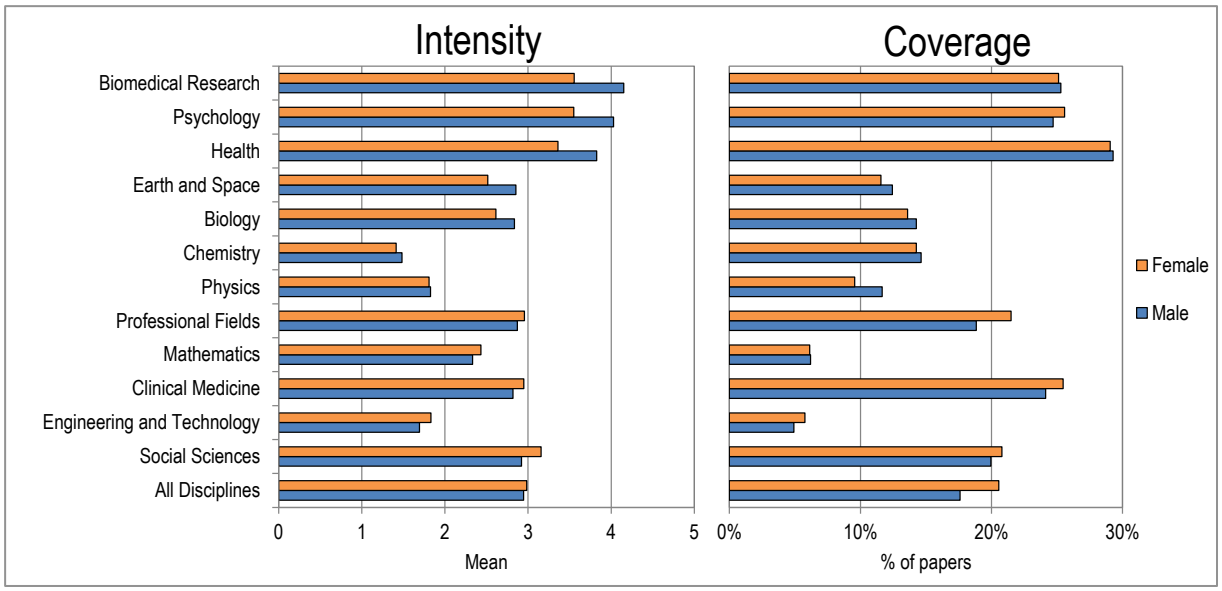

Figure 3. Intensity and coverage of tweets of papers first authored by female and male researchers, by discipline, 2012.

Figure 4 presents intensity and coverage by blog entries of papers first authored by women and men. All disciplines taken together, papers first authored by male researchers show a slightly higher intensity in terms of mean number of blog entries (1.33 for women, 1.40 for men) and higher coverage (1.68% for women, 1.78% for men). As previously shown, Psychology and Biomedical Research present important gender gaps, both in terms of intensity and coverage of blog entries. With respect to intensity, the average of blog entries of papers first authored by female and male researchers are equivalent in Health, Physics and Chemistry and papers authored by women have a slight advantage in Engineering and Technology. Papers authored by female researchers have stronger blog coverage in Clinical Medicine (1.30 % for women, 1.23% for men), Professionals Fields (1.08% for women, 1.02% for men) and Engineering and Technology (0.95% for women, 0.89% for men). However, the extreme gender gap in blog authors—both Puschmann and Mahrt (2012) and Shema, Bar-Ilan and Thelwall (2012) showed that about three quarters of bloggers where male—seems to transfer to the authors cited in blogs as confirmed by the coverage of papers authored by male researchers.

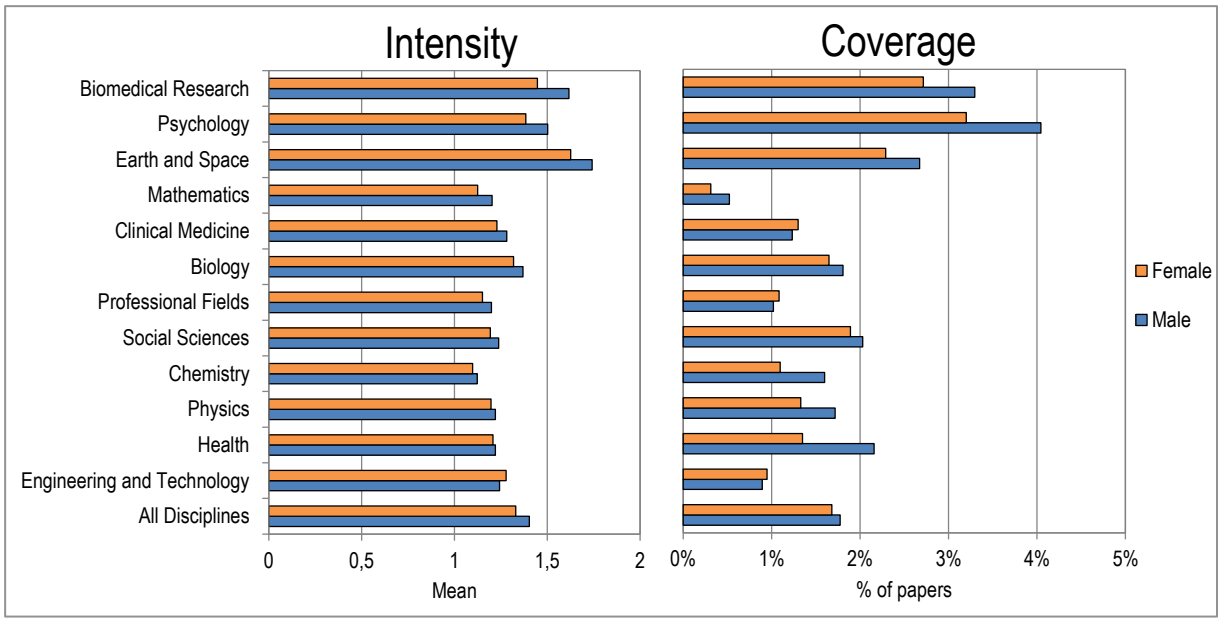

Figure 4. Intensity and coverage of blog entries of papers first authored by female and male researchers, by discipline, 2012.

Discussion and conclusion

Our findings demonstrate a more gender-balanced portrait when considering social media and mainstream media metrics (Figures 2 to 4), than when considering scientific impact as measured by citations (Figure 1). This could be explained by the fact that the impact communities contributing to these metrics are different: the scientific community which constitute the citing audience is more male-dominated than the social media environment (Kimbrough et al., 2013).

However, there is uniformity in the results neither by discipline nor platform. Coverage varied significantly by discipline, as did the mean impact score by gender. Furthermore, gender differences were found when examining microblogging, blogging, and news coverage. This suggests more information is needed before conclusive evidence on gender equality or inequality in social media metrics can be determined.

It could be argued that the diversity of the social media audience gives a broader audience an ability to respond to scholarly communication and therefore these measures of impact are a more honest metric of the absolute value of the work. However, lacking adequate validation of the meaning of social media metrics (Wouters & Costas, 2012), it is perhaps pre-emptive to make such a claim, as many tweets are actually made by bots (Haustein et al., in press). Further research on the nature of highly tweeted research will thus be necessary to assess the underlying mechanisms underneath the observed trends.

PubMed and ArXiv vs. Gold Open Access: Citation, Mendeley, and Twitter Uptake of Academic Articles of Iran

Ashraf Maleki

Malekiashraf@ut.ac.ir
Department of Library and Information Science, University of Tehran, Enqelab sq. Tehran (Iran)

Abstract
Despite contradicting evidence that open access (OA) articles might have greater citation advantage, there is less case studies in developing countries showing whether their global publication availability pattern advantages scientific impact metrics. Also, by addition of altmetrics to the world scientific evaluation system it is less known how different research access channels such as OA publishers, PubMed database and arXiv repository help altmetric indicators. Therefore, this paper investigates the case of WoS publications of Iran (2001-2012) for impact of mentioned publication availability models on citation, Mendeley readership, and tweet counts across four broader disciplines. Findings on 98,453 articles show that gold OA papers (5%) do not benefit significantly more metric counts, except in tweets linking to OA medical publications. Articles in PubMed Central (3%) significantly advantage the three investigated metrics, whereas arXiv preprints (2%) had higher readership advantage only. Different from PubMed publications, tweets to OA medical research were not significantly correlated with citations, suggesting their social impact rather than scientific. Additionally, OA publications are not significantly read by Mendeley users in developing countries, but developed ones, only in life science and biomedicine. Therefore, repository availability appears to be highly impactful in terms of citation and readership, whereas OA publications tend to receive rather high social impact through tweets.

Conference Topic
Altmetric

Introduction
Although traditional citation analysis helps countries to assess academic aspects of research impact and to fund them, so far wider aspects of impact including social and educational influence of research publications have been mainly ignored. However, by developing models of science assessment it seems that there will be better tools to assess influential aspects of research perhaps advantageous for public society rather than academic communities (Bornmann, 2012). Therefore, to improve aspects of wider impact, open access movement encourages researchers to make their research available online using various solutions. The open access (OA) availability of publications was a substantial addition to scholarly communication that enhanced science availability to a wider social audience and the researchers who had no access to subscription-based scientific data sources, especially those in developing countries (Contreras, 2012). With the advent of social networking sites and an access to free and open science, wider audience are now encouraged to publicly distribute science and give feedback about the scientific outputs. Extensive bookmarking of students and academics in research networks such as Mendeley (Mohammadi & Thelwall, 2013; Zahedi, Costas & Wouters, 2014; Haustein & Larivière, 2014) and prevalent reflection of the users' interest in online social networking sites such as Twitter (Haustein et al., 2013; Maleki, 2014) are evidence of wider impact of scientific publications beyond formal citations. Therefore, freely available publications not only advantage more citations (Lawrence, 2001; Gargouri et al., 2010; Laakso & Bjork, 2013), but also there is evidence they benefit from early reflection of impact in online media metrics in a way seemingly different from non-OA. In this respect, many of the top papers with higher altmetric scores in *Altmetric.com* were open access (Van Noorden, 2012). However, in spite of these evidence, there is less case

studies showing whether OA advantage is available for publishing pattern in developing countries, as in this research for Iranian WoS (Web of Science) publications.

The evidence suggests that developing countries have more OA journals than even some distinguished European countries (Bayry, 2013) and institutional repository growth since 2010 (Pinfield et al., 2014), however their journals are less internationally recognized or listed in scientific databases such as PubMed (Bayry, 2013). There are also barriers such as language, lack of knowledge about how OA publishing systems work (Salager-Meyer, 2014), and less funding for the researchers in these countries to contribute in high quality OA journals. Hence, it is less known how availability of their publications advantage citation and altmetric indicators. Therefore currents research aim to test OA impact on formal citations, Mendeley readerships and Twitter mentions (more below) to scholarly publications with Iranian authors, because this country in recent years had a rather noticeable scientific publication growth (e.g. Moin, Mahmoudi & Rezaei, 2005; Brown, 2011).

Furthermore, a fundamental challenge as Moed discussed (2012) is that along with OA journals (gold OA), self-archiving forms of publications (green OA) come a wide variety. There are about 80% of publishers that permit self-archiving (Laakso, 2014) in institutional homepages, subject repositories and web portals that excluding them might decline accuracy of OA advantage analyses (Moed, 2012). Amongst the online repositories, PubMed and arXiv have the highest web presence and impact according to Webometrics ranking (Cybermetrics Lab 2015, see more at http://repositories.webometrics.info), however it is less known how they advantage citations compared to OA journals, which is the subject of current research.

It is necessary to recognize the differences between OA journal and these repositories. PubMed refers to an important search engine for peer-reviewed medical research and has a significant role in research uptake in related fields, whereas arXiv is a preprint repository in *Cornell University* for self-archiving papers even before peer-review, mostly in physical sciences. The gold open access is a widespread solution across disciplines. However, a restricted number of publications in the world currently are published in journals with a free online version, as Harnad estimated gold open access articles about 5% in 2004; and without a considerable change in 2009, this proportion was 5.9% as covered in WoS (Laakso, 2009). However, there were better improvement in green OA reaching to about 12% in 2011 (Björk et al., 2014).

Among altmetric indicators, Mendeley readership and Twitter mentions to articles are known for their prevalent users (Thelwall et al., 2013; Zahedi, Costas & Wouters, 2014). However, evidently the two metrics are different in terms of aspects of impact. Majority of the online users in Mendeley are students (Mohammadi et al., in press; Zahedi et al., 2013; Haustein & Larivière, 2014), but in Twitter are the public audience (Maleki, 2014). They also are different from citation in terms of aspects like statistical distribution pattern (Thelwall & Wilson, in press; Eysenbach, 2011), and incidence, as tweets are fast and immediate (Eysenbach, 2011; Shuai et al., 2012) but Mendeley readerships and citations gradually increase. Also their prevalence is different, as tweets are linking to less publications than Mendeley readerships and citations (Thelwall et al., 2013). Thus, they individually reveal aspects of impact in different ways.

Background Literature

Citation advantage of open access publications

Various studies have reported that OA availability increases citation rate to articles in various fields. The premiere signs of OA citation advantage was reported from conference papers in computer science (Lawrence, 2001). More recently, Gargouri et al. (2010) found both self-selective self-archiving and mandatory self-archiving highly cited. In addition, Laakso and

Bjork (2013) observed that delayed OA policy for 2011 publications with about 78% available within the first year and about 85% within the two year after the publication, increased journal citation rate twice as much as non-OA journals and three times more than immediate OA journals.

In contrast, there are other studies that did not support a citation advantage for OA publications, some of them reviewed in Craig et al. (2007). Amongst more recent evidence Davis did several studies finding no OA citation advantage. He did a randomized control of 11 journals of American Physiological Society, finding no OA advantage after 9-12 month (Davis et al., 2008). His other study included 11 biology and medicine journals among which citations to OA articles fell from 32% in 2003 to 11% in 2007 (Davis, 2011). Gaule and Maystre (2011) also found 17% OA articles in PNAS during 2004 to 2006, where they found no OA diffusion advantage, but rather an author self-selection advantage after adjustment for confounders.

Studies report various evidence that online repositories increase citation advantage of articles, whereas subject repositories are more known to researchers than institutional ones (Cullen & Chawner, 2011). For instance, a study on articles in four math journals deposited in the arXiv indicated 35% more citation on average (Davis & Fromerth, 2007). Wren (2005) also showed that from both OA and non-OA journals with higher Journal Impact Factor (IF) over a third had OA reprints in non-journal websites of which over half had educational domains (.edu), providing a wider access to open research. Furthermore, Jeong and Huh (2014) showed that listing non-OA, non-Medline journals in the open access database of PubMed Central has over years led to an increase in their citation rate and impact factor in comparison with non-OA, non-listed journals.

Wider impact of open access publications

The OA publications were one of the premiere resources of online impact studies of scholarly publications, which revealed aspects of wider impact beyond traditional citations (Kousha & Thelwall, 2006; Vaughan & Shaw, 2007). For instance, Kousha and Thelwall (2006) studied URLs linking to OA publications of library and information science, which were demonstrative of 43% of their formal and 18% informal impact. In another study, Google Scholar unique citation to a sample of articles in 39 WoS OA journals in biology, chemistry, physics and computing was studied finding non-journal Google Scholar citations to OA publications indicator of their wider impact (Kousha & Thelwall, 2008). Other studies revealed usage advantage of online OA publications. Davis (2011) indicated that OA publications had more reader than subscription-based publications but not more citation advantage, for 89% more full-text downloads, 42% more PDF downloads, and 23% more unique visitors.

Only very recently a few studies compared altmetrics across OA publications. Adie (2014) reported that in the *Nature Communication* OA articles attract significantly more Mendeley readers and tweets. Also, Alhoori et al. (2015) displayed that OA papers have 60% more readers and 7% more tweets than non-OA, although non-OA articles were relatively highly covered in both Mendeley and Twitter.

Online Readership Impact assessment in Mendeley

The number of users who bookmarked publications in Mendeley reference sharing site is known as Mendeley readership metric for majority (55%) of users who add papers to their Mendeley libraries for reading or with the intention to read (Mohammadi, Thelwall & Kousha, in press). There is various evidence that Mendeley readerships can be indicative of scientific impact of research and predictor of correlates formal citations (Bar-Ilan, 2012; Thelwall, Haustein, Larivière & Sugimoto, 2013), moderately and weakly in social sciences,

and humanities, respectively (Mohammadi & Thelwall, in press) and strongly in many fields in medical research (Thelwall & Wilson, in press). Wang et al. (2014) reports correlations of Mendeley and citation in a range of 0.36 to 0.61 with 1% significance level in seven PLoS journals and increased html views in correlation with altmetric scores of the articles. A study on arXiv repository examined impact of European astrophysics preprints on Mendeley readerships, finding that 47% of the publications in Scopus are in arXiv, whereas there were more arXiv papers (40%) in Mendeley than Scopus publications (27%) (Bar-Ilan, 2013). Furthermore, Mendeley metric had larger correlation with citations and Journal Impact Factor (IF) than Faculty of 1000 article factors for Genomics and Genetics articles (Li & Thelwall, 2012).

Social Impact Assessment via Twitter mentions

Studies had shown that Twitter is a promising social media to examine social popularity of articles (Thelwall et al., 2013) where tweets linked to about 10% of 1.4 million PubMed articles; and were a fast metric to track comments on arXiv preprints (Shuai et al., 2012). In another study, Wee and Chia (2014) showed that among 20 highly cited WoS articles citations were significantly correlated with altmetric scores in some subject categories including general and internal medicine (Pearson correlation significant in 0.36 level), applied physics (0.39), sociology (0.49), literature (0.62), and music (0.67). The correlation turned out to be significant among articles with highest altmetric scores in multidisciplinary engineering (0.35) and communication (0.31), whilst majority of altmetric scores in various fields coming from Twitter mentions (65% to 89%) rather than Facebook (1% to 11%), news (0 to 19%), and blogs (2% to 11%). Current research is a further exploration into the previous study on Twitter uptake of WoS publications with Iranian authors (Maleki, 2014). The study suggested 5% of publications in 2011-2012 with positive Twitter mentions with the highest uptake was in life science and biomedicine (10%) where links were often created by public society rather than scientific communities (*ibid*).

Research Questions

1. The extent to which are OA, PubMed and arXiv publications by Iranian authors tweeted, read and cited?
2. How do readerships and tweets correlate with formal citations when studies are available through the three above channels across disciplines?
3. Do OA publications advantage more readers in developing countries than developed ones?

Method

As a follow-up study to the previous research on Twitter mentions (Maleki, 2014), the dataset is the same as in the previous research, confined to publications in 2001 to 2012. WoS citations are based on the data available from May 2013 for 98,455 articles with DOIs. Twitter mentions are available according to results in July 2013 through *Altmetric.com* - a subscription based altmetric data provider (see the reasons for choosing *Altmetric.com* in Maleki, 2014); Mendeley readerships are examined via DOI submission to *ImpactStory.org*, another subscription based altmetric data provider which was free at the time of gathering data, in July 2013. *ImpactStory.org* was used because it provided attributes of Mendeley users and because it was different from *Altmetric.com* which provided readers only if papers had social media buzz. However choosing *ImpactStory.org* it was possible to gather a sample of about 30,000 papers rather than all the data.

DOAJ (Directory of Open Access Journals), WOS and Scopus journal datasets are consulted for OA availability of journals and papers OA status is modified based on journals' *Start year* in DOAJ. Data about PubMed archival of the articles was gathered by using DOIs of the publications on the full publication dataset available from PubMed Central. Publications were available via PubMed across four broader research areas for 2,978 papers (3%) the most in life science and biomedicine (2132 papers, 7%). ArXiv preprints of papers were examined using arXiv API, via DOI submission. For this purpose a custom-built program was used to submit 100 DOIs each query to arXiv. The data from arXiv might be not accurate because DOIs are available in arXiv if the authors have provided them for the publications. Results showed that there was overall 489 publication with preprints in arXiv consisting 1.3% of physical science article in 2001 to 2012 and very small proportion in technology (0.1%).

As altmetrics are faster than WoS citations, to learn if tweet and Mendeley uptakes are predictive of later WoS citations the dataset is tested in two time periods. Therefore, an interval is required to be considered for the publications to provide the opportunity to get citations. In case of Twitter, because the reliable and available data is confined to the most recent years (2011 onwards) citations are checked for publications in 2011-2012 in two time intervals after the publication year, the first in July 2013 and the second in December 2014. In Mendeley the data from July 2013 for both recent and older publications could be reliably used, thus the data is compared for recent publications in 2011-2012 and for older publications in 2001-2010. A signed-rank Mann-Whitney test is used to examine differences in medians and means of counts for OA, PubMed and arXiv publication against their counterparts (non-OA, non-PubMed, non-arXiv, respectively) inside each publication period.

A zero inflated negative binomial regressions analysis model is used to assess whether citation, readership and tweet counts dependend on publication access channels. Therefore, articles available via open access journals, PubMed, and arXiv are individually taken as nominal explanatory dummy variables coded as 1, and all the other cases not available in the corresponding availability model coded as 0. The 0 is the reference variable, which is also redundant because OA, PubMed and arXiv are true for minority of the cases. The reason for choosing this model is the overdispersion in the counts or the exceeding variance of the three metric counts from their means.

The analyses were supplemented with users' nationality data on the Mendeley readership counts for the publications. The results are compared across development status of countries for difference in readership of OA, PubMed and arXiv articles in Mendeley. Some articles in Mendeley were recorded with multiple variations, to avoid duplicates the ones with higher readership counts were considered.

Results

The main results of study suggest that out of 98,453 articles in 2001-2012 which had DOIs, 4,772 articles (4.7%) were published in 449 (6%) gold OA journals. There also were 3,043 articles (3%) listed in PubMed Central and 1,489 articles (0.5%) with preprints in arXiv. The articles which were linked by at least one tweet appeared in 1,067 journals, among which there were 116 gold OA journals (11%), 202 journals (19%) with articles indexed in PubMed Central, and 55 journals (5%) with article preprints in arXiv. As mentioned in method a smaller set of publications (35% of all above) were tested for readerships including all articles in 2,522 journals, comprising 273 (11%) gold OA journals, 307 journals (12%) available in PubMed list, and 56 journals (2%) with preprints in arXiv.

The OA journal *PLoS One* with 102 articles all available via PubMed Central had the most articles with tweets (36 papers) and readership counts (83 papers). The following two checked journals with articles available via PubMed with more articles in Mendeley were *Journal of Assisted Reproduction and Genetics* (48 out of 63 papers with readership, and 2 tweeted

papers) and *International Journal of Nanomedicine* (38 out of 47 papers with readership, and 3 tweeted papers). Additionally, the results suggested that tweets link to more articles with preprints in arXiv in the journals *Astrophysics and Space Science* (with 35 tweeted articles and only 20 with preprints in arXiv), *Physical Review D* (27 tweeted articles whereas 75 with preprints in arXiv), and *Physical Review E* (17 tweeted articles, 27 preprints in arXiv) both former journals in astronomy and astrophysics and the latter one in soft-matter physics. However, there were journals with many papers in Mendeley, but poorly available preprints in arXiv; for instance there were 54 articles with readership counts in *International Journal of Theoretical Physics* out of 249 articles whereas only 6 with preprints in arXiv. Other OA journals with numerous articles with both citations and readerships, were *Analytical Science* (84 with readership and 116 with citations out of 118 papers) and *Molecules* (51 articles with readerships and 81 with citations out of 93 and 2 tweeted articles.

Table 1. Spearman correlation between Mendeley readership counts and WoS citations across years in terms of four broader research areas and of OA, PubMed, and arXiv availabilities of articles.

Correlation between altmetrics and citations in terms of availability models

Tables 1 and 2 show the correlation between Mendeley readerships and tweets with citations. The readerships of OA articles in life science and biomedicine are appropriately in moderate correlation with citations, and likewise, PubMed publications are correlated, but in stronger levels (correlation coefficients ranging from 0.31 to 0.55). However, the correlations in non-OA and non-PubMed papers are in lower levels (ranging from 0.20 to 0.34) - all correlations are significant in $p < 0.001$. This advantage were not available for the other three broader research areas, where the correlations were significant about non-OA publications rather than OA. The findings suggest that readership of publications with scientific impact have enhanced over years by OA and PubMed availability of life science and biomedicine articles, since older publications are in stronger correlation with citations than newer ones, although they are less numerous.

The figures in Table 2 suggest that there is a weak and significant correlation between tweets and later WoS citations in life science and biomedicine and physical sciences. Different from PubMed articles, tweet to OA publications did not have significant correlation with citations, perhaps for their social impact rather than scientific. On the other hand, correlations between tweets and citations are usually weak and significant after the interval for articles to receive citations in life science and biomedicine (correlations ranging from 0.07 to 0.17 significant in $p < 0.01$) and physical sciences (correlation significant in 0.13, $p < 0.001$). Correlations in all the fields does not show an OA advantage. Instead, there were weak and significant correlation in PubMed and non-OA publications in life science and biomedicine, and non-arXiv and non-OA articles in physical sciences after the interval.

Table 2. Spearman correlation between Twitter mentions and WoS citations in 2011-2012 in terms of four broader research areas and of OA, PubMed, and arXiv availabilities of articles.

Metrics dependencies to OA, PubMed and ArXiv publications

As figures in Table 3 show, tweeted gold OA publications (301 papers, 0.8%) are less than non-OA (1,975, 4.4%), whereas in fact more OA articles (11% of all OAs) tend to be tweeted than non-OA (5% of all non-OAs). This happens across the four broader fields with the highest occurrence in life science and biomedicine (15% OA vs. 10% non-OA). Also, findings suggest that tweets tend to link to significantly more PubMed publications in life science and biomedicine (24%), whereas this proportion is higher than tweeted OA publications (15%). The same is observed in physical sciences where arXiv preprints (55%) tend to receive tweets more than OA articles (7%). A Mann-Whitney test suggests that tweets to arXiv (206 tweets to 136 articles) were not significantly more than tweets to publications without arXiv preprint (472 tweets to 406 papers).

Also, tweets to PubMed (1,118 tweets to 293 papers vs. 2,105 tweets to 972 non-PubMed papers), and OA articles in life science and biomedicine (778) are significantly higher than their relative counterparts (i.e. non-PubMed and non-OA, respectively) ($p<0.001$). There were no significant difference between tweets to OA and non-OA in other fields, however. Additionally non-OA publications significantly advantage more citations to tweeted articles in 2011-2012 either in the early stage after publication (3.8 mean tweets to non-OA vs 1.6 tweets to OA) or later stage (10.3 vs. 6). This observations is in line with the correlations above which were significant in cases the publications were non-OA rather than OA in all fields excluding life science and biomedicine.

Table 3. Mean and median tweets and citations to articles with at least one tweet across publication availability models.

		Median Mean					
Source/Publication year		OA	Non-OA	PubMed	Non-PubMed	arXiv	Non-arXiv
Twitter mentions	2011-2012	1 2.9**	1 2.0	2 3.6**	1 1.8	1 1.3	1 1.2
Early citations	Jul. 2013	0 1.6	1 3.8**	1 5.1	1 3.2	1 1.5	1 3.5
Later citations	Dec. 2014	3 6.0	4 10.3**	4 13.1	4 9.1	4 6.7	4 9.7
Total articles	2011-2012	315 (14%)	1975 (84%)	336 (15%)	1954 (85%)	35 (6%)	532 (94%)

*significantly more than its counterpart category (OA vs. non-OA; PubMed vs. non-PubMed; arXiv vs. non-arXiv) in $p < 0.01$ level.**significantly more than its counterpart category in $p < 0.001$ level.

Table 4. Mean and median readerships and citations to articles with at least one Mendeley readership across publication availability models.

		Median Mean					
Source/Publication year		OA	Non-OA	PubMed	Non-PubMed	arXiv	Non-arXiv
Mendeley readers	2001-2010	3 4.3	2 4.1	3 6.9**	1 2.4	5 6.1*	2 3.5
	2011-2012	2 4.2	2 3.3	3 5.8**	2 3.2	4 5.3**	2 2.8
Later citations	2001-2010	5 9.0	5 8.9	4 11.4	4 7.5	9 12.6	6 10.7
Early citations	2011-2012	2 3.0	2 3.3**	1 2.2	1 1.8	1 2.2	1 2.3
Total articles	2001-2010	737 (8%)	8850 (92%)	374 (4%)	9213 (96%)	10 (0.3%)	3211 (99.7%)
	2011-2012	743 (11%)	6079 (89%)	558 (8%)	6264 (92%)	75 (4%)	1758 (96%)

*significantly more than its counterpart category (OA vs. non-OA; PubMed vs. non-PubMed; arXiv vs. non-arXiv) in $p < 0.01$ level.**significantly more than its counterpart category in $p < 0.001$ level.

Table 4 shows proportion of publication with positive Mendeley readership 5% OA (1,480 papers) and 52% non-OA (14,929 papers), with the highest article uptake in life science and biomedicine (9% OA and 61% non-OA) and the least in physical sciences (4% OA and 44% non-OA). Further results show that users tend to read non-OA publications (58%) rather similar to OA (55%) while there is no significant difference in their readership patterns across four broader research areas. However, despite in less papers than OA, PubMed publications (932 papers) tend to have higher readerships (5,566 PubMed vs. 4,675 OA readerships), with

the highest occurring in life science and biomedicine (for 76% PubMed vs. 67% OA papers) ($p < 0.05$). The same was seen in arXiv preprints as their read articles (85 papers) tend to have significantly higher readership counts than non-archive ($p < 0.01$).

The OA publications in the two time periods (8% in 2001-2010 and 11% in 2011-2012) are more than PubMed (4% and 8%) and arXiv (0.3% and 4%). The mean PubMed readerships were significantly more than non-PubMed for the publications in older time period of 2001 to 2010 (6.9 PubMed vs. 2.4 non-PubMed) and for articles in 2011-2012 (5.8 vs. 3.2) ($p < 0.001$). ArXiv preprints in Physical science on average also had higher readerships than non-arXiv in both publication periods (significant in $p < 0.01$ in 2001-2010 and $p < 0.001$ in 2011-2012). There were no significant *citation* advantage for OA, PubMed and arXiv papers with Mendeley readerships, neither in the early nor the later stage after the publication year in none of the four research areas, although non-OA publications in social science and humanities and life science and biomedicine had significantly more readerships than OA.

Table 5 shows results of zero-inflated negative binomial regression analysis. The significance of alpha values in Table 5 identifies overdispersions for the three metrics. Voung statistics being above the critical value of 1.96 approves the overdispersion and the need for the zero inflated method. The estimates of the regression coefficients are shown by the values b and the estimated standard errors are the ratios of the coefficients. Therefore, b values show how much the availability of the articles by various models increases metric counts.

The results in Table 5 suggest that PubMed articles significantly advantage the three metric counts. However, (gold) open access were not significant indicator of neither citations nor the two altmetric counts. In addition, publications with preprints in arXiv had significantly more readership counts only.

Table 5. Zero inflated negative binomial regression analysis for citations, readerships and Twitter mentions by variables of availability channels.

	Citations (2001-2012)		Mendeley Readerships (2001-2012)		Tweets (2011-2012)

Publication readership across countries development status

An important limitation of statistics about nationality attributes of users is that Mendeley suggests only top three countries with higher readership counts per paper. Based on these data, users were recognized from 141 countries, including 28,966 readerships from developed countries for 16,472 papers and 21,848 readerships from developing countries for 12,699 papers. Median readerships were more in papers with readers from developed countries rather than developing ones (4 vs. 3 readers per paper). The OA life science and biomedicine publications (excluding other field) had significantly more readers in developed countries ($p<0.05$). PubMed publications also had significantly more readerships in developed countries than developing ones ($p<0.001$), whereas there were no such difference about readership of arXiv preprints. In addition, users in developing countries significantly read more non-OA

articles in technology (3,483, mean users = 1.77 vs. 1.68) and physical sciences (3,628, mean users = 1.73 vs. 1.66) ($p<0.001$). All tests were significant in a signed-rank Mann-Whitney test.

Discussions

A main limitation in this research is that it does not include other potential sources of publication availability such as homepages and institutional repositories and social networking sites for self-archiving. Also, a problem may associate with the regression analysis for which the research is very optimistically focused on direct impact of publication access patterns, whereas results might be affected by other correlates of the metrics such as Journal Impact Factor or Immediacy Index. Therefore, designing more complex models for assessment of availability impact might be subject of future studies.

Regarding the first research question results suggest that there are more OA articles (5%) than PubMed listed articles (3%) and arXiv preprints (2%). Also, there are more OA publication with readers (9%) than PubMed (6%) and arXiv (2%), whereas tweets link to relatively more PubMed (15%) papers than OA (14%) and arXiv (6%). Regarding the second question of research there were a significant correlation between tweets and citations to PubMed articles, indicating their scientific impact. However, tweeted OA publications seem to be reflective of social impact rather than scientific since they do not appear correlated with citations neither in early nor later year. In addition, publications in 2012 are more correlated than 2011, suggesting an overtime increasing publication uptake via tweets. A moderately significant and across years decreasing correlation between readerships and citations to OA and PubMed availability of articles in life science and biomedicine (excluding other fields) suggest that older publication had the opportunity to get higher citations.

The mean tweets to both OA (3.3) and PubMed (3.7) life science and biomedicine papers were significantly more than non-OA and non-PubMed, respectively. These publication strategies have obviously enhanced various aspects of research impact. The difference between the mean tweets to arXiv preprints (1.3) and non-arXiv physical science papers (1.2) is statistically significant, however these tweets are very low and does not reflect an aspects of impact, while generally arXiv papers are regularly tweeted for classification and dissemination purposes. The finding from previous study supports this, as papers in physical science are mainly tweeted by subject specific tweeters for classificatory reasons rather than scientific or social impact (Maleki, 2014). In contrast to OA advantage on Twitter mentions of articles (only in life science and biomedicine), Mendeley readerships was not significantly different across gold open access and non-OA publications in the four field.

The regression models for the three metrics also had results in line with the results from previous section. There is a significant citation advantage only for PubMed publications. Both PubMed and arXiv papers advantage Mendeley readerships. The only difference is in tweets where similar to above results show significantly more tweets to PubMed publications, however unlike the above non-OA advantage significantly more tweets than OA, which shows the effect of other hidden variables.

The expected higher readership of OA papers in developing countries failed to be true. A noteworthy result suggests that Iranian OA medical publication readerships by developed countries were significantly higher than developing countries, whereas this connection was vice versa in technology and physical sciences for non-OA articles. This can be connected to development and competitive abilities in research in these areas and/or the distribution of Mendeley users in various fields across countries. In this respect, the inferences need to be made with caution. However, it seems that Iranian medical research tend to get higher uptake by developing countries by appearing in PubMed index.

Conclusions

An important result of the study suggests that PubMed and arXiv strategies of publication availability can enhance the metric counts especially Mendeley readerships. Citations were mainly influenced by PubMed availability of broader field of life science and biomedical research, whereas tweets mainly link by publications available via gold OA journals. Furthermore, nationality of Mendeley readers appear to be informative about publication uptake patterns worldwide. Also, regarding results in this research with the ones from previous study on tweets it seem that Twitter has the potentials to reflect social impact of medical research for which OA availability and PubMed will help. In addition, subject repositories get higher readerships and tweets chance than papers out of them. Future studies might bring more variables associating these metrics for more realistic look at OA advantage in publication and research impact assessment.

Acknowledgment

The author would like to thank Dr. Kayvan Kousha of the Statistical Cybermetrics Research Group, in University of Wolverhampton, for his inspirations and very useful comments.

Abstract

This article assesses whether academic reviews in *Choice: Current Reviews for Academic Libraries* could be systematically used for indicators of scholarly impact, uptake or educational value for scholarly books. Based on 451 *Choice* book reviews from 2011 across the humanities, social sciences and science, there were significant but low correlations between Choice ratings and citation and non-citation impact metrics. The highest correlations found were with Google Books citations (.350) in science and with WorldCat library holdings counts in the humanities (.304). Books recommended by Choice reviewers for undergraduates were mentioned more often in online course syllabi than were other recommended books. Similarly, books recommended for researchers, faculty members and professionals or graduates tended to receive more Google Books citations than did books recommended for undergraduates. In conclusion, metrics derived from Choice academic book reviews can be used as indicators of different aspects of the value of books but more evidence is needed before they could be used as proxies for peer judgements about individual books.

Conference Topic

Webometrics; Altmetrics

Introduction

Impact assessment in book-based subject areas is more challenging than for article-oriented fields because the major current citation indexes are dominated by academic journal articles, and are therefore inadequate for assessing the research impact of books (Hicks, 1999, Archambault, Vignola-Gagné, Côté, Larivière, & Gingras, 2006, Nederhof, 2006; Huang & Chang, 2008). In recognition of the need to include citations from books (Garfield, 1996), the Thomson Reuters Book Citation Index (BKCI) and Scopus now index selected books, but their coverage seems to be too low to make a difference for impact assessment and they are restricted to just a few publishers and books that are mainly in English (Torres-Salinas et al., 2014). The way that the books are indexed also creates other issues for book impact assessment (Leydesdorff & Felt, 2012; Gorraiz, Purnell, & Glänzel, 2013).

Another important issue is that some academic books, such as textbooks and introductory science books, are primarily written for teaching (Gurung, Landrum, & Daniel, 2012) and other books, such as novels and literary works, may have cultural influence (White, Boell, Yu et al., 2009) or play a public engagement role (Kousha & Thelwall, in press). Moreover, education may be seen as particularly important in the humanities and a core part of its value to society (e.g., Nussbaum, 2012). All of these are unlikely to be reflected by citation counts. Peer review can be used to evaluate the impact of books but it is time-consuming. For instance, in some book-based fields (e.g., history and law) in the 2008 UK Research Assessment Exercise (RAE) reviewers had to assess the research merits of up to 100 books each (Kousha, Thelwall, & Rezaie, 2011). Hence not all of the submitted books may have been examined in detail (Taylor & Walker, 2009). Peer review is also subjective, perhaps

most strongly in the humanities where books are most common. Although critical evaluation is a core skill in the humanities (Small, 2013), it also seems to thrive on controversy and disagreements (Bauerlein, 2002). Moreover, the opinions of reviewers could be more subjective about the teaching or cultural benefits of books than about their research contributions (Weller, 2001).

In response to the weakness of citations for book impact assessment, there have been attempts to assess wider impacts of books (see below), using scholarly book reviews, library holdings statistics, and publisher prestige as well as with altmetrics (Priem, Taraborelli, Groth, & Neylon, 2011). Book reviews are somewhat similar to post-publication reviews for academic articles in systems like Faculty of 1000 (Hunter, 2012; Li & Thelwall, 2012; Mohammadi & Thelwall, 2013; Waltman & Costas, 2014), and both could be useful as additional quality control mechanisms for the critical analysis of published works (Crotty, 2012). The current study explores an alternative source for book impact assessment, *Choice: Current Reviews for Academic Libraries*, which is owned by the American Library Association, and compares it with citation and non-citation metrics. Choice has published reviews of academic books by editors, experts and librarians across different subject areas for about 50 years and is therefore a substantial and successful source of book reviews aimed at librarians making library purchasing decisions. Despite publishing about 7,000 book reviews per year that are relevant to academic libraries, it appears to be an untapped resource in terms of book impact assessment.

Metrics for Book Impact Assessment

Citation Metrics

Web of Science (WoS) and Scopus: Citations to books can be manually extracted from article reference lists (e.g., Cullars, 1998; Krampen, Becker, Wahner & Montada, 2007) or through cited reference searches in WoS (e.g., Bar-Ilan, 2010; Butler & Visser, 2006) or Scopus (Kousha, Thelwall, & Rezaie, 2011), which now includes tens of thousands of books. However, these methods are time-consuming and do not include many citations from books to books. Book to book citations can give different results from article to book citations, especially in book-based fields such as in the humanities and some social sciences (Cronin, Snyder, & Atkins, 1997, Archambault, et al., 2006).

Book Citation Index: The Thomson Reuters Book Citation Index now indexes the references in about 60,000 books and monographs (Book Citation Index, 2014) and is an optional addition to WoS. Nonetheless, only about 3% of BKCI-indexed books are in non-English languages and about 75% of their publishers are from the USA and England (Torres-Salinas et al., 2014). Added to the absence of aggregated citation counts for edited volumes, its use for evaluative purposes would be problematic (Leydesdorff & Felt, 2012; Gorraiz, Purnell, & Glänzel, 2013).

Google Books: Although Google Books (GB) is not a citation index, it can be used to extract citations from digitised books for book impact assessment. GB citations to academic books are more plentiful than citations in traditional citation databases (Scopus and BKCI) in the humanities and in some social sciences but not in science (Kousha & Thelwall, 2009; Kousha, Thelwall, & Rezaie, 2011; Kousha & Thelwall, 2014). For instance, in one study the median number of GB citations was three times higher than the median number of Scopus citations to 1,000 books in the 2008 UK RAE in seven fields (Kousha, Thelwall, & Rezaie, 2011).

Non-Citation Metrics

Book Reviews: Scholarly book reviews are significant academic outputs (Hartley, 2006), especially in some humanities fields, such as history, literature and philosophy (Zuccala &

Van Leeuwen, 2011). One early study found a high correlation (0.620) between the number of reviews in the Book Review Index and the number of library holdings in the OCLC database for 200 novels (Shaw, 1991), suggesting that both indicators may reflect a common factor, such as the popularity of the novels. Another study found that sociology books with more positive reviews tended to attract more citations (Nicolaisen, 2002), although the strength of association between the number of book reviews and citations varies between disciplines (Gorraiz, Gumpenberger, & Purnell 2014). Low but significant Spearman correlations have also been found between the numbers of Amazon book reviews and citation metrics (Kousha & Thelwall, in press).

Libcitations: National or international library holdings statistics can give useful information about potential usage of, or interest in, books (Torres-Salinas & Moed, 2009; White, Boell, Yu et al., 2009). White, Boell, Yu et al. (2009) argued that libcitation statistics could be used as an indication of the cultural benefit of books, especially in the social sciences and humanities. Several follow up studies have found significant, but low, correlations between library holdings statistics and citation metrics for books (Linmans, 2010; Zuccala & Guns, 2013; Kousha & Thelwall, in press), suggesting that library holdings reflect diverse kinds of influence, such as teaching and cultural impacts, that cannot be traced through citations.

Publisher Prestige:

In the absence of credible citation-based indicators for the impact assessment of books, publisher prestige has been proposed as an alternative (Donovan & Butler, 2007). Attempts to estimate the prestige of publishers through surveys of academics have shown that the perception of prestige varies by field (Garand & Giles, 2011; Giménez-Toledo, Tejada-Artigas & Mañana-Rodríguez, 2013). In addition to reputational surveys, BKCI indicators (Torres-Salinas et al., 2012), Scopus citations and matching library holdings data from WorldCat.org (Zuccala, Guns, Cornacchia, & Bod, in press) have also been used to rank academic book publishers.

Syllabus Mentions:

Academics may write textbooks for teaching or monographs that are widely used in teaching rather than, or in addition to, research (Gurung, Landrum, & Daniel, 2012). This kind of teaching contribution may be undervalued or unrewarded (Boyer, 1990; Jenkins, 1995; Healey, 2000) but evidence of inclusion in academic syllabi can reflect some aspects of teaching scholarship success (Albers, 2003; Thompson, 2007). In response, an attempt has been made to capture citations from online course syllabi for WoS-indexed articles across multiple fields, with the results suggesting that online syllabus mentions can be a useful indicator in some social sciences fields (Kousha & Thelwall, 2008).

Research Questions

The following research questions are designed to assess whether ratings and recommendation information in *Choice: Current Reviews for Academic Libraries* could be useful for the impact assessment of academic books.

1. Do Choice book ratings correlate with citation metrics or with other non-citation metrics for books?
2. Are Choice audience recommendations reflected in citation and non-citation metrics? For instance, do books recommended for undergraduates have more syllabus mentions than books recommended for researchers?

Methods

Choice Reviews

The recommendations for 451 book reviews from a free sample issue of *Choice Reviews Online* published in 2011 were extracted from the *Humanities*, *Social & Behavioral Sciences*, and *Science & Technology* categories but omitting reviews for the *Reference* section. The books were selected, with permission of *Choice*, from the collection of free sample reviews. The recommendation levels assigned to Choice reviews (see http://www.ala.org/acrl/choice/about) were converted into a number, from 1 for 'Not recommended' to 5 for 'Essential'.

- *Essential:* A publication of exceptional quality for academic audiences and a core title for academic libraries supporting programs in relevant disciplines.
- *Highly recommended:* A publication of high quality and relevance for academic audiences.
- *Recommended:* A publication containing good content and coverage and suitable for academic audiences.
- *Optional:* A publication that, due to limited value or deficiencies, is marginal for academic audiences.
- *Not recommended:* A poor quality publication or one not suitable for academic audiences.

Choice reviewers include extra information about usefulness for different academic audiences, such as undergraduates, researchers, faculty members and, professionals (Table 1). This information was used for further analyses.

Table 1. Examples of audience recommendations in Choice book reviews.

Audience recommendations	*Examples*
Mainly for undergraduates	*Essential.* Upper-division undergraduates through faculty. *Highly recommended.* Lower-division undergraduates through faculty. *Recommended.* Undergraduate and graduate studies. Optional. Upper-division undergraduates and above.
Mainly for graduates, researchers, professionals and academics	*Essential.* Graduate students, faculty, and professionals. *Highly recommended.* Research libraries and scholars. *Recommended.* All academic and professional audiences. *Optional.* Graduate students, researchers, and faculty.

Google Books Citations

For GB citations, Google Books API searches were used in the previously developed and tested software *Webometric Analyst* (http://lexiurl.wlv.ac.uk, "Books" tab) to extract citations from digitised books indexed by Google Books (for method details see: Kousha & Thelwall, 2014). To locate GB citations in other digitised books, we searched for the first author last name and the first (up to) ten terms of the book title as a phrase search, combined with the publication year.

Lurz "Mindreading animals: The debate over what animals know about other" 2011

For books with three or less words in their titles we added the publisher to the query:

Benford "Performing mixed reality" 2011 "MIT Press"

Syllabus Mentions

For syllabus mentions, an automatic method was used to search for mentions of the 451 books in public online course syllabi indexed by the Bing search engine. *Webometric Analyst* software and a set of rules were used to identify the syllabus mentions in academic websites and to exclude false matches in order to give accurate, although not comprehensive, results. This method was developed to capture academic syllabus mentions for books rather than articles (cf. Kousha & Thelwall, 2008). The first author last name was combined with the book title as a phrase search and either "syllabus" or "course description", with the results of the two combined and false matches automatically filtered out. The automatic syllabus citation extraction method applied in this study seems to give high accuracy (over 90%), although it misses results from non-academic institutions and syllabi stored in password protected databases and systems (see also Kousha & Thelwall, in press).

Barnett "Empire of humanity a history of humanitarianism" "course description"|Barnett "Empire of humanity a history of humanitarianism" "syllabus"

WorldCat Library Holdings

For library holdings, we manually searched for the 451 books in WorldCat online (http://www.worldcat.org) and recorded the number of library holdings for each one.

Mendeley Readers

For Mendeley reader counts, we used the Mendeley API in *Webometric Analyst* with queries combining the last name of the first author, the book title and the publication year for 451 books in the data set (for method details see: Mohammadi & Thelwall, 2014). This returns the number of users of the social reference sharing site Mendeley that have added the book to their personal library.

Amazon.com Reviews

The numbers of customer reviews were automatically extracted from the main Amazon.com URLs for each of the 451 books via *Webometric Analyst* (for method details see: Kousha & Thelwall, 2014 in press).

Sources not used

Not all book impact metrics were collected for the books in the data set. Publisher prestige was not collected because there is not a recognised source of this evidence and it varies by field. WoS/BKCI and Scopus citations were also not collected because Google Books citations have been shown to be superior for book impact assessment in most fields (Kousha & Thelwall, 2009; Kousha, Thelwall, & Rezaie, 2011; Kousha & Thelwall, 2014).

Results

Roughly three-quarters of books with Choice reviews had at least one GB citation (Table 2), and this is higher in the social sciences (80%, median: 3) than in science (68%, median: 2). Moreover, about 45% of the books had one or more academic syllabus mentions and the median number of syllabus mentions is higher in science (1) compared to the humanities (0)

and the social sciences (0). About 30% of the Choice books had at least one Amazon review and all 451 books had at least one WorldCat library holding (median: 394). Nevertheless, only 1.5% of books had at least one Mendeley reader. Follow-up manual investigations with Mendeley searches confirmed that this very low number was not a technical artefact but genuinely reflected the virtual absence of the Choice books from this site. The low Mendeley coverage confirms previous results that, although academic journal articles often have many Mendeley readers (e.g., 78% with one or more readers in the medical sciences, see Thelwall & Wilson, in press), the same is not true for books and monographs (Kousha & Thelwall, in press; see also: Hammarfelt, 2014), suggesting that Mendeley is currently not useful for book impact assessment.

Overall, it seems that GB citations are plentiful enough for book citation impact assessment and academic syllabus mentions, libcitations and Amazon reviews may be common enough to be used to indicate different types of impact, such as teaching, cultural or public interest.

Table 2. Google Books citations, syllabus mentions, libcitation, Amazon reviews and Mendeley reader counts for 451 books with Choice reviews published in 2011 in three broad fields.

Choice subjects	*No. of books*	*Google Books No. (% with GB cites*) median (mean)*	*Syllabus No. (% with syllab.*) median (mean)*	*Libcitation No. (% with holdings*) median (mean)*	*Amazon Rev. No. (% with reviews*) median (mean)*	*Mendeley No. (% with readers*) median (mean)*
Human.	136	474 (69.8%) 2 (3.5)	120 (39.7%) 0 (0.9)	62098 (100%) 356 (456.6)	105 (35.2%) 0 (0.8)	31 (3.7%) 0 (0.2)
Social Sci.	234	1278 (79.9%) 3 (5.5)	349 (45.7%) 0 (1.5)	130018 (100%) 442 (555.6)	951 (34.2%) 0 (4.1)	90 (3.4%) 0 (0.4)
Sci. & Tech	81	367 (67.9%) 2 (4.5)	149 (50.6%) 1 (1.8)	41585 (100%) 391 (513.4)	174 (27.2%) 0 (2.15)	194 (3.7%) 0 (2.4)
Total	451	2119 (74.7%) 2 (4.7)	618 (44.8%) 0 (1.4)	233701 (100%) 394 (518.2)	1230 30.8%) 0 (2.7)	315 (1.5%) 0 (0.7)

*% of books with at least one Google Books citation, academic syllabus mention, WorldCat libcitation, Amazon review and Mendeley reader.

Table 4 compares the metrics between those for books with Choice reviews claiming teaching utility (mainly for undergraduates) and those for books with reviews claiming benefits for graduates, researchers, faculty members and professionals. Books with research or other academic relevance have higher GB citation impact (median 3) than books with benefits for undergraduates (GB median 2). In contrast, books with more teaching utility for undergraduate studies tended to have more academic syllabus mentions (median 1 and 55% with one or more syllabus mentions) than books for academic audiences (median zero and 34% with one or more syllabus mentions). Hence, it seems that Choice reviews are broadly capable of distinguishing between the different types of audiences for books.

Table 3. A comparison of book metrics based on Choice book reviews with different rating recommendation levels.

Recommendation	*No. of books*	*Google Books No. (% with GB cites*) median (mean)*	*Syllabus No. (% with syllab.*) median (mean)*	*Libcitations No. (% with holdings*) median (mean)*	*Amazon Rev. No. (% with reviews*) median (mean)*	*Mendeley No. (% with readers*) median (mean)*
Essential/highly recommended	150	768 (88%) 3 (5.1)	186 (48.6%) 0 (1.2)	85256 (100%) 482.5 (568.4)	440 (40%) 0 (2.9)	51 (5.3%) 0 (0.34)
Other	301	1351 (68.1%) 2 (4.5)	432 (42.8%) 0 (1.4)	148445 (100%) 359 (493.2)	790 (26.2%) 0 (2.6)	264 (2.9%) 0 (0.9)

Table 4. A comparison of book metrics based on Choice recommendations for undergraduates and other academic audiences (graduates, researchers, faculty).

Audience recommendation	*No. of books+*	*Google Books No. (% with GB cites) median (mean)*	*Syllabus No. (% with syllab.) median (mean)*	*Libcitation No. (% with holdings) median (mean)*	*Amazon Rev. No. (% with reviews) median (mean)*	*Mendeley No. (% with readers) median (mean)*
Undergraduates	240	1098 (70.1%) 2 (4.7)	420 (55%) 1 (1.7)	122497 (100%) 394.5 (510.4)	649 (29.6%) 0 (2.7)	267 (5.4%) 0 (1.1)
Graduates, faculty, researchers, profess.	203	1006 (79.8%) 3 (4.9)	197 (34%) 0 (0.9)	108260 (100%) 405 (533.3)	579 (33%) 0 (2.85)	48 (2%) 0 (0.2)

+.Eight books with "Not recommended" Choice reviews were excluded.

There are low but significant positive Spearman correlations between Choice ratings and various citation and non-citation indicators (Table 5). Thus, in general, books with more GB citations, academic syllabus mentions, library holdings or Amazon reviews tended to be recommended more highly by book reviewers. The correlation is highest between Choice ratings and libcitations (0.201). This may reflect academic libraries ordering books based on Choice reviews and recommendations, especially in the United States (About Choice magazine, 2015).

Table 5. Spearman correlations between Choice ratings and other metrics across all fields (n=451).

Metrics	*Choice rating score*	*GB citations*	*Syllabus mentions*	*Libcitations*	*Amazon reviews*
Choice rating score	1	**.142****	**.103***	**.201****	**.141****
GB citations		1	.171**	.189**	.196**
Syllabus mentions			1	.121*	.073
Libcitations				1	.222**
Amazon reviews					1

**. Significant at p=0.01

*. Significant at p=0.05

There are disciplinary differences in the strength of association between Choice ratings and the other metrics (Tables 6-8). The highest correlation is between Choice ratings and GB citations in Science & Technology (0.350), but this correlation is much lower in Social & Behavioural Sciences and in the Humanities category. Hence, it seems that science books with more positive reviews tend to be more cited in other books and so Choice reviews may be a useful indicator for assessing the research contribution of scientific books. This is a surprising finding given that books are not as highly valued in science as in the humanities.

In the Humanities category there is a low and statistically insignificant correlation between Choice ratings and GB citations but this may reflect the weak association between citations and research quality in the humanities more than a lack of correlation between Choice ratings and research value or impact. The higher association between Choice ratings and libcitations (0.304) suggests that books with higher review ratings tend to be more often acquired by academic libraries but that this does not translate into citations. This may represent 'cultural benefits' of humanities books (Belfiore & Upchurch, 2013; White, Boell, Yu et al. 2009) and supports a previous finding that Outstanding Academic Titles in Choice are more likely to be purchased by academic libraries and have slightly higher library usage than non-Choice books (Levine-Clark, & Jobe, 2007). In Humanities there is also a low but significant correlation between Choice ratings and academic syllabus mentions (0.131), suggesting that in some teaching based fields, Choice reviews may reflect the educational merits of books. In Social & Behavioural Sciences, however, there is no relationship between Choice ratings and either citation or non-citation metrics. A possible explanation is that in the social sciences books have very different patterns of scholarly usage in research and teaching and the relationship between the number of book reviews and citations could therefore differ between subject areas (Gorraiz, Gumpenberger, & Purnell 2014).

Table 6. Spearman correlations between Choice rating scores and other metrics in Science & Technology (n=81).

Limitations

This study tested only 451 books with Choice reviews from a free issue of *Choice Reviews Online* published in 2011 and a larger data may give different results. The sample of 451 is from the most public part of Choice, its free samples, and so is atypical in that regard. The small sample size was also not enough for a fine grained analysis of individual subject areas and this is an important limitation for the correlation tests because citation practices and educational norms (e.g., typical class sizes and the role of textbooks) can vary substantially between fields in a way that would systematically reduce correlation results when the fields are grouped together. Another limitation is that the data only included GB citations from books to books and so would miss citations from articles to books. Hence, a future study might use cited reference searches in WoS or Scopus order to check whether stronger relationships can be found.

Discussion and Conclusions

This study seems to be the first to assess whether the book reviews in *Choice: Current Reviews for Academic Libraries* reflect the value of books and could be used for indicators of value or impact. The analysis of a small sample of 451 books published in 2011 found weak but often significant relationships with other indicators, suggesting that Choice should be particularly helpful for books that have uses that do not necessarily attract citations.

In answer to the first research question, books that were highly rated in Choice received more GB citations, academic syllabus mentions, libcitations and Amazon reviews than did lower rated books. In answer to the second research question, books recommended for undergraduates (e.g., textbooks) received more academic syllabus mentions, reflecting teaching influence of books, and books recommended for researchers, faculty and professionals received more citations than did books recommended for undergraduates, indicating the ability of Choice reviews to distinguish between the different audiences for books.

The low (but statistically significant) Spearman correlations between Choice ratings and all citation and non-citation indicators suggest that Choice reviews are either somewhat subjective, or (more likely) do not reflect exactly the same aspects of the value of a book (e.g., teaching, research, cultural or social impacts) as any of the other indicators. Hence, the evidence presented here is insufficient to claim that Choice recommendations are reliable indicators of audience or value at the individual book level. Nevertheless, the correlations will be weakened by the broad categories used (e.g., 200 library holdings might be a spectacular success for a monograph on Old Norse but a failure for one on Shakespeare's women). In addition, the correlations will also be weakened by the fact that the other indicators are not direct *measures* of anything (e.g., educational value) but are indirect (not cause-and-effect) reflections and so strong correlations should not be expected. Hence, the low correlations are not evidence that Choice book reviews have little value but probably reflect the complex multifaceted nature of the value of books and the difficulty in finding indicators to effectively reflect those values. In this context, Choice book reviews are a promising new source of post-publication peer review evidence of the value of books. They are a welcome additional source of evidence for the particularly challenging task of book impact assessment and when positive reviews are used for impact assessments of scholarly outputs by evaluators, funders or perhaps even national research assessments (e.g., PBRF, 2013).

Abstract
One of the determining factors of the quality of Web search engines is the size of their index. In addition to its influence on search result quality, the size of the indexed Web can also tell us something about which parts of the WWW are directly accessible to the everyday user. We propose a novel method of estimating the size of a Web search engine's index by extrapolating from document frequencies of words observed in a large static corpus of Web pages. In addition, we provide a unique longitudinal perspective on the size of Google and Bing's indexes over a nine-year period, from March 2006 until January 2015. We find that index size estimates of these two search engines tend to vary dramatically over time, with Google generally possessing a larger index than Bing. This result raises doubts about the reliability of previous one-off estimates of the size of the indexed Web. We find that much, if not all of this variability can be explained by changes in the indexing and ranking infrastructure of Google and Bing. This casts further doubt on whether Web search engines can be used reliably for cross-sectional webometric studies.

Conference Topic
Webometrics

Introduction
Webometrics (or cybermetrics) is commonly defined as the study of the content, structure, and technologies of the World Wide Web (WWW) using primarily quantitative methods. Since its original conception in 1997 by Almind & Ingwersen, researchers in the field have studied aspects such as the link structure of the WWW, credibility of Web pages, Web citation analysis, the demographics of its users, and search engines (Thelwall, 2009). The size of the WWW, another popular object of study, has typically been hard to estimate, because only a subset of all Web pages is accessible through search engines or by using Web crawling software. Studies that attempt to estimate the size of the WWW tend to focus on the surface Web—the part indexed by Web search engines—and often only at a specific point in time.

In the early days of search engines, having the biggest index size provided search engines with a competitive advantage, but a changing focus on other aspects of search result quality, such as recency and personalization, has diminished the importance of index size in recent years. Nevertheless, the size of a search engine's index is important for the quality of Web search engines, as argued by Lewandowski and Höchstötter (2008). In addition, knowledge of the size of the indexed Web is important for webometrics in general, as it gives us a ceiling estimate of the size of the WWW that is accessible by the average Internet user.

The importance of index sizes in the early days of Web search resulted in several estimation methods, most of which used the overlap between different Web search engines to estimate the size of the indexed Web as a whole. Bharat and Broder (1998) used an overlap-based method to estimate the size of the WWW at around 200 million pages. Lawrence & Giles

(1998, 1999) produced higher estimates of 320 and 800 million pages in 1998 and 1999 using a similar method, and Gulli and Signorini (2005) updated these estimates to 11.5 billion pages. The last decade has seen little work on index size estimation, but a general problem with all of the related work so far is that all the analyses have been cross-sectional. There has been no analysis of index size on a longer time scale that sheds light on the robustness of the different estimation methods. The handful of studies that have taken a longer-term perspective have typically focused on Web page persistence (Koehler, 2004) or academic link structure (Payne & Thelwall, 2008), but never search engine index size.

In this paper we present a novel method of estimating the size of a Web search engine's index by extrapolating from document frequencies of words observed in a large static corpus of Web pages. In addition, we provide a unique longitudinal perspective on our estimation method by applying it to estimate the size of Google and Bing's[1] indexes over a period of close to nine years, from March 2006 until January 2015.[2]

We find that index size estimates of these two search engines tend to vary wildly over time, with Google generally possessing a larger index than Bing. This considerable variability has been noted in earlier work (e.g., Rousseau, 1999; Payne & Thelwall, 2008), which raises doubts about the reliability of previous one-off estimates of the size of the indexed Web. In our analysis, we find that much of this variability can be explained by changes in the indexing and ranking infrastructure of Google and Bing. This casts further doubt on whether Web search engines can be used reliably for one-off Webometric studies, confirming similar sentiments expressed by, for instance, Payne and Thelwall (2008), and Thelwall (2012).

The remainder of this paper is organized as follows. The next section contains a review of related work in webometrics and on estimating the size of the indexed WWW. We then explain our estimation method in more detail, followed by the results of our estimation method and an analysis of the variability we uncover. We then discuss our findings and draw our conclusions.

Related work

Since its inception, researchers have studied many different aspects of the Web. This section provides a brief overview of some of the key studies on measuring different properties of Web search engines and the WWW, in particular work on estimating their size.

Measuring the Web

Over the past two decades many aspects of the WWW have been studied, such as the link structure of the Web that emerges from the hyperlinks connecting individual Web pages. Broder et al. (2000) were among the first to map the link structure of the WWW. They showed that the Web graph can be visualized as a bow-tie structure with 90% of all pages being a part of the largest strongly connected component, which was confirmed in 2005 by Hirate et al. (2008). Payne and Thelwall (2008) performed a longitudinal analysis of hyperlinks on academic Web sites in the UK, Australia and New Zealand over a six-year period. They found that the inlink and outlink counts were relatively stable over time, albeit with large fluctuations at the individual university level. As a result, they concluded that such variability could create problems for the replicability and comparability of webometrics research. Other related work on analyzing the link structure of the Web includes Kleinberg et al. (1999) and Björneborn (2004).

[1] Formerly known as Microsoft Live Search until May 28, 2009.

[2] Recent daily estimates produced by our method can be accessed through http://www.worldwidewebsize.com/. The time series data displayed in Figure 1 are available online at http://toinebogers.com/?page_id=757.

Web search engines are an essential part of navigating the WWW and as a result have received much attention. Many different aspects of Web search have been investigated, such as ranking algorithms, evaluation, user behavior, and ethical and cultural perspectives. Bar-Ilan (2004) and Zimmer (2010) provide clear, multi-disciplinary overviews of the most important work on these aspects.

From a webometric perspective the hit counts, search engine rankings, and the persistence of the indexed URLs are highly relevant for the validity and reliability of webometric research using Web search engines. Rousseau (1999) was among the first to investigate the stability of search engine results by tracking the *hit counts*—the number of results indicated for a query—for three single-word search terms in Altavista and NorthernLight over a 12-week period in 1998. Altavista exhibited great variability over a longer time period, even with only three anecdotal query words. Rousseau attributed this to changes in Altavista's infrastructure with the launch of a new version in 1998. Thelwall (2008) also performed a cross-sectional, quantitative comparison of the hit counts and search engine results of Google, Yahoo!, and Live Search. He extracted 1,587 single-word queries from English-language blogs "based purely on word frequency criteria" (Thelwall, 2008, p. 1704), found strong correlations between the hit count estimates of all three search engines, and recommended using Google for obtaining accurate hit count estimates. Uyar (2009) extended Thelwall's work by including multi-word queries. He found that the number of words in the query significantly affects the accuracy of hit counts, with single-word queries providing nearly double the hit count accuracy as compared to multi-word queries. Finally, Thelwall and Sud (2012) investigated the usefulness of the Bing Search API 2.0 for performing webometric research. They examined, among other things, the hit count estimates and found that these can vary by up to 50% and should therefore be used with caution in webometric research.

Bar-Ilan et al. (2006) compared the rankings of three different Web search engines over a three-week period. They observed that the overlap in result lists for textual queries was much higher than for image queries, where the result lists of the different search engines showed almost no overlap. Spink et al. (2006) investigated the overlap between three major Web search engines based on the first results pages and found that 85% of all returned top 10 results are unique to that search engine.

The issue of Web page persistence in search engine indexes—how long does a Web page remain indexed and available—was first examined by Bar-Ilan (1999) for a single case-study query during a five-month period in 1998. She found that for some search engines up to 60% of the results had disappeared from the index at the end of the period. She hypothesized that the distributed nature of search engines may cause different results to be served up from different index shards at different points in time. Koehler (2004) reported on the results of a six-year longitudinal study on Web page persistence. He also provided an overview of different longitudinal studies on the topic and concluded, based on the relatively small number of studies that exist, that Web pages are not a particularly persistent medium, although there are meaningful differences between navigation and content pages.

Index size estimation

In the last two decades, various attempts have been directed at estimating the size of the indexed Web. Some approaches focus on estimating the index size of a single search engine directly, while a majority focuses on estimating the overlap to indirectly estimate the size of the total indexed Web.

Highly influential work on estimating index size was done by Bharat & Broder (1998), who calculated the relative sizes of search engines by selecting a random set of pages from one engine, and checking whether each page was indexed by another engine. They used 35,000 randomly generated queries of 6 to 8 words selected at random from a Web-based lexicon and

sent these queries to four search engines. One of every top-100 results pages was randomly selected, after which they calculated the relative sizes and overlaps of search engines by selecting this random set of pages from one engine, and checking whether the page was indexed by another engine. By combining their method with self-reported index sizes from the commercial search engines, they estimated the size of the WWW to be around 200 million pages. Gulli et al. (2005) extended the work of Bharat and Broder by increasing the number of submitted queries by an order of magnitude, and using 75 different languages. They calculated the overlap between Google, Yahoo!, MSN Live, and Ask.com, and updated the previous estimates to 11.5 billion pages in January 2005. Most approaches that use the work of Bharat and Broder as a starting point focus on improving the sampling of random Web pages, which can be problematic because not every page has the same probability of being sampled using Bharat and Broder's approach. Several researchers have proposed methods of near-uniform sampling that attempt to compensate for this ranking bias, such as Henzinger et al. (2000), Anagnostopoulos et al. (2006), and Bar-Yossef and Gurevich (2006, 2011).

Lawrence and Giles (1998) estimated the indexed overlap of six different search engines. They captured the queries issued by the employees of their own research institute and issued them to all six engines. The overlap among search engines was calculated on the aggregated result sets, after which they used publicly available size figures from the search engines to estimate the size of the indexed Web to be 320 million pages. Lawrence and Giles updated their previous estimates to 800 million Web pages in July 1999. Dobra et al. (2004) used statistical population estimation methods to improve upon the original 1998 estimate of Lawrence and Giles. They estimated that Lawrence and Giles were off by a factor of two and that the Web contained around 788 million Web pages in 1998. Khelghati et al. (2012) compared several of the aforementioned estimation methods as well as some proposed modifications to these methods. They found that a modified version of the approach proposed by Bar-Yossef et al. (2011) provided the best performance.

Estimating the Size of a Search Engine Index through Extrapolation

On the basis of a textual corpus that is fully available, both the number of documents and the term and document frequencies of individual terms can be counted. In the context of Web search engines, however, we only have reported hit counts (or document counts), and we are usually not informed about the total number of indexed documents. Since it is the latter we are interested in, we want to estimate the number of documents indexed by a search engine indirectly from the reported document counts.

We can base such estimates on a training corpus for which we have full information on document frequencies of words and on the total number of documents. From the training corpus we can extrapolate a size estimation of any other corpus for which document counts are given. Suppose that, for example, we collect a training corpus T of 500,000 web pages, i.e. $|T| = 500{,}000$. For all words w occurring on these pages we can count the number of documents they occur in, or their document count, $d_T(w)$. A frequent word such as *are* may occur in 250,000 of the documents, i.e., it occurs in about one out of every two documents; $d_T(are) = 250{,}000$. Now if the same word *are* is reported to occur in 1 million documents in another corpus C, i.e., its document count $d_C(are) = 1{,}000{,}000$, we can estimate by extrapolation that this corpus will contain about $|C| = \frac{d_C(are) \times |T|}{d_T(are)}$, i.e., 2 million documents.

There are two crucial requirements that would make this extrapolation sound. First, the training corpus would need to be representative of the corpus we want to estimate the size of. Second, the selection of words[3] that we use as the basis for extrapolation will need to be such

[3] We base our estimates on words rather than on multi-word queries based on the findings of Uyar (2009).

that the extrapolations based on their frequencies are statistically sound. We should not base our estimates on a small selection of words, or even a single word, as frequencies of both high-frequency and low-frequency words may differ significantly among corpora. Following the most basic statistical guidelines, it would be better to repeat this estimation for several words, e.g., twenty times, and average over the extrapolations.

A random selection of word types is likely to produce a selection with relatively low frequencies, as Zipf's second law predicts (Zipf, 1995). A well-known issue in corpus linguistics is that when any two corpora are different in genre or domain, very large differences are likely to occur in the two corpora's word frequencies and document frequencies, especially in the lower frequency bands of the term distributions. It is not uncommon that half of the word types in a corpus occur only once; many of these terms will not occur in another disjoint corpus, even if it is of the same type. This implies that extrapolations should not be based on a random selection of terms, many of which will have a low frequency of occurrence.

The selection of words should sample several high-frequency words but preferably also several other words with frequencies spread across the document frequency bands.

It should be noted that Zipf's law concerns word frequencies, not document frequencies. Words with a higher frequency tend to recur more than once in single documents. The higher the frequency of a word, the more its document frequency will be lower than its word frequency. A ceiling effect thus occurs with the most frequent words if the corpus contains documents of sufficient size: they tend to occur in nearly all documents, making their document frequencies about the same and approaching the actual number of documents in the corpus, while at the same time their word token frequencies still differ to the degree predicted by Zipf's law (Zipf, 1995). This fact is not problematic for our estimation goal, but it should be noted that this hinges on the assumption that the training corpus and the new corpus of which the frequencies are unknown, contain documents of about the same average size.

As our purpose is to estimate the size of a Web search engine's index, we must make sure that our training corpus is representative of the web, containing documents with a representative average size. This is quite an ambitious goal. We chose to generate a randomly filtered selection of 531,624 web pages from the DMOZ[4] web directory. We made this selection in the spring of 2006. To arrive at this selection, first a random selection was made of 761,817 DMOZ URLs, which were crawled. Besides non-existing pages, we also filtered out pages with frames, server redirects beyond two levels, and client redirects. In total, the DMOZ selection of 531,624 documents contains 254,094,395 word tokens (4,395,017 unique word types); the average DMOZ document contains 478 words.

We then selected a sequence of DMOZ words by their frequency rank, starting with the most frequent word, and selecting an exponential series where we increase the selection rank number with a low exponent, viz. 1.6. We ended up with a selection of the following 28 words, the first nine being high-frequency function words and auxiliary verbs: *and*, *of*, *to*, *for*, *on*, *are*, *was*, *can*, *do*, *people*, *very*, *show*, *photo*, *headlines*, *william*, *basketball*, *spread*, *nfl*, *preliminary*, *definite*, *psychologists*, *vielfalt*, *illini*, *chèque*, *accordée*, *reticular*, *rectificació*. The DMOZ directory is multilingual, but English dominates. It is not surprising that the tail of this list contains words from different languages.

Our estimation method then consists of retrieving document counts for all 28 words from the search engine we wish to estimate the number of documents for, obtaining an extrapolated estimate for each word, and averaging (taking a mean) over the 28 estimations. If a word is not reported to occur in any document (which hardly happens), it is not included in the average.

[4] DMOZ is also called the Open Directory Project, http://www.dmoz.org/.

To stress-test the assumption that the DMOZ document frequencies of our 28 words yield sensible estimates of corpus size, we estimated the size of a range of corpora: the New York Times part of the English Gigaword corpus[5] (newspaper articles), the Reuters RCV1 corpus[6] (newswire articles), the English Wikipedia[7] (encyclopedic articles, excluding pages that redirect or disambiguate), and a held-out sample of random DMOZ pages. Table 1 provides an overview of the estimations on these widely different corpora. The size of the New York Times corpus is overestimated by a large margin of 126%, while the sizes of the other three corpora are underestimated. The size of the DMOZ sample—not overlapping with the training set, but drawn from the same source—is relatively accurately estimated with a small underestimation of 1.3%. Larger underestimations, for Reuters RCV1 and Wikipedia, may be explained by the fact that these corpora have shorter documents on average.

The standard deviations in Table 1, computed over the 28 words, indicate that the different estimates are dispersed over quite a large range. There seems to be no correlation with the size of the difference between the actual and the estimated number of documents. Yet, the best estimate, for the small DMOZ held-out sample (–1.3% error), coincides with the smallest standard deviation.

Table 1. Real versus estimated numbers (with standard deviations) of documents on four textual corpora, based on the DMOZ training corpus statistics: two news resources (top two) and two collections of web pages (bottom two). The second and third column provides the mean and median number of words per document.

	Words per document					
Corpus	*Mean*	*Median*	*# Documents*	*Estimate*	*St. dev.*	*Difference*
New York Times '94-'01	837	794	1,234,426	2,789,696	1,821,823	+126%
Reuters RCV1	295	229	453,844	422,271	409,648	– 7.0%
Wikipedia	447	210	2,112,923	2,024,792	1,385,105	– 4.2%
DMOZ test sample	477	309	19,966	19,699	5,839	– 1.3%

After having designed this experiment in March 2006, we started to run it on a daily basis on March 13, 2006, and have continued to do so. Each day we sent the 28 DMOZ words as queries to two search engines: Bing[i] and Google[8]. We retrieve the reported number of indexed pages on which each word occurs as it is returned by the web interface of both search engines, not their APIs. This number is typically rounded: it retains three or four significant numbers, the rest being padded by zeroes. For each word we use the reported document count to extrapolate an estimate of the search engine's size, and average over the extrapolations of all words. The web interfaces to the search engines have gone through some changes, and the time required to adapt to these changes sometimes caused lags of a number of days in our measurements. For Google 3,027 data points were logged, which is 93.6% of the 3,235 days between March 13, 2006 and January 20, 2015. For Bing, this percentage is 92.8% (3,002 data points).

Results

Figure 1 displays the estimated sizes of the Google and Bing indices between March 2006 and January 2015. For visualization purposes and to avoid clutter, the numbers are unweighted

[5] https://catalog.ldc.upenn.edu/LDC2003T05.
[6] http://trec.nist.gov/data/reuters/reuters.html.

[8] We also sent the same 28 words to two other search engines that were discontinued at some point after 2006.

running averages of 31 days, taking 15 days before and after each focus day as a window. The final point in our measurements is January 20, 2015; hence the last point in this graph is January 5, 2015. Rather than a linear, monotonic development we observe a rather varying landscape, with Google usually yielding the larger estimates. The largest peak in the Google index estimates is about 49.4 billion documents, measured in mid-December 2011. Occasionally, estimates are as low as under 2 billion pages (e.g. 1.96 billion pages in the Google index on November 24, 2014), but such troughs in the graph are usually short-lived, and followed by a return to high numbers (e.g., to 45.7 billion pages in the Google index on January 5, 2015).

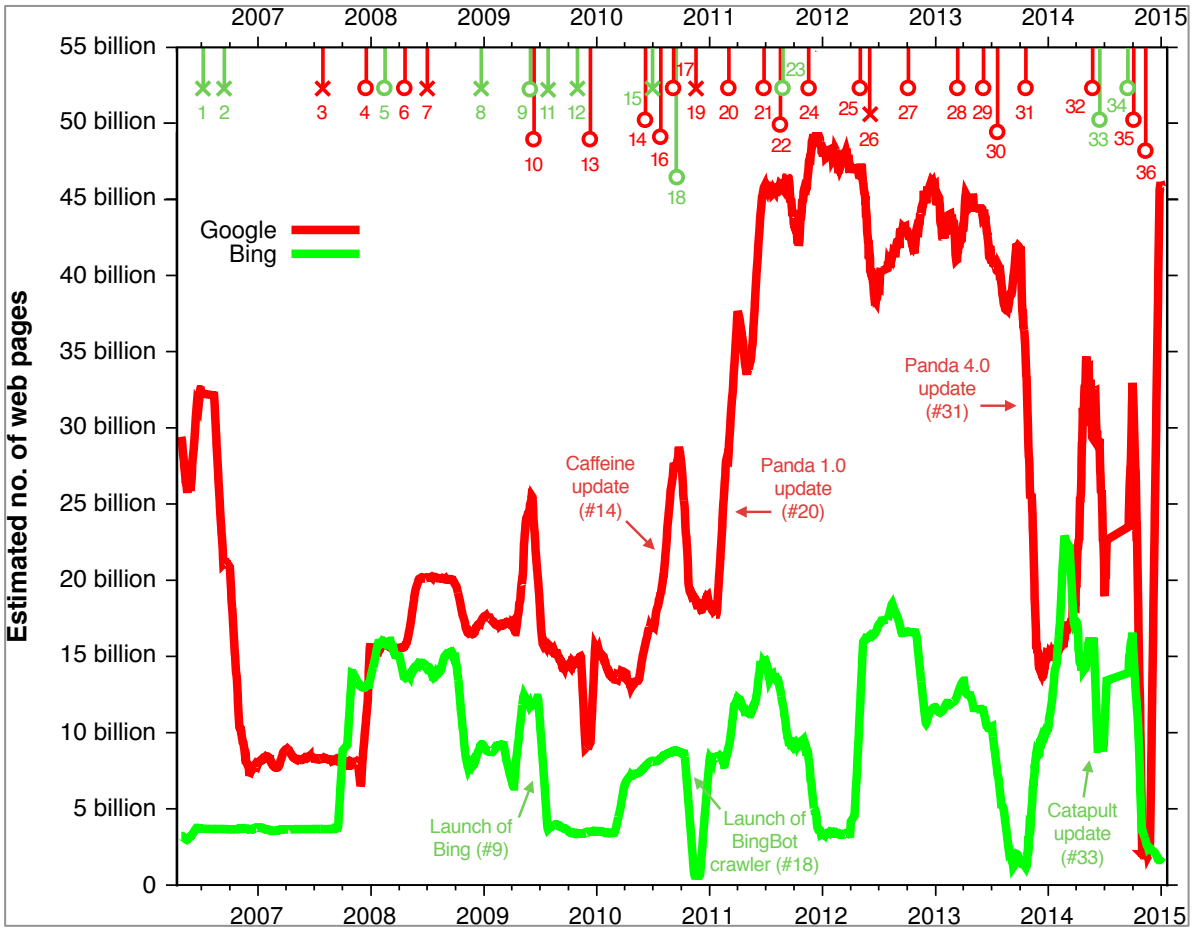

Figure 1. Estimated size of the Google and Bing indexes from March 2006 to January 2015. The lines connect the unweighted running daily averages of 31 days. The colored, numbered markers at the top represent reported changes in Google and Bing's infrastructure. The colors of the markers correspond to the color of the search engine curve they related to; for example, red markers signal changes in Google's infrastructure (the red curve). Events that line up with a spike are marked with an 'O', other events are marked with an '✕'.

Extrinsic variability

The variability observed in Figure 1 is not surprising given the fact that the indexing and ranking architectures of Web search engines are updated and upgraded frequently. According to Matt Cutts[9], Google makes "roughly 500 changes to our search algorithm in a typical year", and this is likely the same for Bing. While most of these updates are not publicized,

[9] http://googleblog.blogspot.com/2011/11/ten-algorithm-changes-on-inside-search.html.

some of the major changes that Google and Bing make to their architectures are announced on their official blogs. To examine which spikes in Figure 1 can be attributed to publicly announced architecture changes, we went through all blog posts on the Google Webmaster Central Blog[10], the Google Official Blog[11], the Bing Blog[12], and Search Engine Watch[13] for reported changes to their infrastructure. This resulted in a total of 36 announcements related to changes in the indexing or ranking architecture of Google and Bing[14]. The colored, numbered markers at the top of Figure 1 show how these reported changes are distributed over time.

For Google 20 out of the 24 reported changes appear to correspond to sudden spikes in the estimated index size, and for Bing 6 out of 12 reported changes match up with estimation spikes. This strongly supports the idea that much of the variability can be attributed to such changes. Examples include the launch of Bing on May 28, 2009 (event #9), the launch of Google's search index Caffeine on June 8, 2010 (event #14), the launch of the BingBot crawler (event #18), and the launches of Google Panda updates, and Bing's Catapult update (events #20, #31, and #33).

Of course not all spikes can be explained by reported events. For example, the spike in Bing's index size in October 2014 does not match up with any publicly announced changes in their architecture, although it is a likely explanation for such a significant change. In addition, some changes to search engine architectures are rolled out gradually and would therefore not translate to spikes in the estimated size. However, much of the variation in hit counts, and therefore estimated index size, appears to be caused by changes in the search engine architecture—something already suggested by Rousseau in his 1999 study.

Discussion and Conclusions

In this paper we presented a method for estimating the size of a Web search engine's index. Based on the hit counts reported by two search engines, Google and Bing, for a set of 28 words, the size of the index of each engine is extrapolated. We repeated this procedure and performed it once per day, starting in March 2006. The results do not show a steady, monotonic growth, but rather a highly variable estimated index size. The larger estimated index of the two, the one from Google, attains high peaks of close to 50 billion web pages, but occasionally drops to small indices of 2 billion pages as well. Are we measuring the extrinsic variability of the indices, or an intrinsic variability of our method? Our method is fixed: the same 28 words are sent to both search engines on every day. The frequencies of our test words are unlikely to change dramatically in a corpus as big as a crawl of the indexed Web; especially the document counts for our high-frequent words in our list should approximate (or at least be in the same order of magnitude as) the total number of documents in the index. We therefore believe that the variability we measure is largely, if not entirely attributable to the variability of the index of Google and Bing. In other words, what we are measuring is the genuine extrinsic variability of the indices, caused by changes (e.g., updates, upgrades, overhauls) of the indices. In Figure 1 we highlighted several publicly announced changes to both search engines' indices, many of which co-occur with drastic changes in index size as estimated by our method (20 out of the 24 reported changes in the Google index, and 6 out of 12 changes in Bing's index).

This variability, noted earlier also by Rousseau (1999), Bar-Ilan (1999), and Payne and Thelwall (2008), should be a cause for concern for any non-longitudinal study that adopts

reported hit counts. It has been pointed out that "Googleology is bad science" (Kilgariff, 2007), meaning that commercial search engines exhibit variations in their functioning that do not naturally link to the corpus they claim to index. Indeed, it is highly unlikely that the real indexable Web suddenly increased from 20 to 30 billion pages in a matter of weeks in October 2014; yet, both the Bing and Google indices report a peak in that period. It is important to note, however, that the observed instability of hit counts does not automatically imply that measuring other properties of search engines for use in webometric research, such as result rankings or link structure, suffer from the same problem.

Our estimates do not show a monotonic growth of Web search engines' indices, which was one of the hypothesized outcomes at the onset of this study in 2006. The results could be taken to indicate that the indexed Web is not growing steadily the way it did in the late 1990s. They may even be taken to indicate the indexed Web is not growing at all. Part of this may relate to the growth of the unindexed Deep Web, and a move of certain content from the indexed to the Deep Web.

The unique perspective of our study is its longitude. Already in 1999, Rousseau remarked that collecting time series estimates should be an essential part of Internet research. The nine-year view visualized in Figure 1 shows that our estimation is highly variable. It is likely that other estimation approaches, e.g. using link structure or result rankings, would show similar variance if they were carried out longitudinally. Future work should include comparing the different estimation methods over time periods, at least of a few years. The sustainability of this experiment is non-trivial and should be planned carefully, including a continuous monitoring of the proper functioning. The scripts that ran our experiment for nearly nine years, and are still running, had to be adapted to changes in the web interfaces of Google and Bing repeatedly. The time required for adapting the scripts after the detection of a change caused the loss of 6-7% of all possible daily measurements.

Our approach, but also the different approaches discussed in the section on related research introduce different kinds of biases. We list here a number of possible biases and how they apply to our own approach:

Query bias. According to Bharat and Broder (1998), large, content-rich documents have a better chance of matching a query. Since our method of absolute size estimation relies on the hit counts returned by the search engines, it does not suffer from this bias, as the result pages themselves are not used.

Estimation bias. Our approach relies on search engines accurately reporting the genuine document frequencies of all query terms. However, modern search engines tend to not report the actual frequency, but instead estimate these counts, for several reasons. One such reason is their use of federated indices: a search engine's index is too large to be stored on one single server, so the index is typically divided over many different servers. Update lag or heavy load of some servers might prevent a search engine from being able to report accurate, up-to-date term counts. Another reason for inaccurate counts is that modern search engines tend to use document-at-a-time (DAAT) processing instead of term-at-a-time (TAAT) processing (Turtle & Flood, 1995). In TAAT processing the entire postings list is traversed for each query term in its entirety, disregarding relevant documents with each new trip down the postings list. In contrast, DAAT processing the postings list is traversed one document at a time for all query terms in parallel. As soon as a fixed number of relevant documents—say 1,000—are found, the traversal is stopped and the resulting relevant documents are returned to the user. The postings list is statically ranked before traversal (using measures such as PageRank) to ensure high quality relevant documents. Since DAAT ensures that, usually, the entire postings list does not have to be

traversed, the term frequency counts tend to be incomplete. Therefore, the term frequencies are typically estimated from the section of the postings list that was traversed.

Malicious bias. According to Bharat and Broder (1998, p. 384), "a search engine might rarely or never serve pages that other engines have, thus completely sabotaging our approach". This unlikely scenario is not likely to influence our approach negatively. However, if search engines were to maliciously inflate the query term counts, this would seriously influence our method of estimating the absolute index sizes.

Domain bias. By using text corpora from a different domain to estimate the absolute index sizes, a domain bias can be introduced. Because of different terminology, term statistics collected from a corpus of newswire, for instance, would not be applicable for estimating term statistics in a corpus of plays by William Shakespeare or corpus of Web pages. We used a corpus of Web pages based on DMOZ, which should reduce the domain bias considerably. However, in general the pages that are added to DMOZ are of high quality, and are likely to have a higher-than-average PageRank, which might introduce some differences between our statistics and the ideal statistics.

Cut-off bias. Some search engines typically do not index all of the content of all web pages they crawl. Since representative information is often at the top of a page, partial indexing does not have adverse effect on search engine performance. However, this cut-off bias could affect our term estimation approach, since our training corpus contains the full texts for each document. Estimating term statistics from, say, the top 5 KB of a document can have a different effect than estimating the statistics from the entire document. Unfortunately, it is impractical to figure out what cut-off point the investigated search engines use so as to replicate this effect on our training corpus.

Quality bias. DMOZ represents a selection of exemplary, manually selected web pages, while it is obvious that the web at large is not of the same average quality. Herein lies a bias of our approach. Some aspects of the less representative parts of the web have been identified in other work. According to Fetterly et al. (2005), around 33% of all Web pages are duplicates of one another. In addition, in the past about 8% of the WWW was made up of spam pages (Fetterly et al., 2004). If this is all still the case, this would imply that over 40% of the Web does not show the quality nor the variation present in the DMOZ training corpus.

Language bias. Our selection of words from DMOZ are evenly spread over the frequency continuum and show that DMOZ is biased towards the English language, perhaps more than the World Wide Web at large. A bias towards English may imply an underestimation of the number of pages in other languages, such as Mandarin or Spanish.

This exploratory study opens up at least the following avenue for future research that we intend to pursue. We have tacitly assumed that a random selection of DMOZ pages represents "all languages". With the proper language identification tools, by which we can identify a proper DMOZ subset of pages in a particular language, our method allows to focus on that language. This may well produce an estimate of the number of pages available on the Web in that language. Estimations for Dutch produce numbers close to two billion Web pages[ii]. Knowing how much data is available for a particular language, based on a seed corpus, is relevant background information for language engineering research and development that uses the web as a corpus (Kilgariff & Grefenstette, 2003).

Abstract
As universities have entered a time of increased demand for public outreach and measurable impact, the universities are also exploring social media for student recruitment and science communication. Because many of the popular social media sites are free to use they could provide more democratic channels for organizational communication and marketing efforts. This research in progress investigates the social media presences of 14 universities in Finland and studies whether the offline performances of the universities are reflected in social media. The results suggest that while the RG score from ResearchGate and the Google Trends score for relative search volume correlate well with both productivity of the universities and university rankings, some of the other social media sites do not reflect the institutional characteristics as well. This is assumed to be a result of different types of usage and different purposes of the different social media sites.

Conference Topics
Webometrics; Altmetrics; Country-level studies

Introduction
Universities have entered a time of increased demand for public outreach and measurable impact. While competing for students the Humboldtian research universities try their best to conduct high quality research for the benefit of the society and to create a foundation for the research based education. At the same time social media has become mainstream in organizational communication (e.g., Badea, 2014; Huang, Baptista & Galliers, 2013; Lovejoy & Saxton, 2012). Organizations use social media for various purposes, both internally and externally, and for universities social media would seem to be an especially efficient tool for public outreach and for recruiting students. Social media are particularly efficient for sharing information through the online social networks, an aspect that would allow universities to efficiently reach their audiences. As the most popular social media sites are free to use, they may provide a more democratic way for universities to reach out to the various audiences and interest groups. This research in progress investigates whether this is true in the case of 14 Finnish universities: are smaller universities taking full advantage of the more democratic ways of communication or are the bigger universities with more resources also "bigger" in social media?

Literature review
Forkosh-Baruch and Hershkovitz (2012) investigated the use of social media sites Twitter and Facebook for scholarly purposes among higher education institutes in Israel. Their findings showed how the social media sites were extensively used for sharing academic or professional news. The authors suggest that use of these social media sites could therefore promote knowledge sharing and informal learning. Based on a content analysis of the messages shared in social media by the group of Israeli HEIs, the authors also discovered that the social media usage patterns followed similar offline usage patterns. The similar patterns here being the perception that colleges are more open and social, while universities tend to focus more on research and involvement in the research community; characteristics that were discovered in the content of the analyzed social media messages. Because of this lack of socializing and

interactivity among the universities, the authors conclude that "*the potential of SNS [social networking sites] as means of sharing academic knowledge in higher education institutes in Israel has not been actualized yet, but is indeed being explored by these organizations…*" With this the authors emphasize the importance of interactivity and audience involvement in organizational communication in social media.

In addition to social media visibility, interest towards universities, as measured by search volume on Google Trends, has also been discovered to have a connection with academic reputation (Vaughan & Romero-Frías, 2014). Vaughan and Romero-Frías (2014) used Google Trends to collect the relative search volume of the top 50 universities in the QS ranking from the US and the 56 Spanish universities included in the ARWU ranking. Their findings indicate that highly ranked universities attracted also more attention, as measured by search volume. In Google Trends the results can also be focused on searches within specific countries; one could for instance look up the search volume for "Kate Upton" in the UK or "Justin Bieber" in Norway. Vaughan and Romero-Frías (2014) discovered that while a great amount of searches for the US universities came from outside the US, only a few searches for the Spanish universities came outside of Spain, which according to the authors also reflects the international positions of the two sets of universities. As searches in English in general and for universities in English in particular may be assumed to be relatively low in non-English speaking countries, it may not make sense in all cases to focus on the country-level search volume in English. For instance in the case of Finnish universities we can assume that searches for them from Finland would mainly use their Finnish names, while the volume of searches in English would mainly reflect the international attention and interest.

Thelwall and Kousha (in press) took another approach to study universities' online presences and investigated whether the usage of ResearchGate and the publications uploaded to it by researchers has a connection with the "academic hierarchies" of different university rankings. ResearchGate is a scholarly social networking site where scholars can create their own profile pages and upload their publications to it, network with other researchers, and find possibly relevant and interesting publications, based partly on their own interests (as indicated on their profile pages) and partly on the interests of those in their social network. Based on researchers' activity on the site and their publications (both number of publications and the journal impact factor of the journals where the papers have been published in) ResearchGate calculates RG scores as a measure of individual researchers' "scientific reputation". The exact formula with which the RG score is calculated is, however, not revealed by ResearchGate. This approach can also be criticized because use of journal impact factors to evaluate or rank individual researchers has increasingly been criticized and condemned (e.g., DORA, 2013). Collectively the RG scores for researchers from a specific institution can give an institutional RG score, supposedly indicating institutional reputation. This is the score that Thelwall and Kousha (in press) used to compare to different university rankings. Their findings showed a moderate correlation between the rankings on ResearchGate and the other university rankings (The Higher Education ranking, QS world university rankings, Academic Ranking of World Universities, CWTS Leiden ranking, and the ranking on Webometrics.info). Because the rankings on ResearchGate are based on researchers' activities on the site and their research work, the findings by Thelwall and Kousha (in press) suggest that the usage of ResearchGate "broadly reflects traditional academic capital."

The current university rankings do place somewhat different weight on different things. For instance the ranking provided by the Webometrics.info measure online visibility, presence and impact, weighting most on visibility as measured by hyperlinks, while the other rankings use more traditional measures of research productivity and impact, i.e. publications and citations, and give them different weights (Aguillo, Bar-Ilan, Levene & Ortega, 2010). Still the different university rankings tend to give similar results, which would suggest that

universities performing well in one area also perform well on other areas. In other words, a university that is performing well when assessed with publications and citations seems to also perform well online. But whether this is reflected to the universities usage of social media and the attention they receive there is unclear. Attention and visibility in social media, as measured with various social media metrics, has been suggested to be a potential indicator of research impact (e.g., Bollen, Van De Sompel, Hagberg & Chute, 2009; Priem & Hemminger, 2010; Lin & Fenner, 2013). These new social media metrics, the so called altmetrics, could potentially give a more nuanced view of the attention towards research outputs. It has also been suggested that altmetrics could provide indicators for the societal impact of research (Bornmann, 2014) or provide knowledge about the interest towards research from a wider audience outside academia (Haustein, 2014). Although not yet extensively studied, altmetrics may also be able to provide country-level indicators of research impact, as Alhoori et al. (2014) have discovered significant correlations between bibliometric data and some altmetrics when aggregated to the country-level.

The research in progress presented here investigates the social media presence of 14 universities in Finland and with that opens research for institutional altmetrics.

Data and methods

The 14 universities in Finland all have online presences in social media. All have profiles, pages or groups on the most popular social media sites Facebook, Twitter, YouTube and LinkedIn, and some also have accounts on Instagram, Flickr or Pinterest. These are usually linked to from the university's webpage. The goal of this research is to 1) study how universities are using social media, 2) how much attention they have attracted, and 3) whether this attention is connected to other offline descriptive metrics about the universities' resources and performance.

Descriptive statistics were manually collected by visiting the universities' official social media profiles, as linked to from the universities' websites. The data consists of the number of tweets, followers and following on Twitter, "likes" on Facebook, subscriptions to and views on the universities' YouTube channel, followers on LinkedIn, and the universities RG score on ResearchGate. In addition to this universities' relative search volumes, as indicated by Google Trends, were retrieved. As the Google Trends score is a score relative to the search volume of the other words searched at the same time (maximum of five different terms compared in one search), we retrieved the scores for the universities' names in English by keeping the two universities with the highest scores included in the search for reference. This way all the scores were relative to those universities with the biggest search volume. The descriptive data about the universities and their performance were retrieved from the report of the State of Scientific Research in Finland, commissioned by the Academy of Finland (http://www.aka.fi/en-GB/A/Decisions-and-impacts/The-state-of-scientific-research-in-Finland/). This performance data consists of variables from 2012; the number of PhDs awarded, total person-years of the teaching and research staff, research funding, and number of publications. In addition to these the rankings of the Finnish universities were retrieved from the following university rankings; CWTS Leiden, ARWU, QS, THE, and Webometrics.info. Only Webometrics.info could provide the rankings for all but one of the 14 universities: the ranking of the fairly new University of the Arts (the former Academy of Fine Arts, Sibelius Academy and Theatre Academy merged to the University of the Arts in 2013). Nine of the 14 universities were found on QS ranking, seven on the CWTS ranking and on THE ranking, and five on the ARWU ranking. Only rankings from Webometrics.info and the QS were used in further analysis.

Spearman rank correlations between the social media metrics and offline data about the universities' performance were investigated to discover whether social media usage would

follow the academic capital at these universities. In addition to this, connections between the social media metrics and university rankings were also tested to see whether the universities reputation and performance was reflected in social media attention and usage.

Results

The different offline university specific metrics are clearly associated, showing how number of students and faculty, funding and publications are all very tightly connected (Table 1). This naturally means that universities with more funding have bigger faculty, more students and produce more publications. As some of these metrics are also used for university rankings it is only natural that the rankings correlate well with these (0.830, n=13, between publications and Webometrics.info; 0.867, n=9, between publications and QS ranking, both Spearman rank correlations significant at level 0.05). The universities that were omitted from the analysis due to non-existent data on Webometrics.info and QS were the universities with the least publications, a probable explanation why they were not covered by the university rankings.

Table 1. Spearman rank correlations between the social media metrics and offline metrics of the 14 universities in Finland. Correlations in bold are significant at the 0.05 level, two-tailed. (RG = RG score; GT = Google Trends score; Tw = Tweets in Twitter; Tw.a = Followers on Twitter; Tw.b = Following on Twitter; FB = Facebook likes; YTs = YouTube subscriptions; YTv = YouTube views; LI = LinkedIn followers; Phd. = PhDs awarded in 2012; Fa. = Faculty in 2012; Fu. = Research funding in 2012; Pu. = Peer-reviewed publications in 2012).

Overall the number of tweets and Facebook 'likes' correlated moderately with the performance metrics of universities (Table 1), with tweets giving somewhat higher correlations on average than Facebook. While the number of followers on Twitter had some connection to the offline metrics, the number of followed accounts only had a very weak connection. This suggests that larger universities are not necessarily more active on Twitter, but that they still generate more attention.

Our findings indicate that research productivity (and the other offline metrics), as measured by the number of peer-reviewed publication from 2012, did correlate almost perfectly with the RG score on ResearchGate (0.969 Spearman, significant at the 0.05 level). The RG score did, however, not correlate well with many of the other social media metrics. Search volume on Google Trends also correlated well with the offline metrics, with the Spearman rank correlation between Google Trends score and number of publications being 0.746, significant

at 0.05 level. The relationships of these two cases are illustrated in figures 1 and 2. In both cases the University of Helsinki, the largest university in Finland, appear as an outlier due to its size. In figure 2 we can see a bit more scattering and how the University of Jyväskylä, and to some extent University of Eastern Finland and Aalto University, although not having exceptionally many publications still have managed to attract significant interest as measured by search volume on Google.

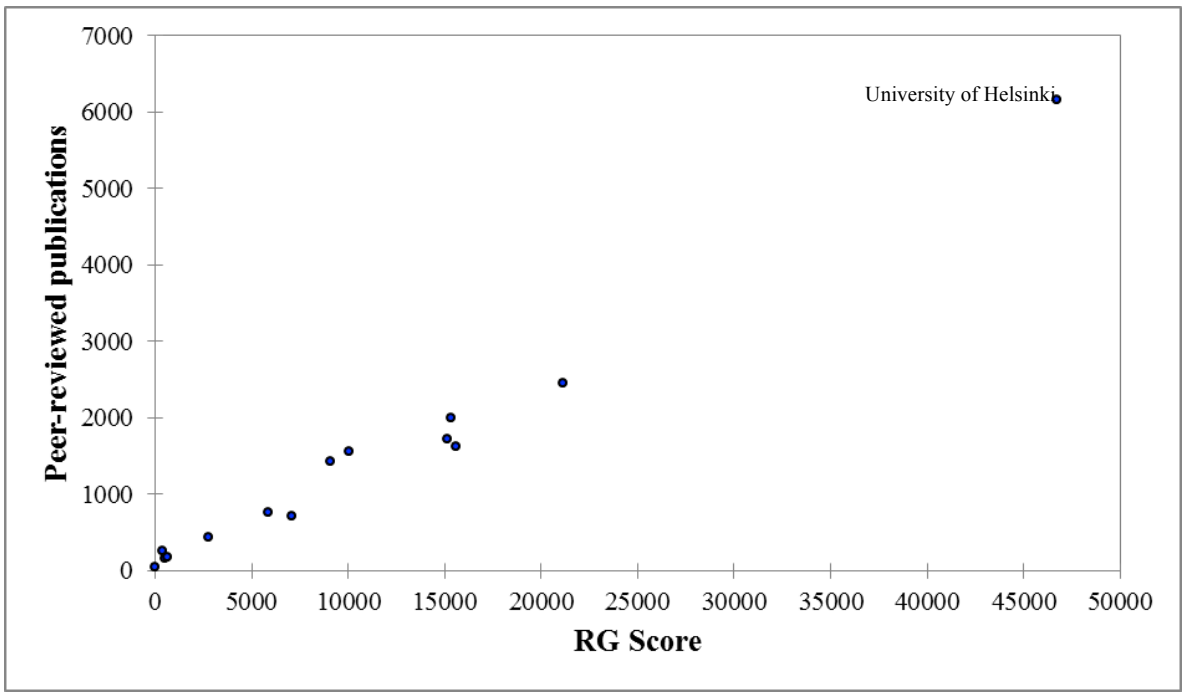

Figure 1. Correlation between the RG score (from ResearchGate) and the number of peer reviewed publications in 2012 at the Finnish universities (0.969 Spearman).

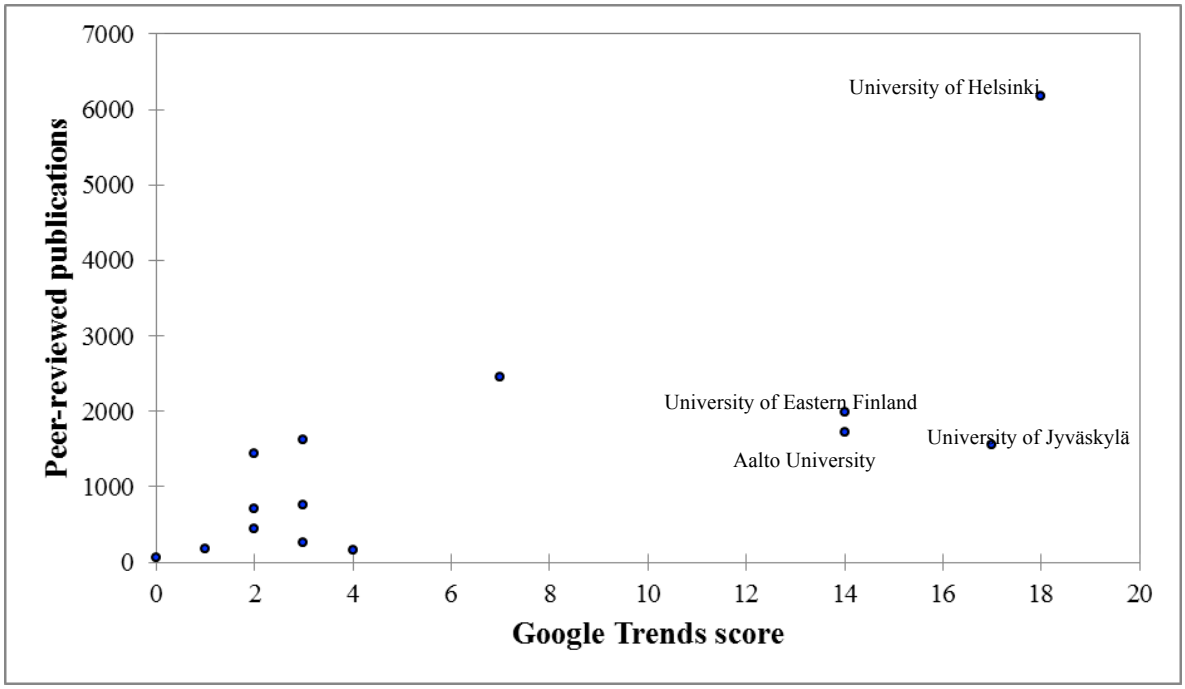

Figure 2. Correlation between the search volume as measured by Google Trends and the number of peer reviewed publications in 2012 at the Finnish universities (0.746 Spearman).

Discussion and conclusions

We set out to investigate the social media presences of 14 universities from Finland and the attention they have received in social media. Our results show that while in many cases the larger and more productive universities are also more active or receive more attention in social media; this is not always the case (Table 1). This suggests that the smaller universities, at least in this small sample, are benefitting from the more democratic channels of social media. Our findings also suggest, in line with the findings by Thelwall and Kousha (in press), that the institutional RG scores and the RG scores for individual researchers on ResearchGate, may be a promising source for altmetrics at institutional and possibly even country level. Due to the uncertainty of how the RG score exactly is calculated and because of the use of journal impact factors in that calculation more research into the topic is clearly needed.

The next step of this research in progress will be a content analysis of the universities social media accounts. This will provide new knowledge about how the universities are represented in social media, for what purposes they use social media, and how attention in social media is created. This will provide important background information for institutional altmetrics.

Abstract
The rank of a journal based on simple citation information is a popular measure. The simplicity and availability of rankings such as Impact Factor, Eigenfactor and SciMago Journal Rank based on trusted commercial sources ensures their widespread use for many important tasks despite the well-known limitations of such rankings. In this paper we look at an alternative approach based on information on papers from social and mainstream media sources. Our data comes from altmetric.com who identify mentions of individual academic papers in sources such as Twitter, Facebook, blogs and news outlets. We consider several different methods to produce a ranking of journals from such data. We show that most (but not all) schemes produce results, which are roughly similar, suggesting that there is a basic consistency between social media based approaches and traditional citation based methods. Most ranking schemes applied to one data set produce relatively little variation and we suggest this provides a measure of the uncertainty in any journal rating. The differences we find between data sources also shows they are capturing different aspects of journal impact. We conclude a small number of such ratings will provide the best information on journal impact.

Conference Topic
Altmetrics

The background and purpose of the study
Journal metrics, such as the Thomson Reuters Journal Impact Factor, were originally developed in response to a publisher need to demonstrate the academic attention accorded to research journals. Over the intervening 50 years since Garfield's work in the field, the Impact Factor and other metrics, such as Eigenfactor (Bergstrom, 2007), have been used and misused in a variety of contexts in academia. An oft-discussed perception is that a journal-level metric is a good proxy for the quality of the articles contained in a journal.

In the evaluation and bibliometrics communities citation counting is generally understood not to be an appropriate proxy for quality but rather a measure of attention. The type of attention being measured in this case is quite specific and has particular properties. What is being measured is the attention to a paper of peers in related fields. The bar for registration of this attention is relatively high – the researcher or researchers making the citation must deem the target article to be of sufficient value that they include a citation in a work of their own that in turn is deemed publishable (e.g. see Archambault & Lariviére, 2009, and references therein). The timescale associated with citations is also long – typically being limited by the review and publication process associated with particular fields. Additionally, it is accepted that journal-level metrics say little regarding the merit of particular articles in the journal since journal-level metrics are often calculated based on thousands of articles and are often biased by the performance of the tails of the distribution of citations. These realisations have led to the recent growth in popularity of article-level metrics or altmetrics.

Altmetrics have broadened the range of types of attention that we can measure and track for scholarly articles. Mostly based in social and traditional media citations, the altmetric landscape is one that is constantly changing with the introduction of different data sources all the time. While, one the one hand, altmetrics suffer from all the unevenness of traditional citations, they occur over different timescales, which provides us with a more nuanced view

of the lifecycle of a scholarly work. Aggregating alternative metrics at a journal level will complement Journal Impact Factor, giving us new insights into different facets of attention.

Traditional citation-based metrics are difficult to calculate since they are based on the bibliometric journal databases, such as Thomson Reuters' Web of Science. Conversely, Altmetrics are conglomerates of disparate sources of references to research output derived from non-traditional sources, primarily modern electronic sources characterised by fast response times (see Bornmann, 2014, for a recent overview). The lack of any systematic peer review is another characteristic of most altmetric data. The open and electronic nature of much altmetric data offers the prospect of alternative paper and journal metrics, which may be more accessible to stakeholders. The rapid response of such data to innovations suggests such metrics might offer improvements over metrics based on slower traditional sources.

This paper considers a number of approaches to the aggregation of altmetric data in order to create a robust journal-level metric that complements the existing citation-based metrics already in use across the academic community. The aim is not to create a contender for a single metric to quantify journal output but instead to create a useful measure that gives "the user" a sense of the non-citation attention that a journal attracts in the same way that Journal Impact Factor, Eigenfactor and other related metrics give this sense for citation attention.

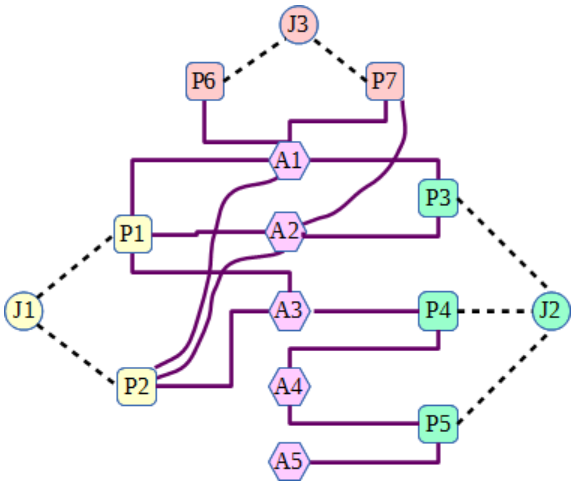

Figure 1. The relationships recorded in our altmetric.com data. The raw data illustrated here contains fifteen "mentions" (solid lines) by five "authors" (hexagons A1 to A5) of seven papers (squares P1 to P7). We also know the journal (circles), which published a paper (dashed lines).

Data Sources

In this paper we use the 2013 IF (Impact Factor) and EF (Eigenfactor) as examples of traditional sources of journal ratings. Our altmetric data comes from 20 months of data from altmetric.com, a commercial company. For each mention about a paper we had the journal in which it was published, the source (twitter, Facebook, etc.) and the account (here termed an 'author'), as shown in Figure 1. In our case, a 'paper' has to be an article coming from a known journal. A single 'author' for us is a single account (e.g. one twitter account) or a single source (a news outlet such as a newspaper). In some cases several different authors may be responsible for one site or one author could provide information to many different sites or accounts (a twitter account, a facebook account, a blog, etc) but in our data such an author appears as many distinct authors.

Methods

The simplest type of journal altmetric is one based on basic counts where each mention of a paper in a journal adds one to that journal's count. We collected counts for social media '*sbc*',

non-social media '*nsbc*' (e.g. downloads) and combined scores '*bc*' (for blind count i.e. with no weighting for different sources). We also obtained the current journal rating produced by altmetric.com (denoted '*ca*'), which is a weighted count rating in which different sources are given different weights (blogs and news sources get highest weighting).

Network Definitions

A criticism of simple count based methods, such as Impact Factor or our altmetric counts discussed above, is that some citations or some altmetric authors are more important than others. Eigenfactor is an illustration of a response to these criticisms in the realm of traditional data (Bergstrom, 2007), as it uses a network based view to arrive at a PageRank style measure. We will also turn to a network-based view in order to look at a wide range of measures, which probe the relationships between journals on a much larger scale.

There are many possible network representations of our data. In this paper we will focus only on networks in which the nodes represent journals. The central idea in our construction of the relationship between two journals is that we only want to consider activity from authors who mention both journals because only these authors are making an implicit comparison between journals. The activity of each author is used to define their own "field of interest" in a self-consistent manner and so the activity of authors is used to make comparisons between journals in the same field as defined by each author's interests. This ensures that at a fundamental level we avoid the much discussed problem of making comparisons between papers or journals from different fields. An author only interested in medical issues will only contribute to the evaluation of Nature, Science and so forth in terms of their interest in these multidisciplinary journals relative to Cell or other specialised journals.

A useful analogy here is that each journal is a team and an author who mentions articles published in two journals represents one game between these journals – our pairwise comparison. The score in each game is the number of mentions so in comparing two journals *j* and *l*, the score for journal *j* from the game represented by author *a* is recoded as the entry J_{ja}.in a rectangular matrix. In Figure 1 the game between J1 and J2 represented by author A2 has the result 2-1, a 'win' for journal 1 over journal J2 suggesting that we should rate journal J1 more highly than journal J2 given the activity of this one author.

We shall consider three different ways of quantifying the journal relationships, the network edges. Our first approach gives us an adjacency matrix *S* where the entry S_{jl} gives the weight of the edge from journal *j* to journal *l*, and this is given by $S_{jl} = \frac{1}{|A_{jl}|}\sum_{a\in A_{jl}} J_{ja}$, where $A_{jl} = \{a|J_{ja} > 0, J_{la} > 0\}$. Here *j* and *l* represent different journals and *a* is one author. J_{ja} is a matrix, which is equal to the number of papers mentioned by author *a* which were published in journal *j*. The expression for S_{jl} is counting the number of times papers published in journal *j* are mentioned by authors who also mention papers in journal *l,* with the total normalised by the number of such authors. Note that this defines a sparse, weighted and directed network. In our conventions if journal *j* is better than journal *l* we will have $S_{jl} > S_{lj}$.

Our second definition gives us an adjacency matrix *P* where $P_{jl} = \frac{1}{|A_{jl}|}\sum_{a\in A_{jl}} \theta(J_{ja} - J_{la})$. Here $\theta(x) = 1$ if $x > 0$ otherwise this function gives 0. This definition counts how many authors mention more papers in journal *j* than they do papers in journal *l*., normalising again by the number of authors who are able to make this pairwise comparison. Again $P_{jl} > P_{lj}$ if journal *j* is better than journal *l*.

Finally we define an adjacency matrix *Q* where $Q_{jl} = \frac{1}{|A_{jl}|}\sum_{a\in A_{jl}} \Theta(J_{ja} - J_{la})$. Here $\Theta(x) = 1$ if $x > 0$, $\Theta(0) = 0.5$ while for negative values this function gives 0. This definition counts how many authors mention more papers in journal *j* than they do papers in journal *l*

but when this is balanced gives an equal weighting to both side. This definition has the useful property that $Q_{jl} + Q_{lj} = 1$ (not generally true for matrix P).

Network Measures

Once we have our network with journals as nodes, we need to find ways to use this structure to define which nodes are the most important. Measures which quantify the importance of a node are known as centrality measures in social network analysis. Unfortunately, many standard measures do not take into account the weights or directions of edges, both of which carry crucial information in our case. We used two well-known network centrality measures to illustrate our approach: PageRank and HITS (e.g. see Langville & Meyer, 2012). Both may be cast as eigenvector problems and there are fast algorithms for large networks which are readily available. We apply these two methods to all three networks, giving six different ratings e.g. 'qpr' indicates a PageRank rating derived from a Q matrix while 'ph' indicates a HITs rating derived using a P matrix.

We also tried a different type of measure known as Points Spread Rating (denoted 'psr') (p.117-120, Langville & Meyer, 2012) where the rating r_j for journal j is $r_j = \sum_l (S_{jl} - S_{lj}) / n_j$, (similarly for the P and Q matrices) and n_j is the number of journals. This expression ensures that the differences $(r_j - r_l)$ in the rating of any two journals j and l are as close as possible to the actual differences in the number of average mentions of papers.

Comparing Ratings

Once we have obtained different ratings, the final task is to make a comparison. The simplest approach is to make a qualitative comparison of the top ranked journals in each case. For a more quantitative approach we used standard methods of multivariate statistics. First we found a correlation matrix whose entries express the similarity of two rating methods: the Pearson correlation matrix based on the numerical values of the ratings obtained, Spearman's matrix which based on the ranking of journals, and finally Kendall's tau. These were analysed using principle component analysis or hierarchical clustering methods.

Findings

In terms of the altmetric data we found typical fat-tailed distributions, both for the number of mentions of a paper from different sources and in terms of the number of mentions put out by a single author. Some sources, such as twitter, are significantly larger than others.

When comparing different journal rating schemes, some results were found only with Spearman and Kendall tau correlation measures (which are based on the ranks of journals). The Pearson measure (based on actual rating values gave slightly different results in some cases. However in most cases there good agreement. Some typical results are shown in Figure 2 and numbers for ranking schemes in the following text refer to the labels in Figure 2.

The variation between different rating schemes for the same altmetric data source gives relatively little variation, roughly on the same scale as the difference we find between IF and EF. The four different methods shown for ratings based on Facebook mentions (6,12,16,19) are a typical example. Clearly our Points Spread Rating scheme (psr, 21,22,23) and our simple counts of non-social media mentions (nsbc, 6) produces outliers.

Some sources, such as Facebook and News, were also noticeably different from IF and EF, but the difference was much smaller than that found with the psr rating. One source, which gave ratings well correlated with IF and EF was blogs (8, 11, 15, 18).

Likewise, most of our simple count based ratings were just as close to IF (3) or EF (5) as these two rating schemes were to each other. This includes our unweighted count of all mentions (bc, 1), the number of times papers are mentioned (pc, 7), counts of just social

media mentions (sbc, 14), and in particular the more sophisticated weighted journal ranking produced by altmetric.com (ca, 2).

Most of our work focused on statistics for the whole collection. A look at the top journals, see Table 1, confirmed that at an individual level our new altmetric network ratings were giving sensible results, but with variations which indicate the uncertainty in such rankings.

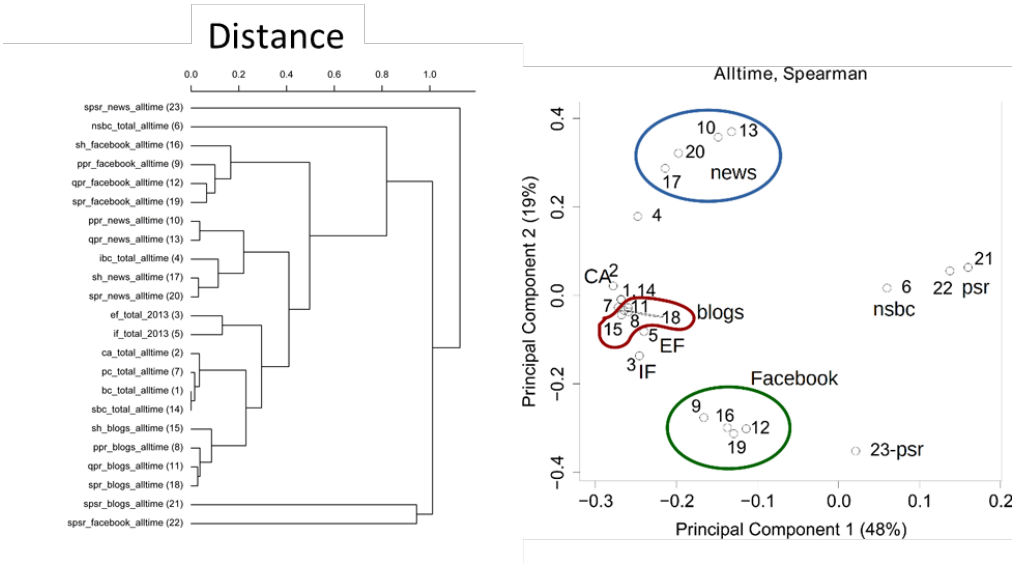

Figure 2. A comparison of some of the different ranking schemes using a Spearman correlation matrix. On the left a dendrogram and on the right a scatter plot using the first two principle components of PCA. For clarity, only a limited subset of our ratings were used in these plots.

Discussion

Given our differences between ranking based comparisons (Spearman and Kendall Tau) and results based on Pearson correlation matrices, this suggests that ratings are dominated by the measurement of the few journals, which have most of the mentions (fat tails). This is one reason we favour Spearman correlation matrices in Figure 2 and would suggest this makes sense in most journal ranking contexts.

Our Points Spread Rating scheme (psr, 21, 22, 23) seems to be reflecting very different patterns in the data from those found using other approaches. Given that the other approaches include Impact Factor, widely accepted as a measure of journal attention, we think it is hard to see a role for PSR to rank journals. Likewise, the simple blind counts of non-social media mentions (nsbc, 6) does not appear to be useful.

The remaining different altmetric sources and rating methods do show enough similarity to suggest that they are all an acceptable measure of journal importance. At the same time there are some interesting differences indicating that our altmetric based schemes are capturing different features of the impact of journals. At the very least this diversity will indicate the level of uncertainty in rating schemes. Two possible reasons for the close correlation of blogs and IF are as follows. Perhaps papers in high IF journals are of intrinsic interest to blog writers. Alternatively blog authors may read a limited number of journals but these tend to be those with high IF. Probably both factors are important, each reinforcing the other to produce the strong correlation we find.

Another interesting feature is that most of our simple count based ratings, which are not normalised by the number of articles per journal, are also well correlated with IF (3) which does use normalised counts. This can be explained if there is a correlation between the number of papers in a journal and its impact, something we can see in of count of number of papers (pc, 7). We will be looking at normalised altmetric counts in the future but it appears

normalisation may not be essential. In particular, we note the altmetric.com journal rating (ca, 2) is well correlated and so provides a good handle on the impact of journals.

Table 1. Top ten journals based on various network based altmetric measures.

Rank	*Q, HITS, Blogs*	*Q, HITS, News*	*S, PageRank, Google+*
1	Nature	Nature	Nature
2	PNAS	PNAS	PLoS ONE
3	Science	PLoS ONE	Science
4	PLoS ONE	Science	PNAS
5	New England J. of Med.	New England J. of Med.	New England J. of Med.
6	British Medical J.-C.R.Ed.	British Medical J.-C.R.Ed.	British Medical J.-C.R.Ed.
7	The Lancet (British Ed.)	Nature Communications	Scientific Reports
8	JAMA	JAMA	JAMA
9	Proc. Royal Soc. B:	The Lancet (British Ed.)	The Lancet (British Ed.)
10	Current Biology	Pediatrics	PLoS Biology

The fact that we tried many different rating methods and that (with the exception of psr based measures) they showed variations on scales no bigger than those found between IF and EF, suggests that no one method is optimal in any sense. However we can use such a suite of metrics to get a handle on the uncertainty associated with any measure. This would be of great utility for users and a contrast to the three decimal point 'accuracy' associated with IF results.

Conclusions

We have shown how to use altmetric data to provide a reasonable journal ranking. Most types of altmetric data appear to give useful information in the sense that the correlation with IF is acceptable. At the same time altmetric data can be sufficiently different that it might reflect different types of impact. Our results suggest that different rating methods can provide a measure of the uncertainty of any journal ranking. Confirming these patterns over longer periods and producing a better understanding of the social reasons for the patterns we have found are future directions for our work. It would also be interesting to compare our results with journal attention measures derived from journal usage patterns, see for example Bollen et al 2009, an aspect not included in our data.

Acknowledgments

We would like to thank Euan Adie (altmetric.com) for providing us with the altmetric data, and for useful discussions along with Jonathan Adams and Daniel Hook (Digital Science).

Abstract
Twitter is currently one of the primary venues for online information dissemination. Although its detractors portray it as nothing more than an exercise in narcissism and banality, Twitter is also used to share news stories and other information that may be of interest to a person's followers. The current study sampled tweeters who had tweeted at least one link to an article in one of four leading journals, with a focus on studying who, precisely, these tweeters were. The results showed that approximately 76% of the sampled accounts were maintained by individuals (rather than organizations), 67% of these accounts were maintained by a single man, and 34.4% of the individuals were identified as possessing a Ph.D, suggesting that the population of Twitter users who tweet links to academic articles does not reflect the demographics of the general public. In addition, the vast majority of students and academics were associated with some form of science, indicating that interest in scientific journals is limited to individuals in related fields of study.

Conference Topic
Altmetrics

Introduction
Twitter is currently one of the primary venues for online information dissemination. Nearly a quarter of adult Internet-users take advantage of Twitter (Pew Research, 2014), and according to Alexa (2015), as of January 22, 2015, Twitter is ranked as the 8th most visited site on the Web (and the 7th most visited in the United States). Although its detractors portray it as nothing more than an exercise in narcissism and banality, Twitter is also used to share news stories and other information that may be of interest to a person's followers. Amidst much vapidity can be found discussions or links of genuine merit, and indeed, it has been found that "academic articles are now frequently tweeted and so Twitter seems to be a useful tool for scholars to use to help keep up with publications and discussions in their fields" (Thelwall, Tsou, Weingart, Holmberg, & Haustein, 2013, p. 1). Previous research has discussed the content of such tweets, their sentiments (Thelwall, Tsou, Weingart, Holmberg, & Haustein, 2013), tweeting behaviour across venues and disciplines (Haustein, Peters, Sugimoto, Thelwall, & Larivière, 2014), the use of Twitter for altmetrics (Thelwall, Haustein, Larivière, & Sugimoto, 2013), and the effect that automated bots have on the legitimacy of using tweets to assess academic impact (Haustein et al., 2014). However, the demographics of tweeters who post links to academic articles have not yet been investigated. This study proposes to address this gap.

Methods

Sampling frame.

The initial sampling frame was a list of individuals who had provided a link to an academic article in a tweet. These tweets were gathered by running a Twitter query approximately every hour from March 17, 2012 to March 17, 2013 for each of a number of URLs of journals (Table 1). The journals were selected as leading journals that were widely tweeted (based on a manual examination of the data) and had a simple URL format for articles that could be collected by a query. Collecting tweets in this way was a practical step because many people link to articles if they mention them and it is easy to search for articles by part of URL. In

each case article URLs had a common starting text, such as a domain name, and queries for this common part matched all articles in the site. Although Twitter shortens almost all URLs in tweets, it is possible to use URL-based queries because Twitter search returns matches for the original URLs rather than the shortened versions.

Table 1. Queries for links to academic articles in Twitter.

Source	Twitter query
Nature journal	"go.nature.com"
PLOS ONE journal	"plosone.org/article"
PNAS journal	"pnas.org/content"
Science journal	"scim.ag"

This method does not retrieve all tweets of academic articles published in the selected journals. In particular, it does not capture links to copies of the articles elsewhere (e.g., self-archived preprints) and does not capture articles mentioned by name rather than by link. Also, Twitter does not guarantee comprehensive matches to all searches so it is likely that not all URLs matching the above set of queries were found. Some data was also lost due to power cuts and an enforced shutdown at Wolverhampton in December 2012. However, this provides an authoritative list of scholarly tweets.

Sample

From this sampling frame, a list of all unique twitter accounts was generated. From this list, a sample of 500 unique tweeters for each journal was randomly selected. Duplicate accounts were removed and replaced so that the sample represented 2,000 unique accounts (this was necessary as some accounts tweeted articles from more than one journal).

Survey

The initial plan was to directly survey the journal tweeters and, accordingly, a survey was set up in Qualtrics and a separate DID Cascades Twitter account was established for the purpose of tweeting a link to the survey to all 2000 account. We set up an automated system to send out invitations to the survey to the identified twitter handles in batches small enough to not violate Twitter's mass tweeting policies. However, even working within these parameters, our account was suspended immediately upon our first batch of survey invitations. We mention this failure here as it is relevant to conducting research in this environment. Although some modes of inquiry (e.g., large-scale survey research) may be more appropriate for answering certain questions, they are untenable due to the current affordances of the platform. These limitations should be taken into consideration for future analyses.

Codebook construction

Given that obtrusive research was not possible, we turned to unobtrusive measures (i.e., content analysis) to analyse the identities of those who tweet about science. The codebook was developed inductively through several iterative explorations with four researchers. Variables such as gender, academic affiliation, and (in the case of non-individuals) organization type were collected. Iterative coding led to refining of the initial categories (e.g., the "Finance" category originally proposed was expanded to "Business/Finance", "Freelance" was incorporated into the coding due to the high frequency of this position, and "Non-profit" was added in the organizational category).

One of the initial desires was to be able to tag those who were "affiliated with science." This was intended to distinguish between the "layperson" and the "scientists". This seemingly

simple distinction proved to be overwhelmingly difficult to code unobtrusively. Those who explicitly identified with academic institutions and were readily associated with science departments within those institutions were easy to identify. However, many of the non-academics were also affiliated with science in some form (e.g., government positions in science and technology). This also led to the issue of determining what constitutes science (e.g., are humanists, entrepreneurs, and technologists scientists?). This was equally difficult for organizations. For example, an online consumer or financial corporation might not have science as the main objective, but have an arm of the organization that conducts research. This question was further complicated by false negatives—that is, instances where we could not provide evidence that the individual was associated with science, but also could not provide evidence that they were not.

The issue of false positives and false negatives on other questions was addressed by adding an "unknown" option in addition to "yes/no" options. For example, one question asked whether the individual was a student. As it was frequently impossible to definitively state whether or not an individual was not a student (i.e., the lack of information regarding a person's reenrolment in a university would not, in itself, extinguish the possibility of their academic involvement at the student level). However a "no" option remained available for those situations in which it could be ascertained with a high degree of certainty that the individual was not or no longer a student (e.g., from a detailed LinkedIn profile or online curriculum vita).

Coding

Initial coding began in May 2013 and was completed on December 15, 2013. Coding was done by two coders for whom a high interrater reliability was ascertained. The twitter handles were used as the initial point of departure for the search. Coders determined what they could from the information provided in the short biographical information on twitter. If a url was provided on twitter, this was followed. Google searches were also employed, using as a seed the person's first name and/or twitter handle and limiting searches to the first three pages of results. Where there was a dispute between sources, the more contemporary source was used.

The first coding variable asked the coder to distinguish whether the account was held by an individual or an organization. Although most accounts are technically managed by a single person, a distinction was made between people who represented themselves and people who represented a company or organization. If a person simply affiliated with an organization, they were still coded as an individual.

Research centers at universities were coded as university. Research centers outside of a university setting were coded as non-profits. Although universities could be considered "government" or "non-profit" (and in some rare cases a corporation), all academic institutions were coded as universities.

Results

Approximately three-quarters of the sampled accounts could be identified as belonging to individuals (n=1520), while slightly under 23% belonged to organizations (n=459) (Figure 1). Of the accounts belonging to people, the majority were associated with a male tweeter (Figure 2). Nearly 12% of the individuals were identified as students (either undergraduate, master's, or doctoral). Of the students, 67.2% were doctoral students or candidates. It should be noted that, for some codes, a failure to mark a quality as "present" does not necessarily indicate that the reverse is true. For example, it is likely not the case that 88.2% of the individuals are *not* students; rather, all that we can say is that we were able to identify 11.8% of the individuals as students.

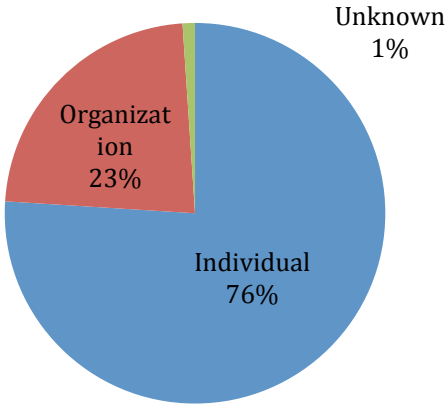

Figure 1. Twitter accounts by type.

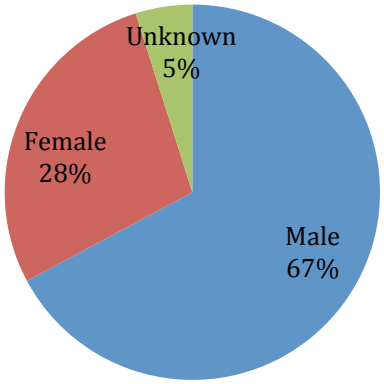

Figure 2. Individual accounts by gender.

In terms of the entire population of individuals, 34.4% were identified as possessing a Ph.D (this discounts the students who were working towards a Ph.D), suggesting that the population of Twitter users who tweet links to academic articles does not reflect the demographics of the general public. STEM fields were dominant both within the group of users identified as students and within the group of users identified as working in academe.

In terms of the students, 52.4% were affiliated with general science, 15.1% were associated with health/medical study, and 10.8% were associated with technology/engineering. In terms of the academics, 62% were associated with general science, 10.4% were affiliated with health/medical study, 8.1% were associated with the social sciences, and 7.5% were affiliated with technology/engineering (Figure 3).

Of the organizations, 41.6% were identified as non-profits, 29.2% were identified as corporations, and 13.1% were identified as universities. 18.9% were classified as news/media/outreach institutions (note that this was considered a non-exclusive category independent of the earlier classifications).

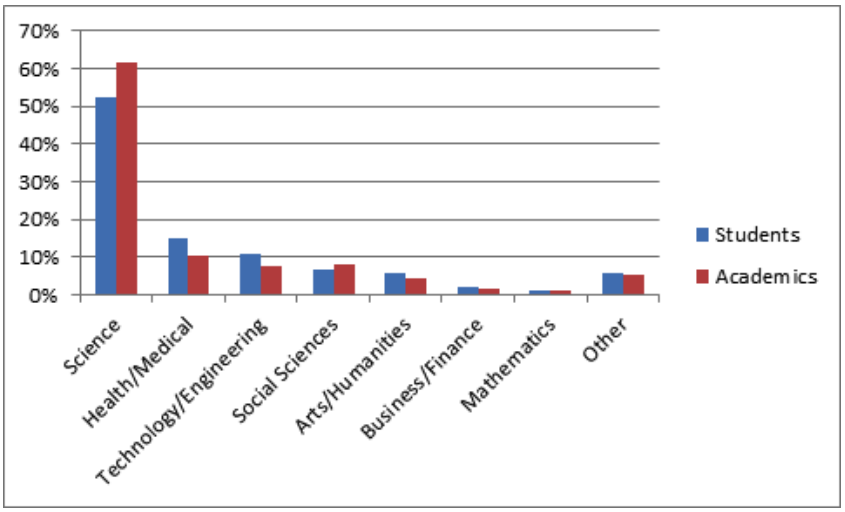

Figure 3. Proportion of twitter accounts by disciplinary domain.

Discussion and Conclusion

The demographics of the individual tweeters did not reflect the general population of Twitter users. Whereas women are overall slightly more likely to take advantage of social networking sites than men are (Kimbrough, Guadagno, Muscanell, & Dill, 2013; Pew Research, 2014), men use Twitter slightly more (24% of male Internet users, compared to 21% of female Internet users). Our study was much more male-baised, with nearly 70% of individual accounts maintained by men. This percentage is in keeping with male to female ratios found in the scientific workforce and scholarly publishing (Larivière et al., 2013).

A growing body of literature seeks to validate social media metrics, or "altmetrics" as valid forms of the social (i.e., public) impact of scholarly research. However, this research indicates that a large portion (i.e., nearly half) of those who tweet about science already have a doctoral degree or are in pursuit of one. This proportion far exceeds the 1% of the US population, for instance, holding a doctoral degree (Petersons, 2014). This suggests caution when utilizing social media metrics as an indication of the value of the work for the public. Rather, this emphasizes the strong use of these tools for dissemination and discussion of scholarship *among scholars*. Acknowledgement of the scholarly context of social media metrics must be taken into account in evaluative uses of these metrics.

Limitations

The study only considered journals that were frequently tweeted. It is possibly that the demographics of users who tweet articles from less popular journals might differ from those of tweeters who share links to the highest echelon of scientific journals. In addition, the information that could be gathered about the tweeters was limited to what was readily available online. Accordingly, the percentages generated by the study represent conservative estimates rather than absolute figures.

Future research might consider a wider variety of journals, as well as employing other methods to ascertain tweeter demographics (e.g., studying the users' tweets in an attempt to ascertain gender, academic affiliation, etc. for those users for whom such information was not publicly available). In addition, it is theoretically possible to directly survey the tweeters who shared links to academic articles, although such an approach would likely rely on publicly available contact information (primarily e-mail addresses), and would most likely face the same issues that were encountered in this study.

Acknowledgments

Funding for this project was provided by the Alfred P. Sloan Foundation ("Understanding the use and meaning of social media metrics in scholarly communication") and the National Science Foundation (grant SMA-1208804) as part of the Digging into Data initiative. We would like to thank Mike Thelwall for providing data for this project.

Classifying altmetrics by level of impact

Kim Holmberg

kim.j.holmberg@utu.fi
Research Unit for the Sociology of Education, University of Turku, 20014 Turku (Finland)

Introduction

In the light of current knowledge we can conclude that altmetrics do not present an alternative for traditional citation-based analysis of research impact (e.g., Haustein *et al*., 2014). Altmetrics have instead the potential to show some other aspects of research activities and provide a more nuanced view of the impact research has made on various audiences (Liu & Adie, 2013; Piwowar, 2013). Altmetrics come in many forms and from many different sources, all of which can represent different aspects of the online activity or of the different levels of impact that various research products have made on different audiences. What exactly the different altmetrics represent we do not yet know, but the greatest advantage of altmetrics may be exactly in this diversity.

Aggregating all altmetrics to a single indicator would remove this advantage. With aggregation of different altmetrics we are just creating another impact factor, another indicator that in the worst case is used for something that it is neither designed for nor capable of indicating. However, because of the wide variety of different sources for altmetrics, some form of aggregation or classification is needed and different types of classifications are already used by some service providers. Here we present another approach, one based on the level of impact. With this we hope to stimulate further discussion about the actual meaning of altmetrics.

Diversity of altmetrics

The diversity of altmetrics has two interesting dimensions; the diversity of people creating the altmetrics, and the diversity of the impact they indicate. In any research assessment what we want to measure is value or quality of research. Quality is of course very subjective and difficult to quantify. Because we cannot evaluate quality directly, particularly not at large scale, we use volume of impact as a proxy for value (i.e. number of citations or more recently number of online mentions).

The different data sources and different data types collected from the mentions of research products in various social media sites can represent a wide spectrum of different levels of impact. For instance, while a tweet does not necessarily hold any indication of impact other than awareness, a blog entry or a Wikipedia citation reflect some level of influence or impact. The people creating the altmetrics then again range from researchers and practitioners to the public.

Aggregating altmetrics

In social media analytics the mentions of brands and products in various social media are often placed and grouped together on a spectrum according to level of engagement, ranging from visibility to influence and finally reaching engagement as the most desired level of reaction. In the context of altmetrics, Piwowar and Priem (2013) write about the different "flavours" of impact that altmetrics could potentially reflect, referring to the diversity of altmetrics and possibility to group similar metrics into these "flavours". This is in line with the ideas presented at PLoS too, with different sources and different timings of altmetrics reflecting engagement from different audiences and possibly also that of different purposes for the engagement (Lin & Fenner, 2013).

This approach has already been taken by some of the altmetrics service providers as they group the data collected from various sources into what reflects different types of activities. PLoS for instance groups the metrics they use into views, saves, mentions, and citations. These do roughly translate to what we can assume to be different levels of impact, reflecting the variety of actions and interactions that one can have with the research products. Saving a research product suggests that the research product have made a bigger impact than just viewing it suggests, mentioning it suggests additionally increased level of impact, and citing it suggests what could perhaps be considered as the ultimate level of impact, at least when the goal is to investigate scientific impact.

Aggregation by the level of impact

Indicators of impact come in many diverse forms on the web and in social media and the different social media sites and the different activities within them can provide various metrics of different levels of impact. A potential approach to aggregating altmetrics would be to use these different levels of impact as they are and to not try to combine them according to source or type of activity they represent.

When the metrics indicate low impact we cannot really be sure whether the research has made any impact at all as evidence of it is usually not clear; a page view, clicking on a tweet button next to the article, or sharing a research article on Facebook, all indicate that the user has seen what they are sharing but nothing indicates that it has made any

impact on them, that they would have been influenced by it, or that they would have changed their behaviour because of it. Metrics indicating a medium level of impact would already come attached with at least some information that the research has made an impact, that it has in some way influenced the user. Whether the research product has been mentioned somewhere online or been bookmarked with the intent to use it later, the metrics generated from the activities at this level suggest that the users have been influenced some way, that the research has made at least some impact. Metrics indicating a high level of impact usually come attached with some additional, perhaps more qualitative data that we can use to investigate how the research has influenced the user and confirm what kind of impact it has made. A rough classification of different types of altmetrics that indicate different levels of impact could follow the one presented in Table 1. Besides impact, we can also measure reach with altmetrics; how many people have become aware of the research and how many of them have been influenced by it in some way.

Table 1. Levels of impact.

	Altmetrics		
Level of impact	Low	Medium	High
Reach	High	Medium	Low
Example activities	Awareness, visibility	Influence, interaction	Usage
Example metrics	Tweets, 'likes', shares, …	Mentions, downloads, bookmarks, …	Blog posts, …

More research is needed and both quantitative and qualitative methods are needed to confirm what level of impact different types of actions in different social media reflect and how they relate to each other.

Benefits of the proposed approach

Focusing future research on the level of impact has a couple of benefits compared to other approaches. First of all, impact is what we want to measure, hence grouping different metrics based on the level of impact they reflect makes sense. Second, using all the unique metrics (e.g., tweets, retweets, blog mentions, link in blogroll, Facebook shares, "likes", and mentions) would create a massive number of different metrics that would be difficult to a) keep track of, b) present, and c) control. Third, aggregating the different metrics by type of activity they represent may not give an accurate picture of the impact they represent, as similar types of activities on for instance different social media sites may be reflecting different levels of impact and/or different types of users. And fourth, aggregating all the metrics into a single indicator would just be creating another impact factor, but this time from a much wider diversity of different metrics indicating different aspects and which probably should not be aggregated at all because of that. And finally, focusing on the different indicators for different levels of impact instead of some specific sites would not be such a vulnerable approach relying on the continued existence and goodwill of the social media sites to allow access to their data.

Conclusions

We propose the classification of altmetrics based on the level of impact reflected by the specific altmetrics. This approach would have some clear benefits compared to aggregations based on activity or source of altmetrics. More research is, however, needed to establish the different levels. The key challenges for future altmetric research are a) identifying the groups of people that create different altmetrics, and b) mapping the different levels of impact the different metrics reflect. This line of research would bring us again one step closer to fully understand what altmetrics indicate, and with that, the meaning of altmetrics. It is nevertheless important to recognize that the true meaning of any altmetrics lies in the stories behind the numbers. Hence it is important that any altmetrics are presented together with the accompanied stories to give the full context in which they have been generated.

Characterizing In-text Citations using N-gram Distributions

Marc Bertin[1] and Iana Atanassova[2]

Introduction

This article focuses on a Natural Language Processing (NLP) approach for the analysis of citation functions in scientific papers. Bibliometric studies traditionally rely on citation metadata and count the number of times a publication has been cited. However, some recent studies rely also on full text processing on papers, e.g. (Boyack et al., 2013), (Bertin et al., 2013, 2014). The full text content of papers and more specifically the sentences containing citations provide valuable information on the functions of citations that can be exploited through NLP. To study citation acts, we need to consider full text papers and their rhetorical structure.

The main question that we want to answer here is whether the most frequent citation patterns are correlated to the rhetorical structure of scientific papers. We investigate the properties of the linguistic patterns that appear in citation contexts. For this, we study the distribution of n-gram classes containing verb forms, and we show the existence of three different types of distributions according to the rhetorical structure.

Method

By analyzing a large corpus of articles, we propose a quantitative study of the linguistic patterns around in-text citations. Some words or sets of words in n-grams are more frequent than others (Cavnar & Trenkle, 1994), and this idea is consistent with Zipf's Law (Zipf, 1949). The difficulty is that the calculation of n-grams in contexts results in a combinatorial explosion. We propose several filters to reduce the number of patterns.

The rhetorical structure of scientific papers is typically organized around a standardized pattern, known as the IMRaD structure (Introduction, Methods, Results and Discussion). We identify the four main section types of this structure by analysing section titles. Then, we consider the set of sentences containing citations and belonging to each section type.

We represent citation contexts by using sequences of words of length n called n-grams where $2<n<=5$. In our approach we consider only n-grams within sentence boundaries because sentences are natural building blocks of the text. For each n-gram we observe its frequencies in the four section types of the IMRaD structure. For our study, we select only the n-grams that contain at least one verb form. In this way, the number of n-grams to process is much smaller and we eliminate word patterns containing only nominal groups like: “In this paper”, “the present article”, “the result of” etc. for 3-grams.

Dataset

We performed an automatic analysis of the seven peer-reviewed academic journals published in Open Access by the Public Library of Science (PLOS). The corpus contains about 85,660 research articles. Most of the articles are in the biomedical domain, but the corpus covers all fields of Human and Natural Sciences, as the publisher’s main journal, PLOS ONE, is multidisciplinary. Around 98% of the articles in the corpus follow the IMRaD structure, which is imposed by editorial requirements.

Results

We select the most frequent verb forms in order to construct n-gram classes from in-text citation contexts. This data will be used to obtain a first typology of the distribution of n-grams depending on the rhetorical structure of articles.

The following figures present distributions of n-grams classes for the IMRaD sections. We can distinguish between three different type of classes, and we give one example of each. The horizontal axis presents the text progression of the section from 0% to 100%. The vertical axis gives the percentage of occurrences of each class relative to its occurrences in citation contexts in the entire article.

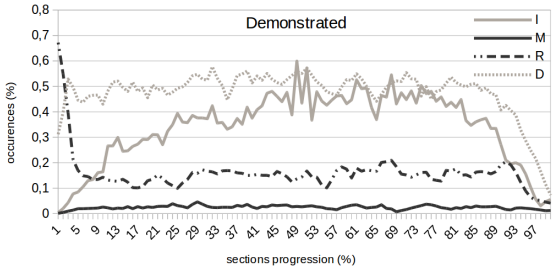

Figure 1. Demonstrated.

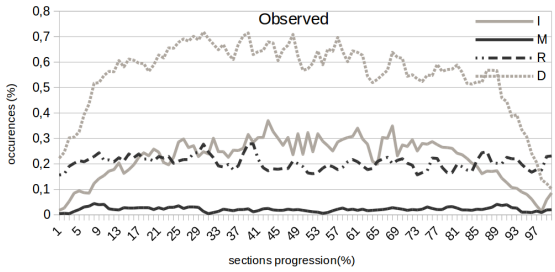

Figure 2. Observed.

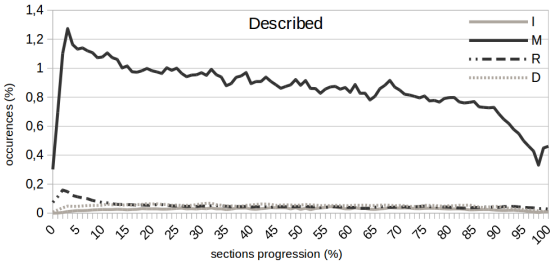

Figure 3. Described.

Discussion

Figure 1 shows the first class, which includes n-grams containing the verb *Demonstrated***.** These n-grams appear with roughly equivalent frequencies in the sections Results and Discussion, but, at the same time the Methods section contains much lower frequencies of these patterns.

Figure 2 shows the second class type, which includes n-grams with the verb *Observed***.** We can observe another type of distribution, with relatively very high frequencies in the Discussion section.

Figure 3 shows the distribution of n-grams with the verb *Described*. We can observe that the structure of the Methods section is unique, as the class *Described* is present with a very high frequency in this section and especially at the beginning of the section. Moreover, Figures 1 and 2 show that on the distributions for the other classes, the Methods section contains relatively few occurrences. In other words, the class *Described* is characteristic of the Methods section, where it appears with very high frequency, and it is very rare in all the other sections. The Methods section displays very low frequencies for all classes except *Described*.

These results imply that each section, depending on its nature, authorizes more or less easily the usage of specific patterns containing verbs. The Methods section is rather closed in nature, where we find a very small number of high frequency verbs. At the same time, the Discussion section is open to different forms and allows a larger number of variations in terms of the linguistic means that authors use in citation contexts.

Conclusion

The purpose of this study is to demonstrate the existence of frequent n-gram patterns in citation contexts and their strong relation with the rhetorical structure of scientific articles. Studying the n-gram classes containing verb forms, we show the existence of three different types of distributions according to the rhetorical structure. From our point of view, the problem of the automatic annotation of citation contexts is strongly related to identifying significant surface patterns for the annotation process.

CITATION AND CO-CITATION ANALYSIS

Citation Type Analysis for Social Science Literature in Taiwan

Ming-yueh Tsay

mytsay@nccu.edu.tw
Graduate Institute of Library, Information and Archival Studies, National ChengChi University (Taiwan)

Abstract
Through citation analysis, this study explored the distribution of document type, language and publication year for citations in social science journals. Samples were research articles published in 2010 from first-rank journals, as assessed by the Department of Humanities and Social Sciences, National Science Council and indexed in Taiwan Social Sciences Citation Index (TSSCI). The section in which citations appeared, namely introductions, methodologies, results, and conclusions, were also examined. Conclusions and suggestions are made based on the research results and interdisciplinary comparisons. For social science studies in Taiwan, the major findings are as follows: 1. Journals and books were the most cited materials, and English was the language of most citations. 2. Social scientists in Taiwan tended to cite materials published within 10 years with a citing half-life of approximately 11 years. 3. The ratio of articles following the IMRAD format was high in Taiwan social science journals. 4. Citations in these social science journals occurred most frequently in the introduction section, while they occurred least frequently in the conclusions. 5. Social scientists mostly cite to set the stage for their current studies. 6. The citation type is highly related to the citation location.

Conference Topic
Citation and co-citation analysis

Introduction
Since the social sciences are associated with human society, its patterns, where it goes and how it works, it can enrich the values and contents of our lives. In contrast, the "hard sciences" have been the focus of attention with the rapid growth of technology grew, and the social sciences have received less attention. This has led to a lack of balance between academic and technical research in many developing countries. To gain attention and support from governments and the public, social scientists need to promote their research outcomes and impacts much more effectively via the presentation and communication of their scholarly articles.

A research article may consist of body text and references; the former is the citing article, and the latter are cited articles. Relations between the citing and the citied may explain the interaction, development and communication among disciplines, and can reveal current research interests and future trends. Citations have multiple roles and unique functions in scholarly communication; for example, a cited article may present broader research contents, explain methods applied in a research or provide information and discussion that support a specific perspective.

The importance of journal articles for scholarly communication and academic assessment motivates the present study on Taiwanese social science journal articles to explore and compare their characteristics and types of citations via methods of bibliometric and citation analysis. The research outcomes may improve the knowledge of citation, and serve as reference for future empirical researches for the social science studies in Taiwan.

Other Citation Studies
Citations have been studied using context or content analysis, whereby the analysis determines the citation type based on the surrounding text. Frost (1979) mentioned the complexity of citation function and that the classification of citation function and proper schemes for classification received little attention in citation studies. To explore the nature of

citation use, some various schemes of classification for different disciplines have been developed to explain the functions of citations and the relations between body text and citations.

In Moravcsik and Murugesan's (1975) study physics citations fall into the "applied/used" category with 60% and 40% of the citations being general acknowledgements. In the study of Voos and Dagaev (1976), inspected the locations of each citation in sample articles and found that articles of biology and medicine were mostly cited within two to three years after their publication, and were cited the most in the introduction section, and next in the discussion section.

Peritz (1983) selected a variety of social science journals in which the basic methodologies of empirical social research were used and analyzed into the categories of a citation classification scheme. That study revealed that generally, "setting the stage for the present study" citations rank first. To carry out the reliability citation classification scheme, Peritz further investigated the association between classification and location and found that the marginal frequencies of the location introduction, methods and discussion were fairly close to the frequencies of the classification categories of setting the stage, methodology, and comparison and argument, respectively.

More recently, Harwood (2008) interviewed six informants who were computer scientists and six who were sociologists on the functions of citations in their writing. His findings reveal that position, supporting, and credit are relatively frequent across both disciplines, although the engaging function is far more frequent in the sociology texts.

Case and Miller (2011) investigated the citation practice of a group of citing authors with an interest in bibliometric or scientometric research, finding that the most popular reason was "this reference is a 'concept marker'," which distantly followed by "reviews prior work in the area" and other reasons.

The above literature survey shows there have been many studies investigating citation category and citation practices, which are likely to vary from discipline to discipline. This motivates the present study to further explore the citation type of articles cited in the social science journals published in Taiwan.

Research Method and Limitation

The journals selected in this research were six first-ranked journals indexed in the Taiwan Social Sciences Citation Index (TSSCI) in the disciplines of sociology, education, psychology, political science, economics and management. In this study, it is assumed that the first ranked journal of each discipline may represent the research characteristics of that discipline.

Articles published in 2010 and following the IMRAD format were selected as research samples, though articles published earlier than 2010 were also collected if there were insufficient samples. The titles of journals and number of articles selected for the six disciplines were: sociology, *Taiwanese Journal of Sociology*, 15 articles (2008-2010); education, *Bulletin of Educational Psychology*, 31 articles (2010); psychology, *Chinese Journal of Psychology*, 16 articles (2010); political science, *Taiwan Political Science Review*, 16 articles (2008-2010); economics, *Academia Economic Papers*, 13 articles (2010); management, *Journal of Management*, 25 articles (2010).

In the present study, if introductions and literature reviews were in two different sections, they were considered as an introduction in combination; if results and discussion were in one section, they would be categorized as result. Citations were categorized, on the basis of the classification scheme proposed by Peritz (1983), which requires little subjective judgment and is easy to carry out even without in-depth knowledge of the subject field.

Full texts and references of all 116 research articles were downloaded from online databases

or photocopied from printed journal and processed with Excel (Microsoft, U.S.) into bibliographical files. Employing bibliometric techniques and citation analysis, this study explored article type of journal, language of citation, citation years, document types of citations, citation types and locations of citations, the relations between citation type and location, and comparison among six disciplines of social sciences in Taiwan.

This study conducted purposive sampling to acquire journal articles for citation analysis, whose results might thus be limited indeed and less representative for each or the whole of humanities disciplines. Nevertheless, the current study aims to distinguish the meaningful characteristics of article structures, citation locations, and citation types of the six social science disciplines of Taiwan; also the method of "citation content analysis" used in this study to explore the nature of citation types is qualitative and justified by the attempt to interpret the existing phenomena. In the above senses, purposive sampling and unequal sample size seemed to be acceptable limitations.

Results

In this study, citation characteristics and locations in body texts are discussed according to article type of journal, language of citation, year of the highest citation and citation half-life, document type of citation, citation location and citation type.

Article Type of Journal

Papers published in social science journals in Taiwan are mainly divided into research articles and review articles. In general, research articles comply with the IMRAD format. The ratio of articles following the IMRAD format was high in the social sciences. Table 1 demonstrates review and research articles, both appeared in the disciplines of political science and sociology, while journals in the fields of psychology, education, economics and management preferred research articles.

Table 1 shows that, among the six disciplines, education, economics and management composed completely (100%) of research articles that follow the format of IMRAD.

Table 1. Article types in social science journals of Taiwan.

Discipline (Journal name)	*Papers*	*English article*	*Chinese review article*	*Chinese research article*	*% of Chinese Research article*
Political Science (*Taiwan Political Science Review*)*	30	1	13	16	55.2%
Sociology (*Taiwanese Journal of Sociology*)*	25	0	10	15	60.0%
Education (*Bulletin of Educational Psychology*)	32	1	0	31	100.0%
Psychology (*Chinese Journal of Psychology*)	23	4	3	16	84.2%
Economics (*Academia Economic Papers*)	18	5	0	13	100.0%
Management (*Journal of Management*)	30	5	0	25	100.0%
Total	158	16	26	116	81.7%

*Semi-annual journal. Sample articles of these journals were dated back to 2008 from 2010; samples of other journals were articles published in 2010.

Language of Citation

Materials in Chinese and English were the major source of references cited in social science articles, with the former accounting for 21.5% and the latter 78% of the total references collected. Most of the references in economics (93.5%) and management (92.1%) were English papers, while Chinese articles were infrequently used in both disciplines. Domestic research articles and reference materials, however, were used quite often by scholars of sociology (30.7%) and political science (43.4%).

Year of the Highest Citation and Citing Half-Life

Table 2 reveals the year of highest citation, citation age and citing half-life of articles in sample journals. Citing half-life refers to the time span from the current year to the year whose accumulated number of citations accounts for 50% of total citations in the journal. For example, the citing half-life of *Chinese Journal of Psychology* shown in Table 2 was 11, indicating that half of its citations were younger than 11 years as the citing articles being published. The time span of citation half-life reflects the currency of cited materials: the longer the citing half-life, the older the cited materials, and vice versa.

Table 2. Distribution of year of the highest citation, citation age of the highest citation and citing half-life.

Discipline (Journal name)	*Year of the highest citation*	*Citation Age*	*Citing half-life*
Political Science (*Taiwan Political Science Review*)*	2007	4	10.6
Sociology (*Taiwanese Journal of Sociology*)*	2006	5	11.5
Education (*Bulletin of Educational Psychology*)	2005	6	11.2
Psychology (*Chinese Journal of Psychology*)	2006	5	11.0
Economics (*Academia Economic Papers*)	2007	4	11.4
Management (*Journal of Management*)	2004	7	11.2
Average	2006	5.2	11.2

Based on the year of highest citations, the number of citations earlier than 2004 is decreasing for earlier articles. In other words, the older the articles were, the fewer citations they received. In general, for articles published in 2010 the peak of citations fell between 2004 and 2007 that suggests citations that received from the sample journals reached a peak after four to seven years of its publication, five years in most cases. A large number of citations came from articles published in the recent several years, indicating that social scientists have a tendency to cite the most recent articles. In the social science fields, scholars tended to cite materials with a citing half-life of approximately 11 years. For social scientists in most disciplines, 50% of their research needs could be satisfied by articles published after 2000, and the tendency to cite the most recent articles indicates the social science research depends on more current literature.

Document Type of Citation

In the six top journals selected as samples in this study, there were 116 Chinese articles following the IMRAD format, citing 6,063 references to the bibliographic files built by this study. According to the bibliographic data collected, journals and books were the most

frequently cited, accounting for 88% (journals 65% and books 23%) of all types of cited materials. The uses of journals and of books in economics were quite different, with the highest interval over 76%, in which journals accounted for 82% of cited materials while books accounted for 6%. The second-highest difference between citations of journals and of books was in management, where journals accounted for 80% of the citations, which was 67% higher than books. For other disciplines, such as social science (journals 53% vs. books 35%) and political science (journals 49% vs. books 34%), the differences between the use of journals and books were not as great, indicating that they have a closer value in both disciplines. On the average, over all types of documents, social scientists preferred to use journals in exploration and support of their own research.

Aside from the citations of journal articles and book materials, the number of theses and dissertations cited in the journal of education was higher than those in journals of other disciplines. Online resources such as websites or electronic files were cited more frequently in the political science journal, suggesting that political scientists use more digital literature as references in their research. Research reports were cited more in the journal of economics than in other disciplines, which indicates that economists tended to prove or support their own research by data or results provided by research reports. Furthermore, the fact that economists and scholars of management cited a few unpublished manuscripts and working papers showed the significance of informal and unpublished materials to these two disciplines.

Citation Location

The number and location of citations from the 116 articles complying with the IMRAD format were calculated to analyze the distribution of citations in structured research articles. There were 11,149 citations collected in the section of introduction (literature review included), methods and materials, results, and discussion.

The distribution of citations in different sections of an article may help to determine the status, research patterns and characteristics of a discipline. As Table 3 shows, citations appeared the most in the introduction section of articles in every discipline of social science. The Introduction may include literature reviews, and both sections need a few references for proving points or serving as motivations. In the six disciplines of social science, the highest number of citations in the introduction sections occurred in the journals of sociology and political science, while the lowest was in the journal of economics. For the method section, scholars of economics and management cite more frequently in the section of methods and materials. In contrast, the sociologists cite the least frequently.

Table 3. Distribution of citation location in social science journals of Taiwan.

Discipline	*Introduction*		*Methodology & Materials*		*Results*		*Discussion*		*Total*	
	No.	*%*	*No.*	*%*	*No.*	*%*	*No.*	*%*	*No.*	*%*
Management[1]	1,799	65.4	480	17.3	256	9.3	216	7.9	2,751	24.7
Economics[2]	499	54.6	164	17.9	189	20.7	62	6.8	914	8.2
Political Sci.[3]	931	70.5	171	13.0	165	12.5	53	4.0	1,320	11.8
Psychology[4]	1,048	58.6	198	11.1	222	12.4	320	17.9	1,788	16.0
Education[5]	1,888	64.1	282	9.6	295	10.0	481	16.3	2,946	26.4
Sociology[6]	993	69.4	63	4.4	254	17.8	120	8.4	1,430	12.8
Total	7,158	64.2	1,358	12.2	1,381	12.4	1,252	11.2	11,149	100

1. Journal of Management; 2. Academia Economic Papers; 3. Taiwan Political Science Review; 4. Chinese Journal of Psychology; 5. Bulletin of Educational Psychology; 6. Taiwanese Journal of Sociology

In the results section, economists tended to cite more articles for comparison and contrast. Aside from economics, the number of citations in the results section of the sociology journal

also high. In the management journal, descriptive statistics and quantitative analysis may be the major causes of its lower number of citations in the results section.

In the discussion section, the number of citations may reflect scholars' degree of concern about deliberations and evaluation of research outcomes. The top two numbers of citations in discussion section occurred in the journals of psychology and education.

Citation Type

In addition to the distribution of citation location, Peritz's classification scheme of citation type is used to classify articles cited in the sample journals. Mapping was made to inspect the relations between citation type and citation location and to analyze the differences among the six disciplines. The eight categories of citation classification scheme proposed by Peritz (1983, pp.304-305) are: 1. Setting the stage for the present study; 2. Background information; 3. Methodological; 4. Comparative; 5. Argumentative speculative, hypothetical; 6. Documentary; 7. Historical and 8. Casual.

Table 4. Distribution of citation type.

Citation type	*Sociology*		*Education*		*Psychology*		*Political Science*		*Economics*		*Management*		*Total*	
	No.	*%*	*No.*	*%*	*No.*	*%*	*No.*	*%*	*No.*	*%*	*No.*	*%*	*No.*	*%*
Setting the stage for the present study	271	56.7	153	53.5	235	58.6	311	56.3	133	48.9	411	63.8	1,514	57.5

Historical	0	0.0	1	0.3	0	0.0	0	0.0	0	0.0	0	0.0	1	0.0
Casual	0	0.0	0	0.0	0	0.0	4	0.7	0	0.0	0	0.0	4	0.2
Total	478	-	286	-	401	-	552	-	272	-	644	-	2,633	-

Based on Table 4, the highest percentage of citations classified as "setting the stage for the present research" appeared in the journal of management (64%), and the lowest in the journal of economics (49%). Compared to other types of citation, citations that set the stage for the present study were significantly high in all six disciplines. The citation type of "background information" was most frequently found in the journal of sociology, while it was least frequent in the journal of management. The journal of economics contained the most methodological citations, which accounted for 31% of total citations, while the journal of sociology the least, which accounted for 7%; the interval between was rather large. Comparative citations were most found in the journal of psychology (17%) and the least in the journal of political science (8%). The journal of education included the most citations (17%), which were used in the presentation of argument, speculation, and hypothesis while the journal of political science the least (merely 3%). Documentary citations accounted for 12% of total citations in the journal of political science, which was the top among the six disciplines; whereas there was no such type of citations found in the journals of education and psychology. The citation types of "historical" and "casual" were hardly found in the journals of six disciplines, with only one historical citation in the journal of education and four casual citations in the journal of political science.

The distribution of citation type may reveal the research characteristics of a certain disciplines. For example, scholars of management tend to cite a large amount of literature to support or motivate their own research, whereas economists cite more methodological materials in their works, which indicates that research methods are valued more in economics. Political scientists tended to cite more raw data to support their studies; whereas scholars of education cited more articles for argumentation, speculation, and hypothesis. Comparative citations appeared the most in the journal of psychology, suggesting that psychological researchers tend to introduce other research in their own studies for comparison, correction, or corroboration.

Citation Type and Citation Location

According to Peritz's study, citation type was highly relevant to citation location. In this study, therefore, the relation between citation type and citation location in the six discipline sample journals was analyzed as follows.

Sociology

As Table 5 shows, in the journal of sociology, the number of citations that set the stage for the present study was 271, accounting for 56.7% of the total citations. Comparative citations accounted for 14.6% of the total citations, suggesting that the materials being cited in the journal articles were used to describe or support the present research. The citation type of "setting the stage for the present study" appeared primarily in the introduction section, while methodological citations that introduced the process of other research were mostly in the methods and materials section. In the results section, comparative, argumentative, speculative, and hypothetical citations accounted for the greatest number of citations. In the discussion session, comparative citations comprised the major part of total citations.

Table 5. Citations in Taiwanese Journal of Sociology by category and location.

Location / Category	Introduction		Methodology & Materials		Results		Discussion		Total	
	No.	%	No.	%	No.	%	No.	%	No.	%
Setting the stage	271	86.0	0	0.0	0	0.0	0	0.0	271	56.7

Documentary	4	1.3	5	20.0	3	4.3	3	4.3	15	3.1
Historical	0	0.0	0	0.0	0	0.0	0	0.0	0	0.0
Casual	0	0.0	0	0.0	0	0.0	0	0.0	0	0.0
Total	315	100.0	25	100.0	69	100.0	69	100.0	478	100.0

Education

In the journal of education, the citation type of "setting the stage for the present study" accounted for the largest percentage of the total citations, 53.5%, as shown in Table 6. The distribution of methodological citations, comparative citations, and argumentative, speculative and hypothetical citations was rather even. Similar to the distribution in the sociology journal, all of the citations that set the stage for the present study appeared in the introduction section, and the citations in methods and materials section were mostly methodological citations, while there were few citations in the results section. As for the

discussion part, the numbers of comparative, argumentative, speculative and hypothetical citations, especially the last three types, greatly exceeded other types of citation, indicating that scholars of education often introduced other research for detailed exploration, or made further inference based on previous studies.

Table 6. Citations in Bulletin of Educational Psychology by category and location.

Category \ Location	Introduction		Methodology & Materials		Results		Discussion		Total

Total	169	100.0	30	100.0	8	100.0	79	100.0	286	100.0

Psychology

In the journal of psychology, as Table 7 presented, over half of its citations were classified as the type of "setting the stage for the present studies" (58.6%). In the discussion section, comparative citations accounting for 71% of total citations appeared in the discussion section, which suggests that psychologists tend to cite other materials as comparisons to examine whether their research results were consistent with previous studies, or to correct previous research and hereafter propose their own unique results.

Table 7. Citations in Chinese Journal of Psychology by category and location.

Category \ Location	Introduction		Methodology & Materials		Results		Discussion		Total	
	No.	%	No.	%	No.	%	No.	%	No.	%

Total	251	100.0	55	100.0	20	100.0	75	100.0	401	100.0

Political Science

From Table 8, it is clear that "setting the stage for the present study" citations were the most numerous of the eight types of citation, accounting for 56% of the total citations in the journal of political science. The second most numerous were the methodological citations, though they comprised only 15% of total citations, while the percentage of other types of citations was even lower. Interestingly, political scientists cited much more statistical data in the introduction section, which indicates that they tended to use quantitative data or factual information to support their studies when writing introduction and literature review. As for the other locations, comparison was often made in the results section, while citations in the discussion section mostly served as bases for inference.

Table 8. Citations in Taiwan Political Science Review by category and location.

Total	386	100.0	96	100.0	54	100.0	16	100.0	552	100.0

Economics

Though the "setting the stage for the present study" citations were more numerous than other types of citations in the journal of economics, its percentage was a bit lower than in other disciplines, accounting for only 49% of all the citations in the journal. Table 9 also shows that economists cited more methodological materials, accounting for 31% of all citations, indicating a preference for empirical study in the field of economics. Models or methods proposed by other research were frequently found in the studies of economics, and comparative citations were mostly made in the section of results, which is consistent with the inference that economists were used to comparing their research results with previous studies. However, few citations in the discussion section revealed little of the characteristics of citation types in the journal of economics.

Table 9. Citations in Academia Economic Papers by category and location.

Category \ Location	Introduction		Methodology & Materials		Results		Discussion		Total

Total	139	100.0	52	100.0	75	100.0	6	100.0	272	100.0

Management

The relations between citation type and location in the journal of management can be seen in Table 10. The percentage of citations that set the stage for the present study was comparatively high (64%) in the journal of management, which was the only discipline whose percentage exceeded 60% among all six disciplines discussed in this study. Unlike economists, who were found to care more about methods and materials, scholars of management focused more on literature reviews, tending to project the importance of their research questions by contrasting them with previous studies. Yet they still valued the implementation of research

methods from other studies, according to the second top percentage (17%) of methodological citations. Comparative, argumentative, speculative and hypothetical citations also appeared in the section of discussion, while comparative citations accounted for more percentage (11%) of total citations in the journal of management.

Total	100.0	100.0	100.0	100.0	100.0	100.0	100.0	100.0	100.0	100.0

In sum, the percentages of "setting the stage for the present study" citations ranked first in the journals of all six disciplines, with management accounting for 63.8%, psychology 58.6%, sociology 56.7%, political science 56.3%, education 53.5%, and economics 48.9%. The percentage of methodological citations to total citations was 15.2%, which made the second high among the six journals, with economics accounting for 13.3%, management 16.9%, and political science 15.4%. As for the comparative citations, psychology (17%) and sociology (14.6%) covered more than other disciplines, while education exceeded other disciplines in the argumentative, speculative and hypothetical citations, with a percentage of 16.8%.

In Peritz's study, the citation type was highly relevant to the citation location, as confirmed by the results of this research shown in Table 11. In the introduction section, most citations belonged to the category of "setting the stage for the present study"; in the section of methods and materials, methodological citations appeared the most; as for the section of results and discussion, although the distribution of citation types varied among the six disciplines,

comparative, argumentative, speculative, and hypothetical citations were the most on the average. Overall, the research outcomes indicated that most social scientists of Taiwan complied with international writing format, and confirmed the hypothesis proposed by Peritz that the citation location was highly relevant to the citation type.

Summary and Discussions

This study explores and compares the distribution of article types of journals, languages of citation, citation years, document types of citations, citation types and locations of citations among citations in the top social science journals of six disciplines published in Taiwan and indexed in the Taiwan Social Sciences Citation Index (TSSCI). The following conclusions may be drawn from the results.

1. Journals and books were the most cited materials; English language articles were the most cited in social science studies in Taiwan.
2. Social scientists in Taiwan tended to cite materials published within the past 10 year, most citations in the sample journals were for articles with four to seven years of the journal publication, indicating that social scientists in Taiwan tend to cite the most recent articles.
3. The ratio of articles following IMRAD format was high in social science journal in Taiwan, suggesting that the top social science journals comply strictly with the IMRAD format of structured articles in Taiwan.
4. In Taiwan, citations in social science journals occurred the most in the introduction section, while the conclusions section had the least: The distribution of citations in different sections of an article may indicate the status and characteristics of a research domain. In this study, citations occurred most frequently in the introduction section for each of the social science disciplines. The introduction may include research background and literature review, and both sections need quite a few references for proving points or indicating motivation. For the methods section, economics and management had high percentage of citations, indicating that scholars in these two disciplines were used to adopting models, designations or operations from previously published research. In the results section, economists and psychologists tended to cite more articles for comparison and contrast. In general, citations appeared least frequently in the conclusions section, though the percentage rates were still a little higher in psychology and education, revealing their concern for further discussion and evaluation of research results.
5. Social scientists mostly cite to set the stage for their present studies: The “setting the stage for the present study” citations were the most frequently used in the sampled social science journals, accounting for 57.5% of all citations. From the distribution of citation type, it is clear that social scientists tended to cite in order to provide support or motivation for their own studies, which as shown by the large number of “setting the stage for the present study” type of citations. Scholars of economics, management and political science used to introduce methods and materials to compare or verify their findings. Psychologists and sociologists tended to compare their research results with previous studies, whereas scholars of education emphasized discussion greater than other sections.
6. Citation type is highly relevant to the citation location, which is consistent with the findings of Peritz’s study.

In this study, citation characteristics of social scientists in Taiwan were analyzed via bibliographic data such as types of cited materials and languages of citations. The results revealed the citation characteristics and information need of Taiwan’s social scientists, which could be valuable in collection development of libraries or refinement of information services. Under the assumption that citations indicate the actual use of materials, the distribution of publication years and citing half-life may serve as evidence for libraries to order or suspend

information resources (electronic journals, for instance), which could help to achieve similar goals on better budget allocation. Providing further exploration and examination of citations, this study is also expected to provide a better understanding of citation nature, and is anticipated to serve as a basis for future empirical studies.

There are limitations for the citation type determination by the textual analyst on the basis of the surrounding text. This is because, first, citation types may not be apparent simply by studying the text and, second, effective analysis sometimes requires specialist knowledge in the discipline of the texts being studied. Therefore, conducting an interview study with authors of the text to obtain their own views of citation types is suggested for further study. The small number of samples involved in this study preclude from making confident generalizations regarding the frequency of the citation types across these social science disciplines as a whole. Thus, the collection and analysis of a larger sample size is also suggested for further study.

Conclusion and Suggestion

The study is still to be improved owing to its restrictions and limitations. For better interpretation of the research trend, paradigm shifts and citation distribution of social sciences, it is suggested that the time frame, scope and quantity of sample collection be extended, including citations from both domestic and foreign articles. Co-research with experts and scholars in concerning disciplines are recommended as well. Even more, to reach a fuller apprehension of research features in academia by means of citation characteristics, samples in humanities and sciences may be examined in the future studies. Though Periz's classification scheme is known for its simplicity and directness, it is not quite suitable for those non-empirical studies. However, the Citation Content Analysis (CCA) framework proposed by Zhang, Ding and Milojevic (2013) may serve as solution to the problem, since it adopts both syntactic and semantic measurement of citation, which thus makes cross-field comparison possible. As for the essence of citation, the purposes and motives of citation are also valuable topics for further studying.

Acknowledgments

This work was supported by grant NSC1007-2410-H-004-153-MY2 from the National Science Council, Taiwan, R.O.C. Bibliometric data collected by Min-yee Lee, Graduate Institute of Library, Information and Archival Studies, National Chengchi University, Taiwan is very much appreciated.

Abstract
In this paper we investigate the characteristics of the citation distributions of the 500 universities in the 2013 edition of the CWTS Leiden Ranking. We use a WoS dataset consisting of 3.6 million articles published in 2003-2008 with a five-year citation window, and classified into 5,119 clusters. The main findings are the following four. Firstly, The universality claim, according to which all university citation distributions, appropriately normalized, follow a single functional form, is not supported by the data. Secondly, nevertheless, the 500 university citation distributions are all highly skewed and very similar. Broadly speaking, university citation distributions appear to behave as if they differ by a relatively constant scale factor over a large, intermediate part of their support. Thirdly, citation impact differences between universities account for 3.85% of overall citation inequality. However, these differences are greatly reduced when university citation distributions are normalized using their MNCS values as normalization factors. Finally, the above results have important practical consequences. On one hand, we only need a single explanatory model for the single type of high skewness characterizing all university citation distributions. On the other hand, the similarity of university citation distributions goes a long way in explaining the similarity of the university rankings obtained with the MNCS and the top 10% indicator.

Conference Topic
Citation and co-citation analysis

Introduction
Universities constitute a key vehicle in the production of knowledge in contemporary societies. However, the evaluation of the quality, or the relevance of the research done by universities in a myriad of scientific fields is a very difficult problem. For the assessment of the performance of research units of all types during the last decades, academic bodies, public officials in charge of science policy, and specialists in the field of Scientometrics have been paying increasing attention to one observable aspect of research in all fields: the citation impact of publications in the periodical literature.

In this paper, we focus on this aspect of research for the 500 universities included in the 2013 edition of the CWTS Leiden Ranking (LR universities) (Waltman et al., 2012a). We use a Web of Science (WoS) dataset consisting of 3.6 million publications in the 2005-2008 period, the citations they receive during a five-year citation window for each year in that period, and a classification system consisting of 5,119 clusters (Ruiz-Castillo & Waltman, 2015).

The construction of university citation distributions in the all-sciences case requires the prior solution of two methodological problems: the assignment of responsibility for publications with two or more co-authors belonging to different institutions, and the aggregation of the citation impact achieved by research units working in different scientific clusters. We solve these problems using a fractional counting approach in the presence of co-authorship, and the standard field-normalization procedure where cluster mean citations are used as normalization factors.

Once these two problems have been solved, specialists typically debate the properties of alternative citation impact indicators. In this paper, we study a basic aspect of the research

evaluation problem that comes *before* the comparison of the advantages and shortcomings of specific indicators, namely, the characteristics of the university citation distributions themselves. These distributions arise from the interplay of a complex set of economic, sociological, and intellectual factors that influence in a way hard to summarize the research performance of each university in every field. In this scenario, it is well known that some universities are more productive or successful than others in terms of the number of publications and/or the mean citation that these publications receive. However, little is known concerning the shape of university citation distributions abstracting from size and mean citation differences. In order to contribute to this knowledge, in this paper we investigate the following four issues.

Firstly, we inquire whether university citation distributions are universally distributed. The universality condition, borrowed from statistical physics, means that, appropriately normalized, citation distributions follow a unique functional form within the bounds set by random variation. Radichhi *et al.* (2008) suggest a statistical test of this condition in their study of 14 WoS journal subject categories. According to this test, the universality condition is not satisfied for our 500 university citation distributions. This is consistent with previous results for large classification systems in WoS datasets consisting of complete field citation distributions that include publications with zero citations (Albarrán & Ruiz-Castillo, 2011, Albarrán *et al.*, 2011a, Waltman *et al.*, 2012a, Perianes-Rodriguez & Ruiz-Castillo, 2014).

Secondly, in view of the above finding, we ask: are at least university citation distributions as highly skewed and as similar among each other as previous results indicate for field citation distributions? Using the same size- and scale-independent techniques that have been used in previous research, we confirm that this is the case in our dataset. This result has been established at different aggregation levels, publication years, and citation window lengths, and independently of whether the problem of the multiple assignment of publications to sub-fields in WoS datasets is solved by following a multiplicative or a fractional approach (Glänzel, 2007, Radicchi *et al.*, 2008, Albarrán & Ruiz-Castillo, 2011, Albarrán *et al.*, 2012, Herranz & Ruiz-Castillo, 2012, Waltman *et al.*, 2012a, Radicci & Castellano, 2012, Li *et al.*, 2013, Ruiz-Castillo & Waltman, 2015, Perianes-Rodriguez & Ruiz-Castillo, 2014). Similar conclusions concerning the skewness and similarity of individual productivity distributions are found when authors are classified into 30 broad scientific fields (Ruiz-Castillo & Costas, 2014).

Thirdly, using the measuring framework introduced in Crespo *et al.* (2013), we investigate how important is the effect of differences in citation impact between LR universities in the overall citation inequality in the union of the 500 LR university citation distributions. Furthermore, we inquire up to what point this effect can be accounted for by scale factors captured by the universities' Mean Normalized Citation Score (*MNCS* hereafter). The answer is that citation impact differences between universities account for 3.85% of overall citation inequality –a much smaller percentage than what is found in the context of production and citation practice differences between scientific fields (Crespo *et al.*, 2013, 2014, Ruiz-Castillo & Waltman, 2015, Perianes-Rodriguez & Ruiz-Castillo, 2014). These differences are greatly reduced when university citation distributions are normalized using their *MNCS* values as normalization factors.

Finally, we discuss the implications of these results for the understanding of the high correlation between the university rankings according to two citation impact indicators: the *MNCS*, and the Top 10% indicator of scientific excellence (the $PP_{top\ 10\%}$ indicator hereafter), defined as the percentage of an institution's output included into the set formed by 10% of the world most cited papers in the different scientific fields. The latter indicator has been recently adopted by well-established institutions, such as the CWTS in the Netherlands, and SCImago in Spain.

The rest of the paper is organized into two Sections. The first section presents the empirical results, while the next section discusses further research.

Empirical results

The universality of university citation distributions

Let $\boldsymbol{c_i}$ be the LR university i field-normalized citation distribution. Note that, for each university, the mean citation of $\boldsymbol{c_i}$ is precisely the Mean Normalized Citation Score (MNCS hereafter). Let $\boldsymbol{c^*_i}$ be the normalized citation distribution of university i using the university MNCS as the normalization factor. Let $\boldsymbol{C^*}$ be the union of the universities' normalized citation distributions, $\boldsymbol{C^*} = \cup_i \{\boldsymbol{c^*_i}\}$, where publications are ranked in increasing order of the number of normalized citations. Let $\boldsymbol{X_z}$ be the set of publications in the top z% of distribution $\boldsymbol{C^*}$, and let $\boldsymbol{x_{zi}}$ be the publications in X_z that belongs to the i-th university, so that $\boldsymbol{X_z} = \cup_i \{\boldsymbol{x_{zi}}\}$. In the terminology of Radicchi *et al.* (2008), if the ranking is fair, or unbiased, the percentage of publications that the set $\boldsymbol{x_{zi}}$ represents within each university should be near z% with small fluctuations. Let N_c and N_i be, respectively, the number of universities and the number of publications in the i-th university. Assuming that publications of the various universities are scattered uniformly along the rank axis, for any value z% one would expect the average relative frequency of the number of articles in any university to be z% with a standard deviation $\sigma_z = \{[z(100 - z)\Sigma_i\ (1/N_i)]/N_c\}^{1/2}$, which is equation (2) in Radicchi *et al.* (2008).

Table 1. Percentage of publications in each sub-field that appear in the top z% of the global rank, together with the standard deviation, σ_z, and the coefficient of variation, σ_z/z.

Theoretical values			Normalised distribution		
z%	σ_z	σ_z/z	z%	σ_z	σ_z/z
(1)	(2)	(3)	(4)	(5)	(6)
1	0.20	0.20	0.96	0.29	0.30
5	0.43	0.09	4.95	0.90	0.18
10	0.59	0.06	10.00	1.46	0.15
20	0.79	0.04	20.03	2.41	0.12
30	0.91	0.03	30.04	3.11	0.10
40	0.97	0.02	40.00	3.49	0.09
50	0.99	0.02	49.88	3.76	0.08
75	0.86	0.01	74.73	4.08	0.05
90	0.59	0.01	88.94	4.08	0.05

For each z value in a certain sequence, column 2 in Table 1 presents the standard deviations σ_z, while column 3 is the theoretical coefficient of variation, namely, σ_z/z. Columns 4 to 6 contain the values for the average z, the standard deviation σ_z, and the coefficient of variation σ_z/z obtained empirically in distribution $\boldsymbol{C^*}$.

Although σ_z varies non-linearly with z, the theoretical coefficient of variation in column 3 raises from 0.01 to 0.20 when we proceed from z = 90% towards z = 1%. In the normalized case, the considerable differences with the theoretical values in column 6, above all for lower values of z, indicate the lack of universality for this set of 500 university citation distributions.

This conclusion contrasts with the universality claim in Chatterjee *et al.* (2014), who study 42 academic institutions across the world, their publications in four years, 1980, 1990, 2000, and 2010, and the citations they receive according to the WoS until July 2014. We should emphasize that this paper has a number of technical problems. The criterion for selecting their

42 academic institutions is not given, and there is no information on how the following three problems have been solved: the assignment of publications in WoS datasets to multiple journal subject categories, the assignment of responsibility for co-authored publications, and the all-sciences aggregation problem. Nevertheless, we will proceed discussing their results. Chatterjee *et al.* (2014) explain that, for each publication year, the university normalized citation distributions fit well to a lognormal for most of the range, although the poorly cited publications seem to follow another distribution, while the upper tail is better described by a power law. This is quite different from the claim that there is a single functional form for the entire domain of definition of the 42 institutions in their sample. Our statistical approach tests whether the universality claim is supported by the data over the entire domain of the 500 LR universities. In this sense, our results do not contradict each other. We both agree that the universality claim over the entire domain is not the case in our respective samples.

On the other hand, the main problem with the still unpublished version of Chatterjee *et al.* (2014) is that, in our opinion, their statistical methods are not clearly explained. Unfortunately, the authors do not explain the following three aspects: (i) how the partition of the domain into three segments is estimated for each university, and whether this partition is universal; (ii) which tests have been used to determine the functional form chosen in each segment versus possible alternatives; (iii) how the confidence interval for the power law parameter has been estimated, and which is the confidence interval for the lognormal parameters. As a matter of fact, the only clear evidence for the distributions collapse into a universal curve is the graphical illustration provided for a sample –whose selection is unexplained– of 24 of the original 42 academic institutions.

The skewness and similarity of university citation distributions

The skewness of citation distributions is assessed by simply partitioning citation distributions into three classes of articles with low, fair, and very high number of citations. For this purpose, we follow the Characteristic Scores and Scale (CSS hereafter) approach, first introduced in Scientometrics by Schubert *et al.* (1987). In our application of the CSS technique, the following two *characteristic scores* are determined for every university: μ_1 = mean citation, which in our context is equal to the *MNCS*, and μ_2 = mean citation for articles with citations greater than μ_1. We consider the partition of the distribution into three broad categories: (i) articles with a low number of citations, smaller than or equal to μ_1; (iii) fairly cited articles, with a number of citations greater than μ_1 and smaller than or equal to μ_2, and (iii) articles with a remarkable or outstanding number of citations greater than μ_2. For each citation distribution, we measure the percentages of publications in the three categories, as well as the percentages of the total citations accounted for by the three categories. The average, standard deviation, and coefficient of variation for the 500 university values of the percentages of publications, the percentages of the total citations in the three categories are included in Table 2.

The results are remarkable. In principle, differences in resources, intellectual traditions, organization, the structure of incentives, and other factors lead us to expect large differences between the 500 LR university citation distributions in different parts of the world. However, judging from the size of the standard deviations and the coefficient of variations for the 500 universities, we find that university citation distributions are extremely similar. At the same time, the distributions are highly skewed: on average, the MNCS values of the 500 universities is 12.9 percentage points above the median, while the 12.5 of outstanding articles account for 44.4% of all normalized citations.

Table 2. The skewness of citation distributions according to the CSS approach. Percentages of articles, and percentages of citations by category. Average, standard deviation, and coefficient of variation over the 500 LR universities, and results for the overall citation distribution.

	Percentage of articles in category:			Percentage of citations in category:		
	1	2	3	1	2	3
Average (Std. deviation)	62.9 (1.9)	24.6 (1.2)	12.5 (1.2)	22.9 (1.7)	32.7 (0.8)	44.4 (1.5)
Coefficient of variation	0.03	0.05	0.10	0.08	0.02	0.03

For the sake of robustness, we have conducted two more sets of computations. In the first place, in the presence of co-authorship we have assigned publications to universities in a multiplicative way. In the second place, we have studied the raw citation distributions without the benefit of any field-normalization procedure. Interestingly enough, the results are very similar to those obtained for field-normalized university citation distributions in the fractional case. Thus, we conclude that the characteristics of university citation distributions are robust to the way the assignment of publications to universities in the presence of co-authorship and the all-sciences aggregation problem are solved.

Finally, we should mention the results of two contributions closer to our own in which research publications are aggregated into the type of organization unit to which the authors belong. Firstly, Albarrán *et al.* (2015) study the partition of world citation distributions into 36 countries and two residual geographical areas using a dataset, comparable to ours, consisting of 4.4 million articles published in 1998-2003 with a five-year citation window for each year. They find that, at least in some broad fields and in the all-sciences case, the country citation distributions are not only highly skewed, but also very similar across countries –a result parallel to our own for the 500 LR universities. Secondly, Perianes-Rodriguez & Ruiz-Castillo (2015) study a set of 2,530 highly productive economists who work in 2007 in a selection of the top 81 economics departments in the world. Contrary to previous results for field or country citation distributions, we find that productivity distributions are very different across the 81 economics departments. However, the data in Perianes-Rodriguez & Ruiz-Castillo (2015) does not consist of department citation distributions of articles published in a certain period of time with a citation window of common length, but of the individual productivity of faculty members in each department, where individual productivity is measured as a quality index that weights differently the articles published up to 2007 by each researcher in four journal equivalent classes. Nevertheless, we cannot rule out that the similarity of citation distributions is a phenomenon present at certain aggregate levels. To settle this issue, we need more work at the department level with citation distributions articles published in a certain period of time with a common citation window.

The importance of citation impact differences between universities

Together with the assessment of the between-group variability concerning the shape of university citation distributions, we are interested in measuring how important are the citation impact differences between universities. Formally, this problem is analogous to the measurement of the importance of differences in production and citation practices between scientific fields. For the latter, Crespo *et al.* (2013) suggested to measure the impact of such differences on the overall citation inequality for the entire set of field citation distributions applying an additively decomposable citation inequality index to a double partition into scientific fields and quantiles. Similarly, in our case we measure how much of the overall citation inequality exhibited by the union of the 500 LR university citation distributions can be attributed to the citation impact differences between universities (this is also the approach adopted in Perianes-Rodriguez & Ruiz-Castillo, 2014a, to assess the effect of citation impact between countries).

For that purpose, we begin with the partition of, say, each university citation distribution into Π quantiles, indexed by π = 1,.., Π. In practice, in this paper we use the partition into percentiles, that is, we choose Π= 100. Assume for a moment that, in any university u, we disregard the citation inequality within every percentile by assigning to every article in that percentile the mean citation of the percentile itself, μ_u^{π}. The interpretation of the fact that, for example, $\mu_u^{\pi} = 2\,\mu_v^{\pi}$ is that, on average, the citation impact of university u is twice as large as the citation impact of university v in spite of the fact that both quantities represent a common underlying phenomenon, namely, the same *degree of citation impact* in both universities. In other words, for any π, the distance between μ_u^{π} and μ_v^{π} is entirely attributable to the difference in the citation impact that prevails in the two universities for publications with the same degree of excellence in each of them. Thus, the citation inequality between universities at each percentile, denoted by $I(\pi)$, is entirely attributable to the citation impact differences between the 500 LR universities holding constant the degree of excellence in all universities at quantile π. Hence, any weighted average of these quantities, denoted by *IDCU* (*I*nequality due to *D*ifferences in *C*itation impact between *U*niversities), provides a good measure of the total impact on overall citation inequality that can be attributed to such differences. Let $\boldsymbol{c_i}$ be university i citation distribution, and let $\boldsymbol{C}$ be the union of the universities citation distributions, $\boldsymbol{C} = \cup\,\{\boldsymbol{c_i}\}$. We use the ratio

$$IDCU/I(\boldsymbol{C}) \qquad (1)$$

to assess the relative effect on overall citation inequality, $I(\boldsymbol{C})$, attributed to citation impact differences between universities (for details, see Crespo *et al.*, 2013).

Finally, we are interested in estimating how important scale differences between university citation distributions are in accounting for the effect measured by expression (1). Following the experience in other contexts, we choose the university mean citations as normalization factors. To assess the importance of such scale factors, we use the relative change in the *IDPD* term, that is, the ratio

$$[IDCU - IDCU^*]/IDCU, \qquad (2)$$

where *IDCU** is the term that measures the effect on overall citation inequality attributed to the differences in university distributions after the normalization of university citation distributions using university mean citations as normalization factors (for details, see again Crespo *et al.*, 2013). The estimates for expressions (1) and (2) in our dataset are included in table 3:

Table 3. The effect on overall citation inequality, I(C), of the differences in citation impact between universities before and after MNCS normalization, and the impact of normalization on this effect.

	Normalization impact = 100 [*IDPD – IDCP*/IDCP*]	
Before MNCS normalization, 100 [*IDPU*/*I*(*C*)]	3.85 %	-
After MNCS normalization, 100 [*IDPU/*I*(*C*)]**	0.72 %	81.9 %

It is interesting to compare these figures with what was obtained in two instances in the previous literature. The first case concerns the partition into 36 countries and two residual geographical areas in the all-sciences case (Albarrán *et al.*, 2014), while the second case

refers to 219 WoS sub-fields (Crespo *et al.*, 2014). Two comments are in order. Firstly, the effect on overall citation inequality due to citation impact differences between the 500 LR universities (3.85%) is comparable to the effect due to citation impact differences between countries (5.4%). However, both of them are considerably smaller than the corresponding effect on overall citation inequality attributable to differences in production and citation practices across the 219 sub-fields (approximately 18%). Secondly, the reduction of the total effect generated by *MNCS* normalization in our dataset (81.9% of the total effect) is of a comparable order of magnitude to the same phenomenon in the context of country (85.2%) or sub-field citation distributions (83.2%).

It should be noted that these results summarize in a pair of scalars a complex phenomenon that takes place along the entire support of our university citation distributions. As a matter of fact, the term *IDCU* is simply a weighted average of the $I(\pi)$ terms, $\pi = 1,\ldots, 100$, that capture the effect on overall inequality of the citation impact differences between the 500 LR universities holding constant the degree of excellence in all universities at percentile π. Therefore, it is instructive to study how $I(\pi)$ changes with π both before and after the MNCS normalization. The results appear in Figure 1 (since $I(\pi)$ is very high for $\pi < 27$, for clarity these percentiles are omitted from Figure 1), which deserves the following two comments. Firstly, the strong impact of *MNCS* normalization is readily apparent. Secondly, it is useful to informally partition the support of our citation distributions into the following three intervals: [0, 57], [58, 96], and [98, 100]. In the first and the third one, $I(\pi)$ values are very high. This means that, since in these two intervals university citation distributions differ by more than a scale factor, the universality condition can hardly be satisfied in them. However, $I(\pi)$ is approximately constant for a wide range of intermediate values in the second interval. Thus, this is the range of values where the search for a single functional form in Chatterjee *et al.* (2014) may give good results in our dataset.

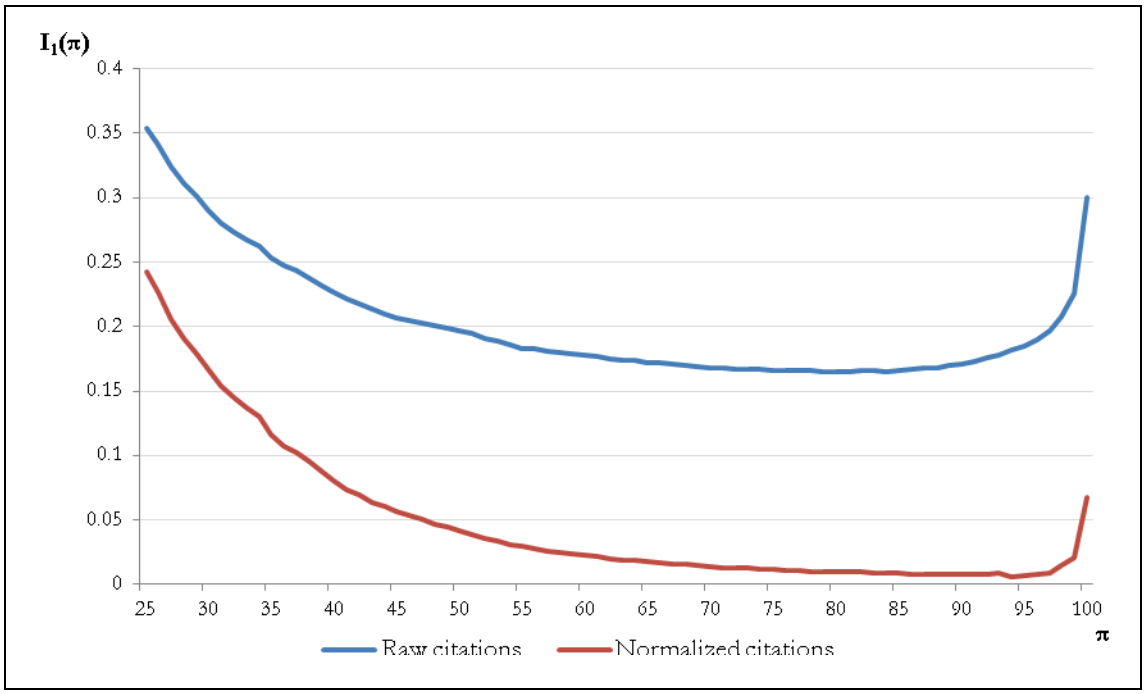

Figure 1. Citation Inequality Due to Differences in Citation Practices, I(π), as a function of π. Results for the [27, 100] quantile interval.

Implications of the results

Our results have two types of practical implications. In the first place, assume that the top,

intermediate, and worse universities have different types of citation distributions. In this case, we would need to build different models to explain the citation impact variability within the universities of the three types. On the contrary, since we have found that, although not universal, university citation distributions are rather similar, we need a single model to explain the high within-universities variability.

In the second place, recall that the move in the CWTS and SCImago rankings from an average-based citation impact indicator –such as the *MNCS*– towards a rank percentile approach that throws all the weight on the top *x*% of most cited papers –such as the $PP_{top\ 10\%}$ indicator– is surely due to the idea that, for highly skewed citation distributions, average-based indicators might not represent well the excellence in citation impact. However, the two rankings are rather similar: the Pearson correlation coefficient between university values is 0.981, while the Spearman correlation coefficient between ranks is 0.986. The situation is illustrated in Figure 2, where the positive slope indicates that to low (high) *MNCS* values there correspond lower (higher) $PP_{top\ 10\%}$ values.

We conclude that ordinal differences between the university rankings according to the MNCS and the $PP_{top\ 10\%}$ indicators are of a small order of magnitude. As a matter of fact, we find a strong, more or less linear relationship between the $PP_{top\ 10\%}$ and the MNCS in two other instances: for the 500 universities in the 2011/2012 edition of the Leiden Ranking (see Figure 2 in Waltman *et al.*, 2012b), and for the partition of the world into 39 countries and eight geographical areas studied in Albarrán and Ruiz-Castillo (2012). How can we explain these results? We have seen already that, university citation distributions behave as if they differ by a relatively constant scale factor over the [58, 96] percentile interval in their support. In this empirical scenario, it is not surprising that the MNCS values, which are reached at approximately the 63th percentile of citation distributions, and the $PP_{top\ 10\%}$ indicator that focus on the last 10 percentiles, provide very similar rankings. A convenient practical consequence is that the citation impact university ranking provided by the MNCS indicator is an adequate one. The $PP_{top\ 10\%}$ indicator would only add greater cardinal differences between the best and worse universities with relatively few re-rankings.

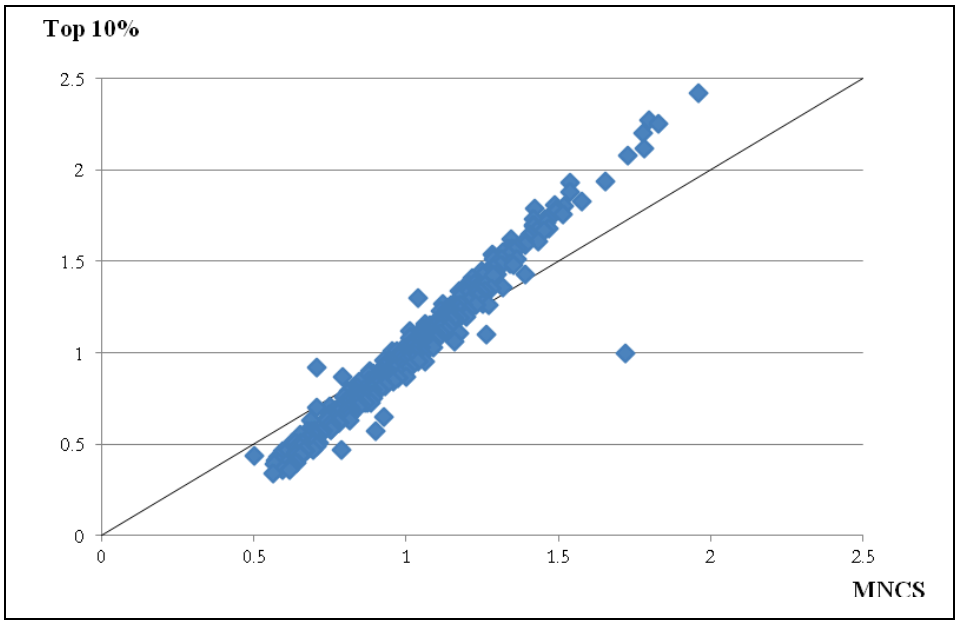

Figure 2. Scatterplot of the relation between the MNCS indicator and the PPtop 10% indicator for the 500 Leiden Ranking universities

It should be noted that further details concerning the following topics can be found in the Working Paper version of this paper, Perianes-Rodriguez & Ruiz-Castillo, 2014b): (i) the distribution of the total number of publications by universities; (2) the means μ_1 and μ_2, as well as the results of the CSSS approach for individual universities; (3) the graphical illustration of these results; (4) the measurement of the skewness of university citation distributions by means of a skewness index robust to extreme observations; (5) the robustness of all skewness results for the assignment of publications to universities in a multiplicative way, as well as the treatment of raw citation distributions without the benefit of any field-normalization procedure; (6) the re-rankings involved in the move from the MNCS towards the $PP_{top\ 10\%}$ indicator, as well as the cardinal differences between their values. In any case, the robustness of all of our results must be investigated with other datasets characterized by other publication years, and other citation windows, as well as other data sources different from the WoS.

Further research

Here are the possibilities for further research:

1. The effect on overall citation inequality attributable to the differences in citation impact between universities shows a characteristic pattern: broadly speaking, university citation distributions appear to behave as if they differ by a relatively constant scale factor over a large, intermediate part of their support. Consequently, it might be interesting to compute the exchange rates introduced in Crespo *et al.* (2013, 2014) to exploit this feature, and to use them as normalization factors. More generally, one could experiment with other normalization approaches that have been found useful in other contexts, notably the two parameter scheme introduced by Radicci & Castellano (2012).
2. Chatterjee *et al.*'s (2014) idea of fitting specific functional forms to university citation distributions in different intervals of their support is worth pursuing. The threshold determining the upper tail where a power law might be the best alternative could be estimated following the methods advocated in Clauset *et al.* (2009). Similar grid techniques could be applied to determine the lower bound of the interval where a lognormal might be the best alternative. In any case, standard methods should be used to test which specific functional form is best in each interval, as well as to estimate the parameters' confidence intervals (Thelwall & Wilson, 2014, and Brzezinski, 2015).
3. As we have seen in Section III.4, differences in citation impact between universities after MNCS normalization tend to rise when we reach the last few percentiles including the most highly cited articles. The question left for further research is how to complement average-based or $PP_{top\ 10\%}$ indicators with other measurement instruments that highlight the behavior of citation distributions over the last few percentiles. Given the important role of extreme observations in citation distributions, robustness of alternative high-impact indicators to these extreme situations will be an important element in the discussion.
4. Consider an array of citation distributions with a smaller number of scientific fields than in this paper in the columns, and the 500 LR universities in the rows. We already know much concerning field citation distributions and university citation distributions in the all-sciences case. A possible next step is to study the characteristics of university citation distributions column by column, that is, restricted to each field. The results will determine to what extent the similarities between citation distributions is a question depending on the aggregation level at which the study is conducted.

Exploration of the Bibliometric Coordinates for the Field of 'Geography'

Juan Gorraiz and Christian Gumpenberger

christian.gumpenberger, juan.gorraiz@univie.ac.at
University of Vienna, Library and Archive Services, Bibliometrics and Publication Strategies, Boltzmanngasse 5, A-1090 Vienna (Austria)

Abstract
This study is a bibliometric analysis of a highly complex research discipline, namely geography, in order to identify the most used and cited publication channels, to reveal publication strategies, and to analyse the discipline's coverage in the three main data sources for citation analyses: Web of Science, Scopus and Google Scholar. The results show very heterogeneous and individual publication strategies when considering the selection of adequate publication channels even in the same research fields. Monographs, journal articles (including proceedings papers) and book chapters are the most cited document types. Differences between research fields more related to the natural sciences than to the social sciences are clearly visible but not so considerable when taking into account the higher number of co-authors. General publication strategies are more established in the fields related to the natural sciences. Although an "iceberg citation model" is suggested, citation analyses for monographs, book chapters and reports (working papers) should be conducted separately and include complementary data sources, such as Google Scholar, in order to enhance the coverage and improve the quality of the citation analysis.

Conference Topics
Citation and co-citation analysis – Social Sciences

Introduction and background
From a bibliometric point of view, geography is a very challenging discipline, because it belongs to the natural sciences (geography, physical) as well as to the social sciences (geography), as it is clearly depicted in each edition of Journal Citation Reports (see Table 1).

Table 1. Category data of geography in both Editions of JCR (2013)

JCR EDITION 2013	*Category*	*Total Cites*	*Median IF*	*Aggregate IF*	*Aggregate Immediacy Index*	*Aggregate Cited Half-Life*	*# Journals*	*# Articles*
Sciences	GEOGRAPHY, PHYSICAL	159297	2.152	2.574	0.72	7.5	46	4972
Social Sciences	GEOGRAPHY	79207	1.059	1.612	0.343	7.4	76	3762

Table 1 shows very different citation characteristics according to the corresponding JCR edition. Furthermore, geography is a highly interdisciplinary field, very strongly related to geosciences, environmental sciences, ecology and remote sensing (natural sciences), or to economics, urban studies and political sciences (social science), as a quick search and refine analysis in WoS (Web of Sciences - core collection) illustrates.

Although there are many studies illustrating the differences between natural and social sciences and the different publication cultures depending on the discipline (e.g. Nederhof, 2006; Australian Research Council, 2012; Ossenblok et al., 2012; van Leeuwen, 2013; Moksony, 2014), no literature focusing on this specific could be retrieved by the authors.

The main research questions of this study are:

- What are the publication characteristics depending on the different research field?
- Can differences be observed concerning research fields? What is their time evolution?

- Which are the most used publication channels? Which document types are the most cited ones? Is it possible to identify publication strategies?
- What is the coverage in the three main citation data sources, Web of Science, Scopus and Google Scholar? Could Google Scholar be used as a complementary data source?

Data sources and methodology

This study is primarily based on publication data collected for three professorial appointments at the University of Vienna (Department for Geography): the first one, related to Geosciences and comprising of twelve candidates, and the second one, related to Social and Economic Geography and comprising of ten candidates, were performed during 2013. The third one, related to Demography and comprising of nine candidates, was performed in August 2014.

All the publication data were delivered directly by the applicants, whose identity has to remain anonymous. All bibliometric indicators added to the list of publications by the authors themselves, such as citation counts, impact factor or the h-index, were controlled or recalculated in order to enable a correct and comparable analysis (Gorraiz, J. & Gumpenberger, C., 2015). Document types used by the authors in their list of publications were manually reassigned to the following standard groups: Monographs (Books), Book chapters, Journal articles, Proceedings Papers, Conferences (including meeting abstracts and talks), Reports (Working Papers), Book Reviews, Edited Books and Journals Issues, and other publications (or Miscellaneous). A clear distinction between "Proceedings Papers" and "Conferences" was not always possible when relying on the lists of publications.

The main data source for coverage and citation analyses was Web of Science - Core Collection (WoS) including the Conference Proceedings and Book Citation Index. Since coverage in the usual multidisciplinary bibliographic and citation databases (Web of Science, Scopus) is very low and unsatisfactory for citation analyses, we have included Google Scholar (GS) as an additional data source in a first explorative attempt (Jacso, 2005; Kousha & Thelwall, 2007; Meho, & Yang, 2007; Gorraiz et al., 2013).

The analysis in GS was performed by using the Google Scholar Citation Profiles (applicants for the third appointment were invited to create their individual profiles and make them publicly available for a couple of weeks) as well as by applying the tool 'Publish or Perish' particularly designed for this purpose.

In spite of the fact that citations were checked and the percentage of self-citations was determined, citation analyses in GS should be taken with a pinch of salt. Google Scholar is not a database but a search engine, and therefore indexing remains non-transparent and documentation is lacking. That is why the analyses were also performed in Web of Science, including the Cited Reference Search (which means considering citations originating from Web of Science (WoS) 'core journals' to all document types without any restrictions), and in Scopus.

Publication windows were the last ten years (general for all authors, appointments no.1 and 2) and the career length of each applicant (for all appointments). In order to distinguish individual scientific career lengths, the year of the first publication activity is always included.

The observed citations window was identical for all applicants per professorial appointment procedure. It covers the date from publication until April - May 2013 for appointments no. 1 and 2, and until July - August 2014 for appointment procedure no.3.

Visibility analyses were performed according to the data in the Journal Citation Reports (JCR), Science Edition 2012 (appointments no. 1&2).

The quartiles (Q1= top 25%; Q2= top 25-50%; Q3= top 50-75% and Q4= top 75-100%) were calculated according to the 2-years impact factor (IF) in the corresponding WoS category.

Results

Comparison between appointments no.1 and no.2

Table 2 and 3 show the most important publication document types used by the candidates for both appointments. The spectrum is much more heterogeneous in the social sciences, where journal articles are not always the most common publication channel.

Table 2. Publication spectrum and WoS coverage according to provided publication list for appointment no.1 – Geosciences - 12 candidates. (In parenthesis, the number of document types indexed in WoS; PY=all years; *no distinction).

Candidate no.	1st Pub Year	Books	Edited Books/ Issues	Book Chapters	Proceedings & Conference Papers*	Book Reviews	Miscellaneous	Journal Articles (JA)

10	2000	3	1	17	*72	0	49	22 (11)

Miscellaneous were principally Reports and Working Papers in both appointments. Therefore this document type was considered separately in the second part of the study.

In appointment no. 2, other document types such as Films, Policy Briefs, Newspapers and Special Issues were mentioned but only individually. For two candidates (one in appointment no.1 and one in no.2), articles in other (non-scientific or non-peer-reviewed) journals were also assigned to the group Miscellaneous.

Concerning the coverage in WoS both tables corroborate the low coverage of books and book chapters in both editions of the Book Citation Index. For articles in peer-reviewed journals, the WoS coverage in appointment no.1 varies between 60 and 100% and the trend in the last 10 years was constantly increasing until it reached a quota of almost 90% for all candidates. In appointment no. 2, the coverage was lower, varying between about 30 and 60%, but a similar trend was also observed even if not as steep.
Tables 4 and 5 show the results of the visibility (publication strategies) and citation analyses performed for both appointments. Only publications indexed in WoS in the last ten complete years (2003-2012) were considered.

These results corroborate the higher number of publications and citations in the discipline related to the natural sciences (about twice as many). But taking into account the number of co-authors and the percentage of self-citations, which is almost twice as high in the natural sciences, there is not really a considerable difference.

The visibility analysis (number of Q1- journal articles) shows that publishing in top journals with impact factor, result in a much higher visibility in the appointment related to natural sciences than in the one related to the social sciences.

Finally, tables 6 and 7 show that the citation differences, according to the aggregate impact factor of the main WoS category, are higher in appointment no.1 than in no.2.

Table 6. First and second research field according to WoS categories for appointment no. 1 - Geosciences – 12 candidates.

Results obtained in appointment no. 3 (Demography &Population Geography)

Applicants were invited to create their individual Google Scholar Citations profiles and make them publicly available for a couple of weeks.

From the nine applicants:

- six created a GS Citation Profile

- two refused to create one
- one followed the invitation, but the profile was incomplete

The tool 'Publish or Perish', particularly designed for this purpose, was then used for collecting and checking the data.

First of all, two key aspects (Focus 1 and 2) of each candidate's publications were determined in GS (free keywords) and in Web of Science according to the assigned Subject Categories (WoS categories) in the database. The results are shown in Table 8.

Table 8. First and second research field in WoS categories and GS for appointment no. 3– 9 candidates.

Table 9 represents the publication activity for each scientist according to the most relevant publication types. The data are based on the list of publications submitted by the candidates. In order to distinguish individual scientific career lengths, the year of the first publication activity has been included.

The results hint at very heterogeneous and individual publication strategies taking into account publication types. The three next sections contain coverage and citation analyses performed in the three considered data sources. Table 10 shows the percentage of coverage in Google Scholar for each publication type. Monographs (Books) and Edited Books or Issues are very well covered, probably due to the inclusion of Google Books (Kousha & Thelwall, 2009).

The coverage of Journal Articles is also much higher than in WoS or Scopus (see Table 11). Also of interest is the high coverage of Reports (Working Papers). Chapters in Books are not so well covered, but this is probably due to incidental incorrect citations.

Table 11 shows the results of the coverage and citation analyses performed in WoS, including the Cited Reference Search, in Scopus and in Google Scholar. The higher coverage scores in WoS over those in Scopus are due to the inclusion of the Cited Reference Search. This enabled citations not only of journal articles and book indexed in WoS to be retrieved, but also of other books, reports and other document types cited by the core journals in WoS.

All sections include the same indicators for each data source: 1) number of indexed publications; 2) percentage of publications covered according to the provided publication list; 3) number of cited documents; 4) total number of citations; 5) number of citations per cited publication; 6) maximum number of citations attracted by a publication; 7) total h-index and 8) i-index (number of publications with more than 10 citations).

The percentage of self-citations was only calculated for GS, where the number of citations was of sufficient significance.

Table 11 confirms that the values of the main citation indicators (number of citations, citations per cited publication and h-index) are different in absolute values in GS, WoS and Scopus, but are comparable in terms of relative values. Spearman correlations performed for these indicators (number of citations, citations per cited publication and h-index) in the three data sources (WoS, Scopus and Google Scholar) were very strong (varying from 0.8 to 0.95).

A detailed coverage and citation analysis for the three most cited document types in Google Scholar, Monographs, Book Chapters and Journal Articles (see Table 12) is shown in Table 13.

Table 11. Coverage and citation analysis in the three data sources for each candidate (Appointment no. 3)

Conclusions and discussion

The main conclusions of this case study for the field geography can be summarized in the following points:

Differences between research fields more related to the natural sciences than to the social sciences are clearly visible. However, the higher productivity (number of publications per year) and citation counts, are relativized when also considering the higher number of co-authors and percentage of self-citations

- General publication strategies, especially these based on the impact factor, are still more evident in the fields related to the natural sciences
- The results hint at very heterogeneous and individual publication strategies considering the selection of adequate publication channels even in the same research fields
- Journal Articles and Book Chapters are the most used publication channels
- Monographs, Journal Articles (including Proceedings Papers) and Book Chapters are the most cited document types
- The coverage, especially books, is much higher in Google Scholar and suggests the recommendation of this data source as complementary one, although this data source is still a black box (no transparency, missing content information, etc.). In this study the accuracy of the citations in GS was very high (~95%). Nevertheless further

measures are needed to reduce the noise of Google Scholar data in order to increase the significance of this alternative data source for evaluative purposes.

- The values of the main citation indicators might differ in absolute values in GS, WoS and Scopus, but are comparable in terms of relative values.
- This fact suggests a "citation iceberg model" (see Figure 1). The citation analysis in WoS or Scopus shows only the 'visible part' but this is generally still related to and indicates the 'invisible part'.
- Therefore, citation analyses for monographs, book chapters and reports (working papers) should be conducted separately and require the inclusion of complementary data sources. Otherwise relevant publications can be easily missed, resulting in wrong interpretations.
- Peers still have to be aware of blind spots in 'citation analyses' (e.g. 'non cited' document types and publications) with potentially harmful consequences in evaluation exercises

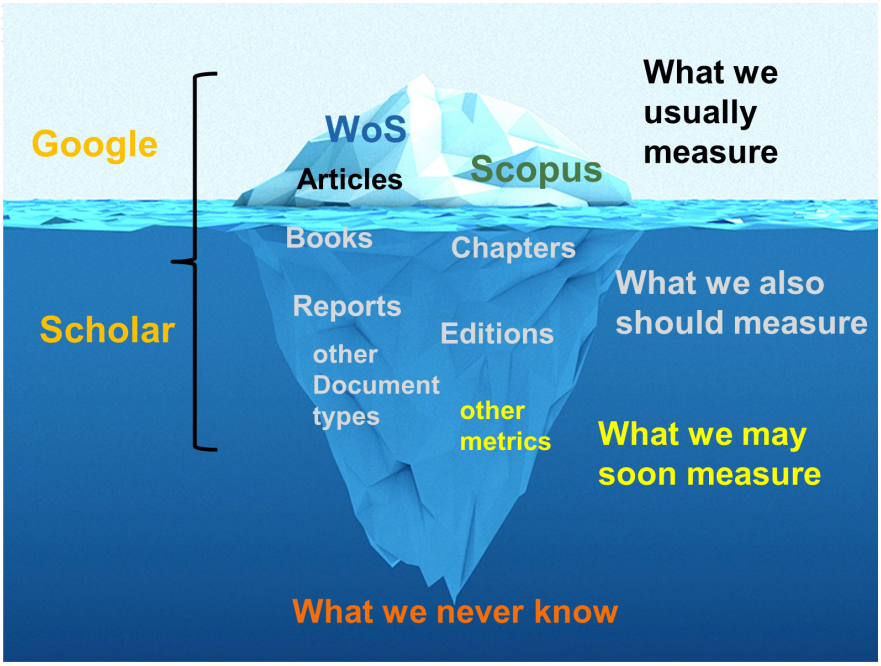

Figure 1. Citation "iceberg" model.

Finally, it should be stressed that citations can only used as a proxy for impact (and not for the quality) of publications produced in the 'publish or perish' community (i.e. the scientists who are committed to publishing their results). However, the scientific community is much broader and also comprises teaching academics as well as representatives from government or industry, who rather use than cite scientific output. Furthermore, our society has become progressively informed ('societal impact'). Unfortunately alternative metrics (like usage metrics and altmetrics) are still in their infancy (Kurtz M.J. & Bollen. J., 2010; Priem, J. et al., 2012; Gorraiz, J. et al., 2014; Hammarfelt, B., 2014) to measure the impact beyond citations and could not yet be applied to the described appointment procedures due to the current lack of available and reliable data.

Acknowledgments

We wish to thank Christian Buchmayer for his help collecting and disambiguating the data, and Prof. Thomas Glade for his support and suggestions.

Abstract
The aim of this paper is to collect the most-cited articles of the 21st century and to study how this group changed over time. Here the term "most-cited" is operationalized by considering yearly h-cores in the Web of Science. These h-cores are analysed in terms of authors, research areas, countries, institutions, journals and average number of authors per paper. We only consider publications of article or proceedings type. The research of some of the more prolific authors is on genetics and genomes publishing in multidisciplinary journals, such as *Nature* and *Science*, while the results show that writing a software tool for crystallography or molecular biology may help collecting large numbers of citations. English is the language of all articles in any h-core. The core institutions are largely those best placed in most rankings of world universities. Some attention is given on the relation between h-core articles and the information sciences. We conclude by stating that the notion of an h-core provides a new perspective on leading countries, articles and scientists.

Conference Topic
Citation and co-citation analysis

Introduction
The objective of this paper is to collect the most-cited articles of the 21st century and to study how this group changed over time. The term "most-cited" is operationalized by considering the h-core (Hirsch, 2005; Rousseau, 2006) in the Web of Science (WoS) for each period of time, starting with the period 2001-2005, continuing with 2001-2006 and ending with 2001-2013. These periods refer to the publication and the citation window. We recall that the h-core at a given moment in time, for instance on January 1, 2009, consists of the set of articles which at that time received a number of citations at least equal to their rank among all articles published during the period 2001-2008. This approach is different from the one taken in (Van Noorden et al., 2014) where a fixed number, concretely 100, of articles is considered. Furthermore, we study the papers making up the corresponding h-cores in terms of authors, research areas, countries, institutions, journals and average number of authors per paper.

Methodology
We have to point out that the 21st century starts on January 1, 2001. This implies that we only consider publications from 2001 on. Moreover, we only consider publications in Thomson Reuters' Web of Science (WoS) and we restrict ourselves to publications of article or proceedings type.
Although finding today's h-core for a set of articles in the Web of Science is easy, finding an h-core in the past needs some specific knowledge of the tools available in the WoS. First one retrieves the set for which one wants to determine the h-core (ending in the year Y). Its

articles are ranked from most cited to least cited. These are collected as a marked list. This is possible for at most 5,000 items. Clicking on Marked List shows this list and now, on this page, the system can provide a Citation Report, which is downloaded as an Excel file showing yearly citations for each of these records. Now we add the same data for the next 5,000 items (more was not necessary for our investigation). In this Excel file, we remove the columns corresponding to the year Y+1 and all later ones. In a next step we sum all remaining citations of each article. Sorting these sums from highest to lowest and comparing with a column of natural numbers leads to the h-index and the h-core. More details of this procedure are provided in (Rousseau & Zhang, 2014).

Results

The most-cited papers

The most-cited articles over the period 2001-2013 (the latest h-core) are shown in Table 1. It is clear that writing a software tool for crystallography or molecular biology may give one's paper a huge boost. The article by the National Cholesterol Education Program Expert Panel (2001) was the most-cited one from 2005 till 2008. From the year 2009 on Sheldrick's became the most-cited one.

Table 1. Most-cited articles over the period 2001-2013.

Rank	Article cited	Times cited
1	Sheldrick, G.M. (2008). A short history of SHELX. *Acta Crystallographica Section A*, 64, 112-122.	34,533
2	Livak, K.J. & Schmittgen, T.D. (2001). Analysis of relative gene expression data using real-time quantitative PCR and the 2(T)(-Delta Delta C) method. *Methods*, 25(4), 402-408.	24,796
3	Tamura, K., Dudley, J., Nei, M. & Kumar, S. (2007). MEGA4: Molecular evolutionary genetics analysis (MEGA) software version 4.0. *Molecular Biology and Evolution*, 24(8), 1596-1599.	17,049

Time evolution of h-index and h-cores

The difference between the h-index and the number of items in the h-core is due to the possible existence of more than one document with the same number of citations as the h-index, as illustrated in Table 2. For the year 2005, for example, there were five articles with 359 citations.

Table 2. H-indices and h-cores for the periods 2001-2005 till 2001-2013.

End year	h-index	# articles in the h-core
2005	359	363
2006	441	442
2007	526	527
2008	614	616
2009	704	704
2010	800	800
2011	902	902
2012	1014	1014
2013	1122	1122

It is obvious that only a small percentage of articles included in the WoS belongs to the h-core of a specific period. In order to show the evolution of the ratio of the h-core with respect to all articles we put their values for the period 2001-2004 equal to 100. Figure 1 shows the total number of papers in each period and the number of papers in each h-core when this rescaling has been performed. Linear regression is almost perfect for the two lines: all publications (R^2= 0,9982) and h-core (R^2= 0,9967). For this reason we can forecast the 21st century h-index for, at least, the next years to come. This would lead to an h-core of 1195 documents in 2014 and 1290 in the year 2015.

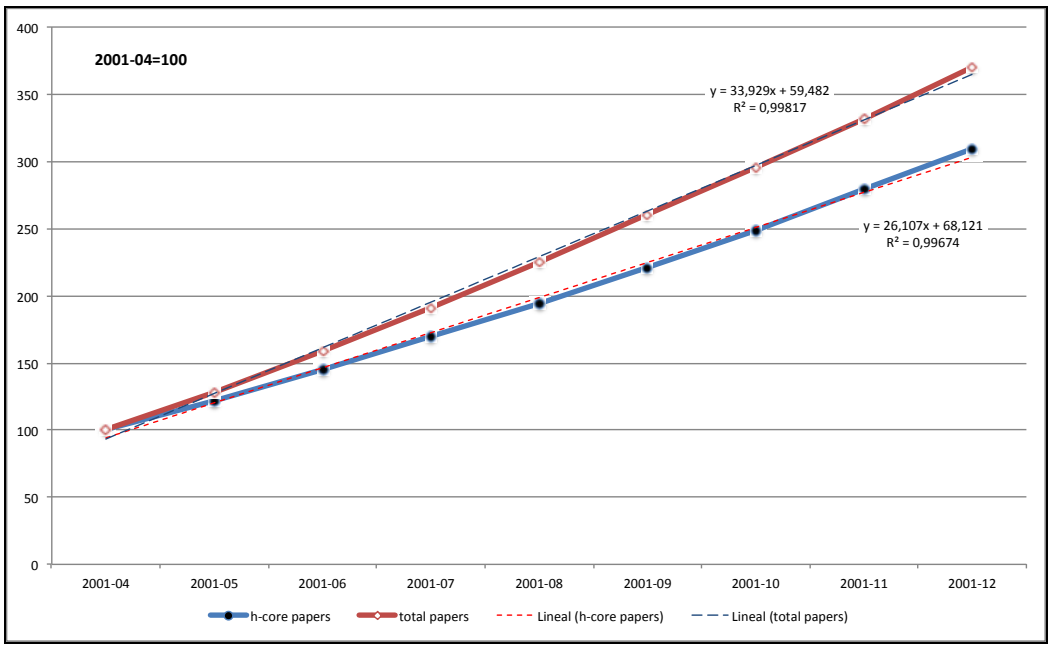

Figure 1. Evolution of the h-core.

In Table 3, we show the number of articles published in the years 2001 to 2011 included in each of the h-cores. For each h-core these numbers follow the order of publication, i.e. most

articles are published in the year 2001 and least in the latest year included in the core. Core13 has exactly the same number of articles published in 2001 as in 2002 (209 articles), while it does not contain articles published in 2013.

Table 3. Evolution of h-cores.

Year of Publication	Core-05	Core-06	Core-07	Core-08	Core-09	Core-10	Core-11	Core-12	Core-13
2001	196	210	218	217	217	213	213	209	209
2002	116	137	158	173	187	197	201	205	209
2003	43	72	96	120	138	151	159	163	169
2004	7	21	41	62	82	99	117	138	146
2005	1	2	11	31	49	74	93	110	121
2006			3	9	17	35	56	70	95
2007				3	10	23	36	47	58
2008				1	3	6	19	39	54
2009					1	2	6	21	32
2010							2	9	19
2011								3	8
2012									2
Total	363	442	527	616	704	800	902	1014	1122

Table 4 shows the number of articles in the h-core (on the diagonal) and on the last line the number of unique articles in the union of all h-cores until the year indicated on top of the column. The other numbers refer to the number of articles originally belonging to the core referred to on the left, but which do not anymore belong to the h-core. We note that there is one article that left the core (in 2007) but re-entered (in 2008) and from then on stayed in the core. This paper is:

> Minokoshi, Y., Kim, Y., Peroni, O., Fryer, L., Muller, C., Carling, D., & Kahn, B. (2002). Leptin stimulates fatty-acid oxidation by activating AMP-activated protein kinase. *NATURE*, *415* (6869), 339–343. doi:10.1038/415339a

H-cores characteristics

All articles in any h-core are written in English. We note that the 2001-2005 h-core contains one article that was later retracted (Chang and Roth, published in *Science*, which has now 533 citations and had 359 citations by the end of 2005, being the last one in the 2005 core). Some of the more prolific authors (E.S. Lander, M.J. Daly, R.A. Gibbs, J. Wang) perform research on genetics and genomes publishing in multidisciplinary journals, such as *Nature* and *Science*, often in hyper co-authored papers (with dozens and even hundreds of authors). A. Jemal and E. Ward publish yearly statistics on cancer, which all enter the h-core. R. Collins and R. Peto work on internal medicine and publish almost exclusively in *Lancet*. The fields of

nanotechnology and grapheme research are represented by C.M. Lieber and Nobel Prize winners A.K. Geim and K.S. Novoselov (Table 5).

Table 5. Authors with highest number of papers in the h-core (Authors with more than 7 papers in the latest core).

The multidisciplinary areas (which include journals such as *Nature*, *Science* and *PNAS*), and the ones related to general and internal Medicine (such as *Lancet* or the *New England Journal of Medicine*) occur the most in each of the cores, as illustrated in Table 6.

Table 6. H-cores in different research areas (Areas with more than 10 papers in the last core).

Research area	Core-05	Core-06	Core-07	Core-08	Core-09	Core-10	Core-11	Core-12	Core-13
Science & Technology - Other Topics	39,1%	38,0%	35,3%	34,9%	32,8%	33,4%	32,7%	32,0%	31,9%
General & Internal Medicine	27,8%	26,2%	26,4%	25,0%	24,6%	23,1%	21,6%	20,4%	20,0%
Biochemistry & Molecular Biology	8,3%	9,0%	8,3%	9,7%	10,1%	10,6%	11,4%	12,8%	13,3%

Table 7 shows a list of most used sources, where we observe, together with the mentioned multidisciplinary journals, the presence of medicine-related journals, including the specialized journal, *CA-A Cancer Journal for Clinicians*, whose presence is due to the systematic publication of the highly-cited annual statistics on cancer (all of them are in core 13). Other journal in the top positions, such as *Physical Review Letters* or *Nature Materials* occur less frequently.

Table 7. Journals of h-core publications (sources with 10 or more papers).

Source Titles	Core-05	Core-06	Core-07	Core-08	Core-09	Core-10	Core-11	Core-12	Core-13

NATURE GENETICS	2,5%	2,0%	1,9%	1,6%	1,8%	1,6%	1,4%	1,3%	0,9%

We observe that the shares of the top journals such as *Nature*, *Science* and the *NEJM* are slowly declining over the years, while the share of *Cell* is increasing. This corresponds with recent findings (Lozano et al., 2012; Larivière et al., 2014; Acharya et al., 2014) that more and more highly-cited publications are published in journals that do not have the highest impact factors, say "non-elite journals". Of course, this is as such not surprising as the number of publications world-wide increases faster than the publication opportunities provided by so-called elite journals.

In Table 8 we show the distribution of countries in the h-cores, where an article is classified as belonging to a country if at least one author has an address in this country. The first place goes to the USA. If, however, we consider the European Union (EU-28) as one entity then it leads the rankings in all except one year. Our results correspond to those obtained by King (2004) for the percentage of documents published by USA in the 1% most cited papers. Our results are also similar to those found by Leydesdorff et al. (2014). In their work the EU-28 gains gradually in the top-10% segment at the expense of the USA, and one can expect a cross-over between the EU28 and the USA in the near future within the top-10% segment. However, the distance between the U.S. and the EU is much larger in the top-1% segment.

Also here we see that the top performers (USA, EU-28 and Germany) lose in the share of h-core articles. This observation also holds for the Netherlands and most Scandinavian countries. England and Scotland consolidate their share, while Brazil and New Zealand show an increase. Although China's share in publications shows an exponential growth (Jin & Rousseau, 2005; Zhou & Leydesdorff, 2006, 2008) its share in h-core papers is much lower and shows at best a small increase in the latest years, after a decrease in the period 2008-2009.

Core institutions are shown in Table 9. Leading institutions are those that one can find in most rankings of world universities, although The University of Texas (Austin) is only 39th in the latest ARWU ranking.

Table 8. Countries of publication (with 10 or more papers in the latest core).

Countries	Core-05	Core-06	Core-07	Core-08	Core-09	Core-10	Core-11	Core-12	Core-13

Univ Pittsburgh	7	9	11	16	16	18	19	22	25

In table 10 we have calculated average co-authorship values of articles in h-cores by research areas. For several research areas these values are higher than the co-authorship values of all publications: for example, in Clinical Medicine the co-authorship value for all publications was 4.5 authors per document and 5 in Bioscience and Biomedical Research (Bordons & Gómez 2000; Glänzel & Schubert, 2005). For several research areas these values are higher than the co-authorship values expected from previous research. For example, in Clinical Medicine the co-authorship value for all publications was 4.5 authors per document and 5 in Bioscience and Biomedical Research (Bordons & Gómez 2000; Glänzel & Schubert, 2005).

Table 10. Average numbers of authors for papers in the h-cores by research areas (areas with more than 10 papers in 2013).

Research Area	Core-05	Core-06	Core-07	Core-08	Core-09	Core-10	Core-11	Core-12	Core-13	Average
Science & Technology - Other Topics	15,5	16,1	14,6	13,9	14,7	14,5	14,5	17,0	15,9	15,3

Cardiovascular System & Cardiology	12,6	10,5	8,8	10,1	10,1	9,7	9,8	11,9	13,5	10,9
Evolutionary Biology		2,0	2,0	3,0	3,4	3,1	2,6	2,7	2,9	2,8
Immunology	8,1	7,3	7,2	7,4	7,5	7,7	7,6	7,6	7,8	7,6
Biophysics			2,5	2,3	3,3	4,0	3,8	5,1	5,9	4,5
Environmental Sciences & Ecology	7,0	4,0	4,0	7,0	5,0	3,1	2,9	2,6	2,8	3,2
Radiology, Nuclear Medicine & Medical Imagin		6,0	4,5	5,7	6,3	5,0	4,3	5,0	5,5	5,1
Endocrinology & Metabolism	7,2	7,2	6,8	8,4	6,9	6,9	6,9	6,6	5,9	6,9

Areas with an average of less than 5 authors (in 2013) are: computer science, engineering, mathematics, mathematical and computational biology, crystallography, evolutionary biology, biophysics and environmental sciences & ecology. Areas with an average larger than 15 are: science & technology – other topics, general & internal medicine, physics and astronomy & astrophysics.

The 21st century h-core (2001-2013) and the information sciences

Only one article classified by Thomson Reuters as *Information science and library science* belongs to this h-core, namely Venkatesh, V., Morris, M.G., Davis, G.B. et al. (2003). User acceptance of information technology: toward a unified view. *MIS Quarterly*, 27(3), 425-478 (cited 2261 times in total).

Yet, other ones were used and cited in *Information science and library science* articles. We list those that were cited at least 30 times by ILS researchers (on December 25, 2014).

1. Hirsch, J.E. (2005). An index to quantify an individual's research output. *Proceedings of the National Academy of Sciences of the USA*, 102(46), 16569-16572. Cited 682 times by ILS researchers.

2. Venkatesh, V., Morris, M.G., Davis, G.B. et al. (2003). User acceptance of information technology: toward a unified view. *MIS Quarterly*, 27(3), 425-478. Cited 595 times.
3. Newman, M.E.J. (2001). The structure of scientific collaboration networks. *Proceedings of the National Academy of Sciences of the USA*, 98(2), 404-409. Cited 118 times.
4. Blei, D.M., Ng, A.Y. & Jordan, M/I. (2003). Latent Dirichlet allocation. *Journal of Machine-Learning Research*, 3(4-5), 993-1022. Cited 93 times.
5. Zhara, S.A. & George, G. (2002). Absorptive capacity: a review, reconceptualization, and extension. *Academy of Management Review*, 27(2), 185-203. Cited 91 times.
6. Berners-Lee, T., Hendler, L. & Lassila, O. (2001). The semantic web. *Scientific American*, 284(5), 28-37. Cited 64 times.
7. Newman, M.E.J., Strogatz, S.H. & Watts, D.J. (2001). Random graphs with arbitrary degree distributions and their applications. *Physical Review E*, 62(2), article number 026118. Cited 60 times
8. Girvan, M. & Newman, M.E.J. (2002). Community structure in social and biological networks. *Proceedings of the National Academy of Sciences of the USA*, 99(12), 7821-7826. Cited 50 times.
9. Newmann. M.E.J. & Girvan, M. (2004). Finding and evaluating community structure in networls. *Physical Review E*, 69(2), article number 026113. Cited 36 times
10. Breiman, L. (2001). Random forests. *Machine Learning*, 45(1), 5-32. Cited 30 times.

Besides Hirsch's famous article on the h-index (Hirsch, 2005), we see also Berners-Lee's article on the semantic web (Berners-Lee et al., 2001) and note the fact that Mark Newman occurs four times in this ILS h-core.

Conclusions

-Using the notion of an h-core provides a new perspective on leading countries, articles and scientists.

-The scientific contribution to the h-cores by the EU-28 is slightly higher than the USA's.

-The trend of annual h-cores since 2001 can predict future values of this indicator.

Of course, the view provided in this contribution is highly biased in favor of certain research areas such as General & Internal Medicine, or Biochemistry & Molecular Biology, and certain methodologies (writing heavily used software programs). Yet, it is a fact of life that these areas provide today's leading research. One should clearly realize that publishing highly cited research is different from realizing outstanding intellectual achievements.

Abstract
We have investigated the citation impact of four pairs of journals in four subject categories including the category of multidisciplinary journals, journals in environmental sciences, applied mathematics, as well as metallurgy and metallurgical engineering. Each pair is composed of one Chinese journal and one leading international journal in the same subject category. Comparison is done between the selected Chinese and international journals in each pair. The four Chinese journals are selected because of priority funding by the Chinese CIU Plan in categories A and B. Compared with leading international journals in the same subject category, citation impacts of the four Chinese journals in their relevant environments are low, although they have been improving from 2004 to 2013. Leading international journals are more intensively and systematically cited than Chinese ones in the same subject category of the JCR. Regarding the CIU Plan, the level of funding seems not to follow exactly the citation impacts: Journals receiving larger amounts of funding do not necessarily perform better in citation impact, and journals receiving the same amount of subsidy may have different citation performances.

Keywords:
Citation and co-citation analysis

Introduction
Right after the United States, China has been the second largest producer of scientific publications since 2006 (Zhou & Leydesdorff, 2008; ISTIC, 2013). With citation impact rising continuously China jumped to the fifth position in 2013 in terms of national total citation impact from the eighth in 2010 (ISTIC, 2013), two years earlier in reaching the target set by the Ministry of Science and Technology (MOST) of China in the 12th National Plan for the Development of Science and Technology (NPDST). In terms of total citations received by disciplines, however, China's performance was not evenly distributed: chemistry, materials science, engineering technology, mathematics, computer science, and physics performed best by taking the second position in the world total (ISTIC, 2013).

In addition to being a second largest producer of academic papers, China is also the second largest publishing nation of academic journals. Of the 9,884 journals, approximately 5,300 are in science and technology (Liu, 2012; Yao et al., 2014). Nevertheless, international visibility of Chinese journals is still low (Jin & Rousseau, 2004; Leydesdorff & Jin, 2005; Zhou & Leydesdorff, 2007a, 2007b; ISTIC, 2014). In 2013, only 162 Chinese journals (i.e., about 3% of China's total S&T journals) were indexed in the Science Citation Index (SCI) of Thomson Reuters. Journals to be indexed in the SCI are required to satisfy basic criteria, and thus one can expect these 162 Chinese journals to be of relatively higher quality among the 5,300 Chinese S&T journals. Nevertheless, most of the SCI indexed Chinese journals do not perform well in terms of citation impact as measured by the Impact Factor. Take the data of 2011 for example, of the 114 Chinese journals indexed in the SCI, only four were in the first

quartile and 23 in the second of the corresponding subject categories of JCR 2011 (Liu, 2012).

The administrative structure of Chinese journals is special, and sometimes, confusing because of the involvement of both government agencies and the practical management by editorial boards. Administration at the national level is carried out by the General Administration of Press and Publication (GAPP) that is directly led by the State Council of China. At the provincial/regional level, the Administration of Press and Publication (APP) is responsible in each province or municipality. In addition to making regulations and policies relevant to journal publication and development, the GAPP is responsible for the approval of new journals and regular censorship; provincial APPs are responsible for administration and controls (including censorship) of local journals.

Practical management of Chinese academic journals is carried out by the editorial boards affiliated to research institutes, universities, and academic associations/societies. These institutions are affiliated to respective government agencies. Different governmental agencies are responsible for different sets of journals with different policies aiming at quality improvement with a special focus on international visibility. For example, at the national level are projects such as 'Journal Phalanx of China' of the GAPP, the 'Development Strategy Research for Competitive S&T Journals' of the Ministry of Science and Technology (MOST), and the 'Key Academic Specific Foundation' of the National Natural Science Foundation of China (NSFC). Years have passed since these projects were adopted, but the original targets of raising journal quality and international visibility have remained too far to reach.

In November 2013, in order to fasten the process towards international visibility of Chinese journals, six government agencies including the China Association for Science and Technology (CASST), the Ministry of Finance, the Ministry of Education (MOE), The State Press and Publication Administration (SPPA), the Chinese Academy of Sciences (CAS), and Chinese Academy of Engineering (CAE) jointly issued a unified standard of journal selection and funding: the International Impact Upgrading Plan for Chinese S&T Journals (abbreviated as CIU Plan). The CIU Plan is carried out in two steps. The objective of the first step is to raise the Journal Impact Factor (JIF) of a selected set of Chinese journals published in English to Quartile 1 and 2 of the Impact Factor in the Journal Citation Reports (JCR), by the end of the 12th Five-Year Plan (2011-2015), and to establish a journal set in the English language that can represent research frontiers or dominant fields of China, or in fields in which China does not yet have its own journals. The second step is to form a world top-journal set to which China has independent intellectual property rights by the year 2020.

Candidate journals must be in English and under the management of the above listed six government agencies. To ensure high-quality journals to be funded, the selection scheme combines bibliometric indicators, expert reviews, and a response by editorial boards. Journals being funded are classified into four categories, namely A, B, C and D. Those in categories A, B and C already have English version and are funded for three years. The funding amount in categories A, B, and C are respectively 2 million RMB or 322,092 US$, 1 million RMB (US$ 161,046), and 0.5 million RMB (US$ 85,230), respectively. Journals in category D are those that do not but will have an English edition; they receive 0.5 million RMB each. Of the nearly 5,300 scholarly journals in science and technology, only 76 are covered by the CIU Plan, among which 66 are in the categories of A, B, and C (Yao et al., 2014).

Journals receiving the largest funding are distributed among different Subject Categories and with different performances as measured by Journal Impact Factor (JIF) in the *Journal Citation Reports*. The rank of *Nano Research* is the highest whereas that of the *Journal of Zhejiang University-Science A* is the lowest. Questions arise such as: Are these journals selected because they outperform the rest of Chinese journals in the same subject category

based on the selection scheme mentioned above? How do they perform in comparison with their past, and their international counterparts?

Comparative studies between Chinese and international journals have been done before (Li, 2006; Zhou, et al., 2010; Jin & Leydesdorff, 2005; Zhou & Leydesdorff, 2007a, 2007b). Based on data of the *Journal Citation Reports* (*JCR*) of Thomson Reuters and the China Scientific and Technical Papers and Citations Database (CSTPCD) of the Institute of Scientific and Technological Information of China (ISTIC), Zhou and Leydesdorff (2007a, 2007b), for example, compared journal-journal citation relations from different perspectives, and found that international visibility of high-quality Chinese journals was low. These studies were based on data of ten or more years ago (i.e., *JCR* 2003 and 2004). The situation has changed given China's rapid development in science and technology and its increasing R&D investment during the last ten years (MOST, 2012; NBS, 2013). The CIU Plan further stimulated our interests in mapping an updated picture of the citation performance of Chinese journals in the international scholarly community. To highlight scholarly impact the current study mainly focuses on the citation impact environments of Chinese journals supported by the CIU Plan.

Methods and materials

We use routines developed by Leydesdorff & Cozzens (1992): aggregated journal-journal citation matrices of the environment of a seed journal can be harvested from *JCR* data. A seed journal is the one under investigation and acts as a starter to run the routines. Any journal indexed in the Science Citation Index (*SCI*) or Social Science Citation (*SSCI*) can be used as a seed. The relevant citation networks of the seed journal is determined by including all journals which cite or are cited by the seed journal to the extent of a contribution of (e.g.) 1% of its citation rate (He & Pao, 1986; Leydesdorff, 1986). By default the threshold is 1%, but this can be changed so as to include an appropriate number of journals in a local citation environment. For a network with too many journals, one may raise the threshold to reduce the size of the network, and vice versa.

Each journal in a network is represented by a node, which can be a circle or an ellipse in a Pajek map. The size of an ellipse is determined by the corresponding journal's contribution to the citing or citation impact environment in the year under investigation. The distinction of the vertical and horizontal size of the ellipse, informs the reader about the extent to which within-journal (self-) citations participate in the citation impact (Leydesdorff, 2007; Zhou & Leydesdorff, 2007). Note that within-journal citations can be author self-citations or citations among authors publishing in the same journal. Citation excluding journal self-citations can be considered as a measure of inter-journal communication.

In a citation impact environment, a journal's node size in the representation is determined by the logarithm of its contribution to the total number of citations in a local environment during the year under investigation. Citation counts are total of a journal during the current year; citation counts are combined for both the *SCI* and *SSCI*.

Many programs such as VOSviewer, Pajek, or Gephi can be used to visualize journal citation networks. In this study, we use Pajek because it serves the purpose of illustrating relative cited size of individual journals in local environments. Data of a citation impact environment can be imported into Pajek after being generated by the routines. The cosine between two vectors (Salton & McGill, 1983) is used to measure the similarity between the distributions for the various journals included in a citation environment (Leydesdorff, 2007). A visualized citation network showing strength of citation relations between journals in a local environment can thus be obtained.

Table 1. Journals to be investigated.

Journal Pair	*Journal Title*	*Country*	*Items in 2012*	*CIU Plan Category*	*JIF 2013*	*Rank in JIF*	*Quartile in Category*	*Category Name*
1	Chinese Science Bulletin	China	631	A	1.365	14/55	Q2	Multidisciplinary Sciences
	Science	USA	832		31.47	2/55	Q1	
2	Journal of Environmental Sciences-China	China	281	A	1.922	95/216	Q2	Environmental Sciences
	Environment International	USA	199		5.664	7/216	Q1	
3	Journal of Computational Mathematics	China	42	B	1.049	73/251	Q2	Mathematics, applied
	Foundations of Computational Mathematics	USA	23		2.152	13/251	Q1	
4	Acta Metallurgica Sinica	China	215	B	0.548	42/75	Q3	Metallurgy & Metallurgical Engineering
	Acta Materialia	USA	681		3.940	1/75	Q1	

In 2004, 71 Chinese journals were indexed in the *JCR*. Only a few journals satisfied the above three conditions; four journals were selected for the current study. For horizontal comparison, both Chinese and foreign journals must be in the same subject category of the *JCR*. Furthermore, the foreign journals do not have to be ranked first in the corresponding subject categories, but they should be in the first Quartile of Impact Factors and in the same subject category of the JCR as the selected Chinese journals. Table 1 lists journals satisfying the above conditions and will be used to study.

Results

Cited patterns of the selected journals will be investigated. The threshold is set at 1%, which means in a seed journal's citation environment, only journals contributing to 1% or more of the seed journal's total citations will be included. Due to the page limit of the ISSI 2015, only the results of the first two pairs of journals listed in Table 1 will be presented in detail. Conclusions and discussion, however, are based on the results of the four pairs of journals.

Chinese Science Bulletin versus Science

Chinese Science Bulletin. Only 10 journals contributed at least 1% of the total citation counts of *Chinese Science Bulletin* (*CSB*) in 2004, and these journals were all from China. In other words, visibility of *CSB* among foreign journals that were indexed in the *SCI*/*SSCI* was very low. As a multidisciplinary journal, citation impact of *CSB* was multidisciplinary with specific impacts in the geosciences, geology, and chemistry (Fig. 1a). In the citation impact environment of *CSB*, citation to *CSB* was highest even if within-journal citations were excluded. Within-journal citations of some Chinese journals took high proportions in their total citations, among which journals like *Acta Physica Sinca* and *Advances in Atmospheric*

Sciences were most obvious. In terms of Impact Factor, however, *Acta Geologica Sinica-English Edition* (2.150), *Science in China Series D – Earth Sciences* (0.909), *Acta Chimica Sinica* (0.895), and *Acta Petrologica Sinica* (0.805) performed relatively better than *CSB* (0.683) (Fig. 1a).

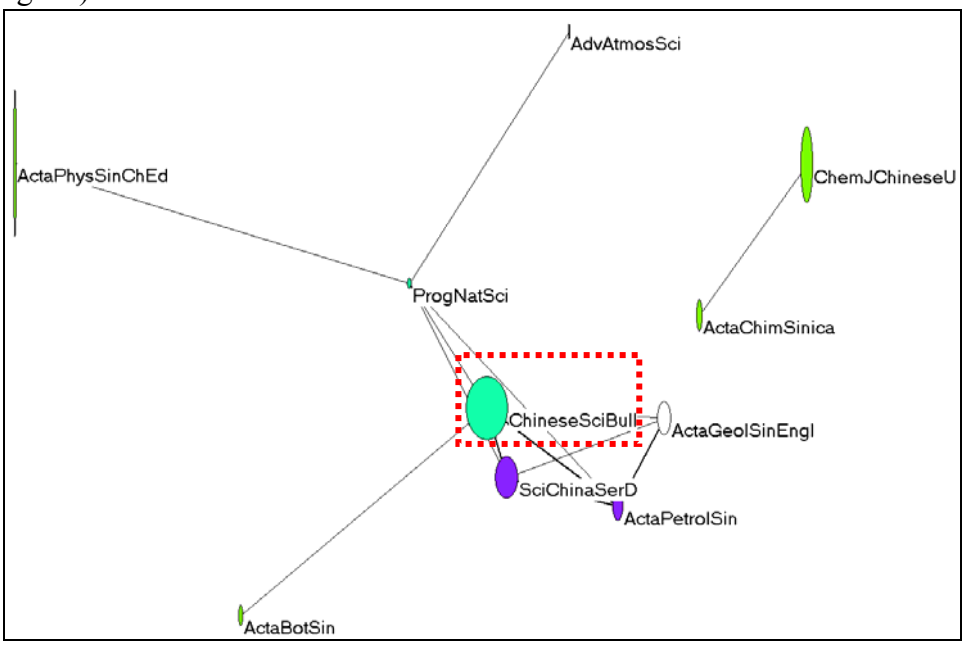

Figure 1a. Citation impact environment of *Chinese Science Bulletin* in 2004 (threshold = 1%, cosine ≥ 0.2).

Citation impact of *CSB* was enlarged to 13 journals in 2013 in terms of number of journals contributing at least 1% to the total citations of *CSB*. Most importantly, of these 13 journals eight were from other countries, which is a significant progress for Chinese journals in terms of citation impact on foreign journals compared to the year 2004. Within-journal citations contributed the most to the total citations of *CSB*. Citation impact of *CSB* on disciplines was similar to that in 2004 – involving multidisciplinary areas, geosciences, geology, and chemistry (Fig. 1b).

Impact Factor value of *CSB* were increased from 0.683 in 2004 to 1.365 in 2013.With the addition of foreign journals in the citation impact environment of *CSB*, journals with the highest citation impact is no longer *CSB* itself as in the year 2004; but instead, foreign journals such as the *Journal of Geophysical Research*, *Lithos*, and *Precambrian Research*, take the lead. In other words, in the citation impact environment of the Chinese journal *CSB*, citation impact of foreign journals was higher than that of Chinese journals. In terms of within-journal citations, *Journal of Geophysical Research* and *PLoS ONE* are most pronouncedly present. The heavy within-journal citations made the node of *PLoS ONE* a vertical line - citations from other journals in this environment were almost negligible (Fig. 1b).

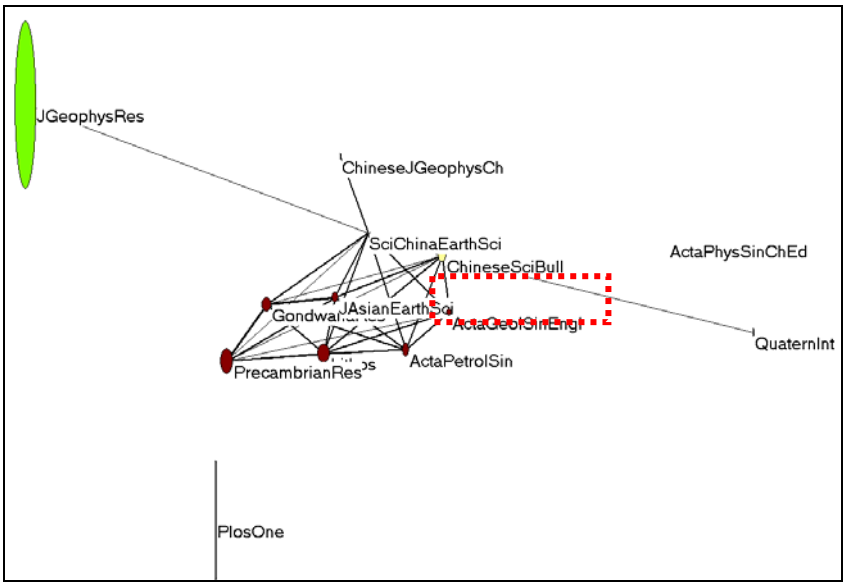

Figure 1b. Citation impact environment of *Chinese Science Bulletin* in 2013 (threshold = 1%, cosine ≥ 0.2).

Science. The citation impact network of *Science* was very much focused in 2004: Three journals contributed mostly to the citations of *Science*, and none of these three was from China. Except within journal citations of *Science*, the other two top contributors were *Journal of Biological Chemistry* (*JBC*) and *Proceedings of the National Academy of Sciences of the United States of America* (*PNAS*) (Fig. 2a). Unlike the multidisciplinary journal *Chinese Science Bulletin* with distinct impact on geosciences and geology, citation impact of *Science* was more in biochemistry, in addition to impact in multiple disciplines. In terms of citation impact in the citation environment of *Science*, all the three journals are high with *JBC* having the highest impact. When within-journal citations are excluded, however, *PNAS* performed the best, and *Science* came next. In other words, compared with *JBC, PNAS* and *Science* had higher visibility in other journals. The distinct performance of citation impact of *JBC* and *PNAS* might largely be attributed to their high volumes of publications. In 2003, publications of *JBC*, *PNAS*, and *Science* were 6,585, 3084, and 845, respectively. In terms of average citation impact measured by the Impact Factor, however, *Science* performed the best (IF = 31.85), and followed by *PNAS* (IF = 10.452) and *JBC* (IF = 6.355).

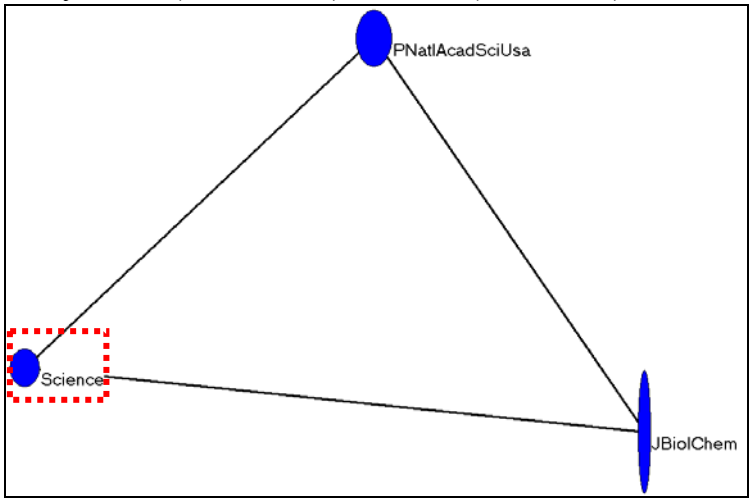

Figure 2a. Citation impact environment of *Science* in 2004 (threshold = 1%, cosine ≥ 0.2).

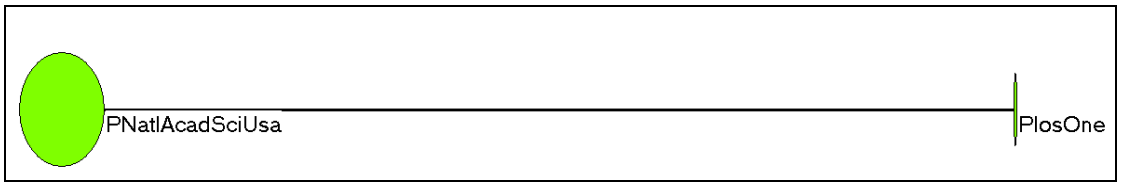

Figure 2b. Citation impact environment of *Science* in 2013 (threshold = 1%, cosine ≥ 0.2).

In the citation environment of *Science* in 2013, the percentage of within-journal citations of *Science* declined to less than 1% of its total citations. As a result, *Science* did not appear in its citation impact environment. In other words, the citation impact of *Science* was even more concentrated than in 2004. Impact Factor value of *Science* had increased from 31.853 in 2004 to 34.463 in 2013. Again, no Chinese journals appeared in this environment. *Science* was mostly cited by two multidisciplinary journals – *PNAS* and *PLoS ONE*, implying the multidisciplinary citation impact of *Science* with no distinct field emphasis like the situation in 2004. The high total citation impact of *PNAS* and *PLoS ONE* can be partially attributed to their high volume of publications: In 2013 *PLoS ONE* published 31,496 papers, which was eight times of that of the *PNAS* (3,901) and 37 times of that of *Science* (841). In terms of average citation impact (i.e., JIF), however, *Science* performed the best (31.477), and *PNAS* (9.809) came next. Average citation impact of *PLoS ONE* was the lowest (3.534), and furthermore, with heavy within-journal citations (Fig. 2b).

In summary, *Science* is widely cited in many journals in a range of different disciplines. When the threshold is set at 1%, however, only two or three journals are left in the citation impact environment of *Science*. In other words, these journals cited *Science* more intensively than other journals.

Journal of Environmental Sciences-China versus Environment International

Journal of Environmental Sciences-China. By 2004, the *Journal of Environmental Sciences-China* (*JES*) only received in total 193 citations of which 27 within-journal citations contributed the most; the other citations were scattered among journals in the environmental sciences, geosciences, chemistry, and biosciences. Although journals contributing 1% or more to *JES*'s total citation were mostly foreign and were as many as 26, these journals cited *JES* for only two or three times. In other words, except within-journal citations, there were no other journals citing *JES* systematically. Impact Factors of journals citing the *JES* were also low, between the highest of *Applied Catalysis B- Environmental* (4.042) citing *JES* six times in total and the lowest (0.172) of *Journal of the Chemical Society of Pakistan* citing *JES* four times (Fig. 3a). In other words, the *JES* had very low impact on other journals, citation impact in terms of Impact Factors of those citing *JES* occasionally was also very low.

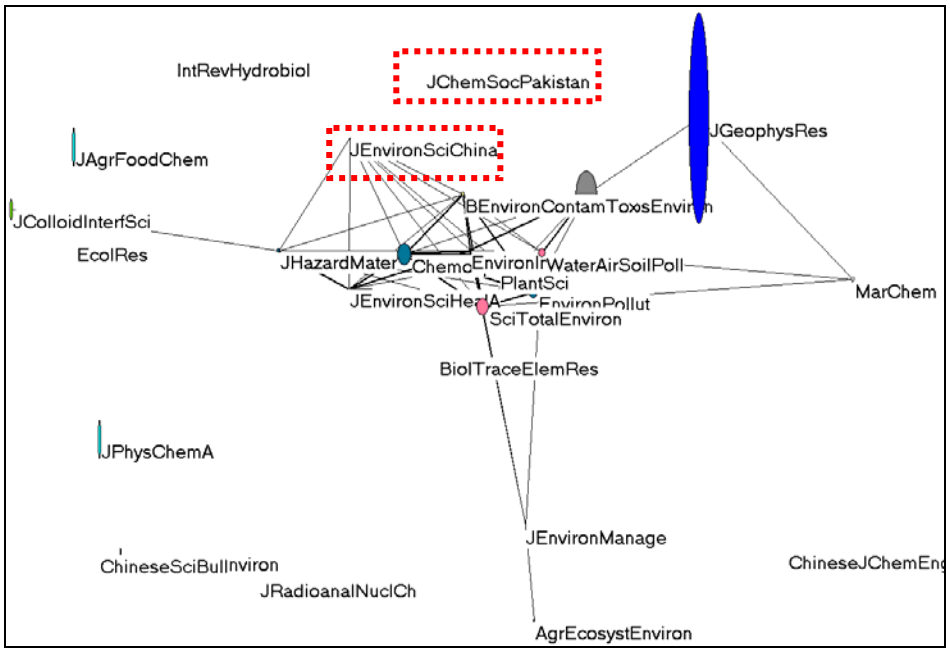

Figure 3a. Citation impact environment of *Journal of Environmental Sciences-China* in 2004 (threshold = 1%, cosine ≥ 0.2).

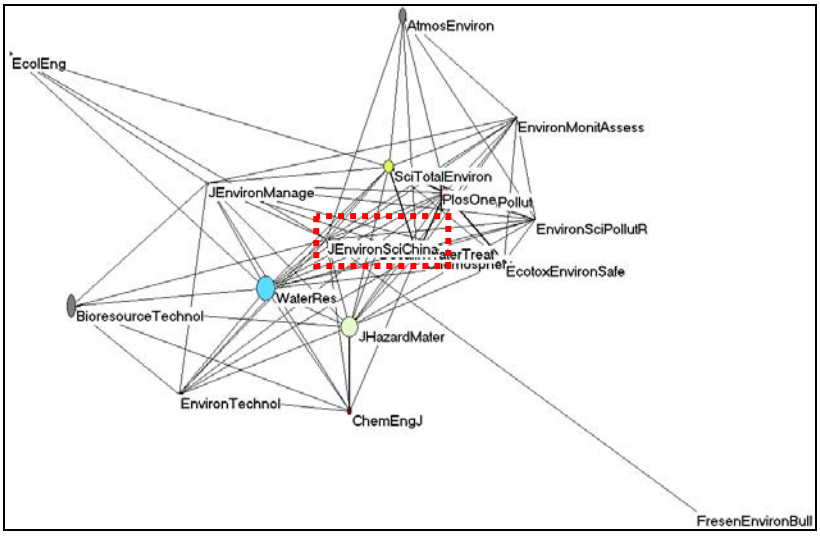

Figure 3b. Citation impact environment of *Journal of Environmental Sciences-China* in 2013 (threshold = 1%, cosine ≥ 0.2).

Performance of *JES* had been improved significantly in 2013, in addition to a large increase of the Impact Factor value from 0.254 in 2004 to 1.922 in 2013. Compared with the citation impact environment in 2004, the number of journals citing *JES* was less (i.e., 18 journals) but each contributed more citations. Journals citing *JES* were mostly foreign, although within-journal citations were still the first contributor. Instead of being cited occasionally like it was ten years ago, *JES* received more focused citation from other journals, and citation impact was more focused instead of scattering among different disciplines. For example, the foreign journal *Environmental Science and Pollution Research* contributed 28% of *JES*'s total citation by 2013, but did not appear in the citation environment of *JES* in 2004. Furthermore, journals citing *JES* had higher citation impact than those in 2004 ranging from 0.527 to 5.323. Citation relations among journals in the citation impact environment of *JES* formed closer relationship and thus interlinked with one another (Fig. 3b).

Environment International. In 2004, the citation impact of the *Environment International* was concentrated on environmental science. The journal contributing most to the total citations of *Environment International* was *Environmental Science & Technology*. Within-journal citations played much less a role than that of the *Journal of Environmental Sciences-China*. Impact Factors of journals citing the *Environment International* were much higher than those of the *Environment International*. For example, the Impact Factor of *Environmental Science & Technology*, the largest citation contributor to the citation impact of *Environment International*, was 3.557, which was even higher than that of *Environment International* (2.335). In other words, the *Environment International* had significant citation impact on high-quality journals. In the citation environment of *Environment International*, its citation impact was negligible whereas that of *Environmental Science & Technology* was highest (Fig. 4a).

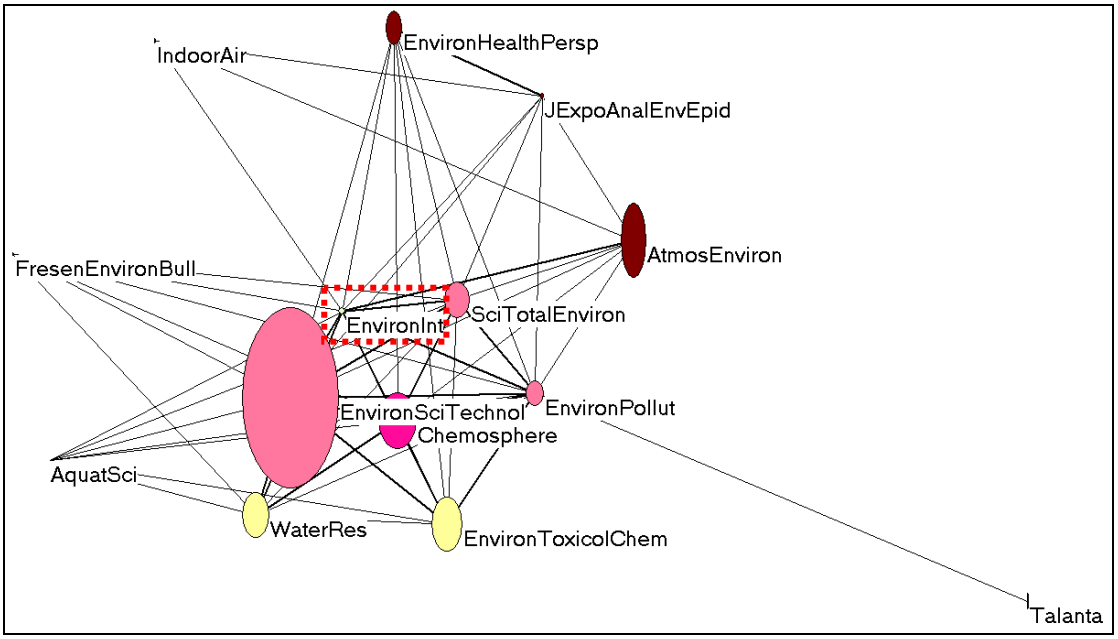

Figure 4a. Citation impact environment of *Environment International* in 2004 (threshold = 1%, cosine ≥ 0.2).

From 2004 to 2013, the Impact Factor value of *Environment International* increased from 2.335 to 5.664. Citation impact on number of journals extended from 14 to 18. Journals citing *Environment International* most frequently were *Chemosphere* (IF = 3.499) and *Science of the Total Environment* (IF = 3.163). Impact Factors of journals contributing at least 1% to the citation of *Environment International* were ranging from 1.679 to 5.664. In the citation impact environment of *Environment International*, the citation impact of *Environment International* itself became visible whereas that of *Environmental Science & Technology* was still the highest (Fig. 4b).

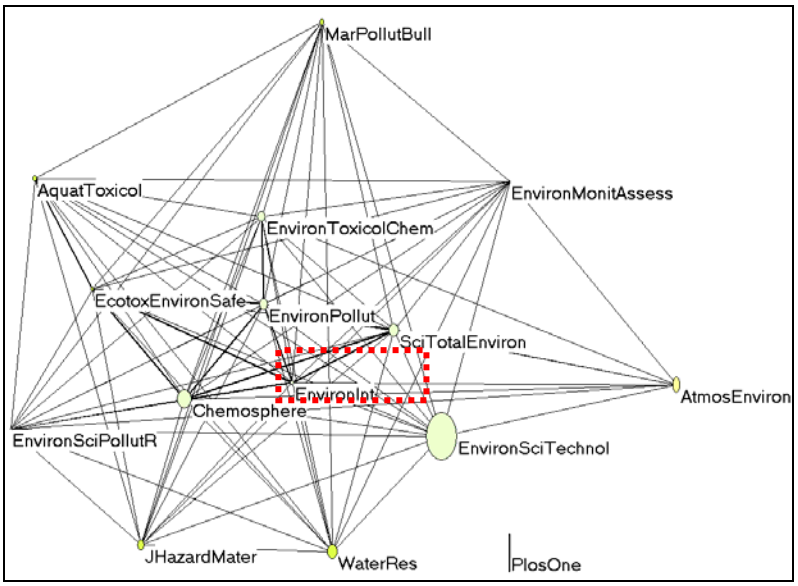

Figure 4b. Citation impact environment of *Environment International* in 2013 (threshold = 1%, cosine ≥ 0.2).

Conclusions and discussion

We have carried out a comparative study on journal citation impact between four pairs of journals in multiple disciplines, environmental sciences, applied mathematics, as well as metallurgy and metallurgical engineering. The four Chinese journals are selected because of additional funding by the Chinese CIU Plan in categories A and B. In Category A are *Chinese Science Bulletin* (*CSB*) and *Journal of Environmental Sciences-China* (*JES*), and in Category B are *Journal of Computational Mathematics* (*JCM*) and *Acta Metallurgica Sinica* (*AMS*). Leading foreign journals were used as matched pairs with the four Chinese journals. These are *Science*, *Environment International*, *Foundations of Computational Mathematics*, and *Acta Materialia* respectively.

International visibility of *CSB* was very low in 2004 although being indexed in the SCI and with a citation impact only on Chinese journals. The situation has been improved ten years later in 2013. More foreign journals cited *CSB*, but this may be by Chinese authors. Citation impact measured by Impact Factor of *CSB* has also been increased, but is still a long distance away from the best. Compared with *CSB*, *Science* has citation impact on higher quality journals measured by Impact Factor, and was cited more intensively with just two or three multidisciplinary journals contributing most to the citation counts of *Science*. By the year 2013, most citations to *Science* were from two multidisciplinary journals - *Proceedings of the National Academy of Sciences of the United States of America* (*PNAS*) and *PLoS ONE*.

Within-journal citations were the first contributor of *CSB*, whereas this is not the case for *Science*. As a multidisciplinary journal, *CSB* did not appear in the citation impact environment of *Science*, implying a weak contribution of references in *CSB* to *Science*. On the other hand, the absence of *Science* in the citation environment of *CSB* implies that *CSB* has a long way to go before coming into the sight of authors publishing in *Science*.

Although being cited by foreign journals in 2004, citations received by the *Journal of Environmental Sciences-China* (*JES*) remained occasional. The situation has improved ten years later in 2013. Citation impact of *JES* has been increased significantly, but is still far behind that of the leading foreign journals in the same subject category. Compared with the *JES*, *Environment International* has citation impact on journals with higher quality measured by Impact Factor. The citation impact of the *Environment International* was more focused: Fewer journals contributing to 1% of the total citations of *Environment International* but each

journal contributed more; within-journal citations of *Environment International* were less significant to total citation counts than that of the *JES*.

Similar to the *Journal of Environmental Sciences-China*, the citation impact of the *Journal of Computational Mathematics* (*JCM*) was very low and was distributed among many journals in 2004. The situation was improved in 2013 with citation impact of the *JCM* being increased significantly, but still far behind that of leading foreign journals in the same subject category. The starting point of *Foundations of Computational Mathematics* was not high in 2004 because of a short history of being indexed in the *SCI*. Compared with the *JCM*, *Foundations of Computational Mathematics* (*FCM*) has citation impact on journals with higher quality measured by Impact Factor. Citation impact of *FCM* is also more focused: Fewer journals contributing to 1% of the total citations. Within-journal citations of *Foundations of Computational Mathematics* contributed less to its total citation than that of the *JCM*.

In 2004 the citation impact of *Acta Metallurgica Sinica* (*AMS*) was low and scattered among many journals, most of which were from China. Within-journal citation was rather heavy and became even heavier in 2013. Citation impact had been improved slightly in 2013 but was still very low. Furthermore, journal quality measured by Impact Factors of journals citing *AMS* had not been improved during 2004-2013. In contrast to *AMS*, *Acta Materialia* was able to generate citation impact in journals with higher quality measured by Impact Factors. Similar to *Acta Metallurgica Sinica*, within-journal citations of *Acta Materialia* also contributed first to its own total citation.

In general, the citation impact of leading Chinese journals has improved during the period 2004-2013, but there is still a long distance to catch up with leading foreign journals. Although being funded under Category B in the CIU Plan, *Journal of Computational Mathematics* performed as well as the other two in a higher rank of category – Category A of the CIU Plan. Being funded at the same level under Category B, the *Journal of Computational Mathematics* performed better than *Acta Metallurgica Sinica*. Foreign journals of higher Impact Factor are more intensively cited than Chinese journals at a given threshold (e.g., 1%) in the same subject category of the JCR, which may imply a positive correlation between journal quality and citation intensity in a specialist citation environment. In other words, journals with higher Impact Factor in the same subject category may be cited more intensively, or by a relatively stable number of journals in their citation impact environment across different years.

Abstract
The study explores the citedness of research data, its distribution over time and how it is related to the availability of a DOI (Digital Object Identifier) in Thomson Reuters' DCI (Data Citation Index). We investigate if cited research data "impact" the (social) web, reflected by altmetrics scores, and if there is any relationship between the number of citations and the sum of altmetrics scores from various social media-platforms. Three tools are used to collect and compare altmetrics scores, i.e. PlumX, ImpactStory, and Altmetric.com. In terms of coverage, PlumX is the most helpful altmetrics tool. While research data remain mostly uncited (about 85%), there has been a growing trend in citing data sets published since 2007. Surprisingly, the percentage of the number of cited research data with a DOI in DCI has decreased in the last years. Only nine repositories account for research data with DOIs and two or more citations. The number of cited research data with altmetrics scores is even lower (4 to 9%) but shows a higher coverage of research data from the last decade. However, no correlation between the number of citations and the total number of altmetrics scores is observable. Certain data types (i.e. survey, aggregate data, and sequence data) are more often cited and receive higher altmetrics scores.

Conference Topic
Altmetrics, Citation and co-citation analysis

Introduction
Recently, data citations have gained momentum (Piwowar & Chapman, 2010; Borgman, 2012; Torres-Salinas, Martín-Martín, & Fuente-Gutiérrez, 2013). This is reflected, among others, in the development of data-level metrics (DLM), an initiative driven by PLOS, UC3 and DataONE[1], to track and measure activity on research data, and the recent announcement of CERN to provide DOIs for each dataset they share through their novel Open Data portal[2]. Data citations are citations included in the reference list of a publication that formally cite either the data that led to a research result or a data paper[3]. Thereby, data citations indicate the influence and reuse of data in scientific publications.
First studies on data citations showed that certain well-curated data sets receive far more citations or mentions in other articles than many traditional articles (Belter, 2014). Citations, however, are used as a proxy for the assessment of impact primarily in the "publish or perish" community; to consider other disciplines and stakeholders of research, such as industry, government and academia, and in a much broader sense, the society as a whole, altmetrics

[3] http://www.asis.org/Bulletin/Jun-12/JunJul12_MayernikDataCitation.html

(i.e. social media-based indicators) are emerging as a useful instrument to assess the "societal" impact of research data or at least to provide a more complete picture of research uptake, besides more traditional usage and citation metrics (Bornman, 2014; Konkiel, 2013). Previous work on altmetrics for research data has mainly focused on motivations for data sharing, creating reliable data metrics and effective reward systems (Costas et al., 2012).

This study contributes to the research on data citations in describing their characteristics as well as their impact in terms of citations and altmetrics scores. Specifically, we tackle the following research questions:

- How often are research data cited? Which and how many of these have a DOI? From which repositories do research data originate?
- What are the characteristics of the most cited research data? Which data types and disciplines are the most cited? How does citedness evolve over time?
- To what extent are cited research data visible on various altmetrics channels? Are there any differences between the tools used for altmetrics scores aggregation?

Data sources

On the Web, a large number of data repositories are available to store and disseminate research data. The Thomson Reuters Data Citation Index (DCI), launched in 2012, provides an index of high-quality research data from various data repositories across disciplines and around the world. It enables search, exploration and bibliometric analysis of research data through a single point of access, i.e. the Web of Science (Torres-Salinas, Martín-Martín & Fuente- Gutiérrez, 2013). The selection criteria are mainly based on the reputation and characteristics of the repositories[4]. Three document types are available in the DCI: data set, data study, and repository. The document type "repository" can distort bibliometric analyses, because repositories are mainly considered as a source, but not as a document type.

First coverage and citation analyses of the DCI have been performed April-June 2013 by the EC3 bibliometrics group of Granada (Torres-Salinas, Jimenez-Contreras & Robinson-Garcia, 2014; Torres-Salinas, Robinson-Garcia & Cabezas-Clavijo, 2013). They found that data is highly skewed: Science areas accounted for almost 80% of records in the database and four repositories contained 75% of all the records in the database; 88% of all records remained uncited. In Science, Engineering and Technology citations are concentrated among datasets, whereas in the Social Sciences and Arts & Humanities, citations often refer to data studies.

Since these first analyses, DCI has been constantly growing, now indexing nearly two million records from high-quality repositories around the world. One of the most important enhancements of the DCI has undoubtedly been the inclusion of "figshare[5]" as new data source which led to an increase of almost a half million of data sets and 40.000 data studies (i.e. about one fourth of the total coverage in the database).

Gathering altmetrics data is quite laborious since they are spread over a variety of social media platforms which each offer different applications programming interfaces (APIs). Tools, which collect and aggregate these altmetrics data come in handy and are now fighting for market shares since also large publishers increasingly display altmetrics for articles (e.g., Wiley[6]). There are currently three big altmetrics data providers: ImpactStory[7], Altmetric.com, and PlumX[8]. Whereas Altmetrics.com and PlumX focus more on gathering and providing

[4] http://thomsonreuters.com/data-citation-index, http://thomsonreuters.com/products/ip-science/04_037/dci-selection-essay.pdf
[5] http://figshare.com

[7] https://impactstory.org
[8] https://plu.mx

data for institutions (e.g., publishers, libraries, or universities), ImpactStory's target group is the individual researcher who wants to include altmetrics information in her CV.

ImpactStory is a web-based tool, which works with individually assigned permanent identifiers (such as DOIs, URLs, PubMed IDs) or links to ORCID, Figshare, Publons, Slideshare, or Github to auto-import new research outputs like e.g. papers, data sets, slides. Altmetric scores from a large range of social media-platforms, including Twitter, Facebook, Mendeley, Figshare, Google+, and Wikipedia[9], can be downloaded as .json or .csv (as far as original data providers allow data sharing). With Altmetric.com, users can search within a variety of social media-platforms (e.g., Twitter, Facebook, Google+, or 8,000 blogs[10]) for keywords as well as for permanent identifiers (e.g., DOIs, arXiv IDs, RePEc identifiers, handles, or PubMed IDs). Queries can be restricted to certain dates, journals, publishers, social media-platforms, and Medline Subject Headings. The search results can be downloaded as .csv from the Altmetric Explorer (web-based application) or via the API. Plum Analytics or Plum X (the fee-based altmetrics dashboard) offers article-level metrics for so-called artifacts, which include articles, audios, videos, book chapters, or clinical trials[11]. Plum Analytics works with ORCID and other user IDs (e.g., from YouTube, Slideshare) as well as with DOIs, ISBNs, PubMed-IDs, patent numbers, and URLs. Because of its collaboration with EBSCO, Plum Analytics can provide statistics on the usage of articles and other artifacts (e.g., views to or downloads of html pages or pdfs), but also on, amongst others, Mendeley readers, GitHub forks, Facebook comments, and YouTube subscribers.

Methodology

We used DCI to retrieve the records of cited research data. All items published in the last 5.5 decades (1960-9, 1970-9, 1980-9, 1990-9, 2000-9, and 2010-4) with two or more citations (Sample 1, n=10,934 records) were downloaded and analysed. The criterion of having at least two citations is based on an operational reason (reduction of the number of items) as well as on a conceptual reason (to avoid self-citations). The following metadata fields were used in the analysis: available DOI or URL, document type, source, research area, publication year, data type, number of citations and ORCID availability[12]. The citedness in the database was computed for each decade considered in this study and investigated in detail for each year since 2000. We then analysed the distribution of document types, data types, sources and research areas with respect to the availability or non-availability of DOIs reported by DCI.

All research data with two or more citations and with an available DOI (n=2,907 items) were analysed with PlumX, ImpactStory, and Altmetric.com and their coverage on social media platforms and the altmetric scores was compared. All other items with 2 or more citations and an available URL (n=8,027) were also analysed in PlumX, the only tool enabling analyses based on URLs, and the results were compared with the ones obtained for items with a DOI. We also analysed the distribution of document types, data types, sources and research areas for all research data with 2 or more citations and at least one altmetric score (sample 2; n=301 items) with respect to the availability or non-availability of the permanent identifier DOI reported by DCI (items with DOI and URL or items with URL only).

[9] http://feedback.impactstory.org/knowledgebase/articles/367139-what-data-do-you-include-on-profiles
[10] http://support.altmetric.com/knowledgebase/articles/83335-which-data-sources-does-altmetric-track
[11] http://www.plumanalytics.com/metrics.html
[12] The DCI field "data type" was manually merged to more general categories; e.g. "survey data in social sciences" was merged with the category "survey data".

Results and discussion

General Results

Table 1 gives an overview of the general results obtained in this study. The analysis revealed a high uncitedness of research data, which corresponds to the findings of Torres-Salinas, Martin-Martin and Fuente-Gutiérrez (2013). A more detailed analysis for each year (see Table 2) shows, however, that the citedness is comparatively higher for research data published in recent years (published after 2007) although the citation window is shorter.

Table 2. Evolution of uncitedness in DCI in the last 14 years.

PY	*Items*	*uncited*	*% uncited*
2000	28282	18152	64.18%
2001	36397	25367	69.70%
2002	64781	51464	79.44%
2003	115997	93538	80.64%
2004	141065	122802	87.05%
2005	212781	178146	83.72%
2006	299443	275216	91.91%
2007	362405	333136	91.92%
2008	398931	364236	91.30%
2009	435941	394099	90.40%
2010	390957	349623	89.43%
2011	270932	224790	82.97%
2012	492534	428752	87.05%
2013	448489	386507	86.18%
2014	24756	19556	78.99%

The results also show a very low percentage of altmetrics scores available for research data with two or more citations (see Table 1). But, two different trends can be observed: the percentage of data with DOI referred to on social media-platforms is steadily increasing while the percentage of data with URL only is steadily decreasing in the same time frame.

The percentage of research data with altmetrics scores in PlumX, the tool with the highest average in this study, is lower than expected (ranging between 4 and 9%) but actually has doubled for data published in the last decades, which confirms the interest in younger research data and an increase in social media activity of the scientific community in recent years.

Table 3. Overview on citation distribution of Sample 1 (n=10,934 items).

items with at least 2 citations	*Document Type*	*# items*	*Total Citations*	*Mean Citations*	*Maximum Citations*	*Standard Deviation*	*Variance*

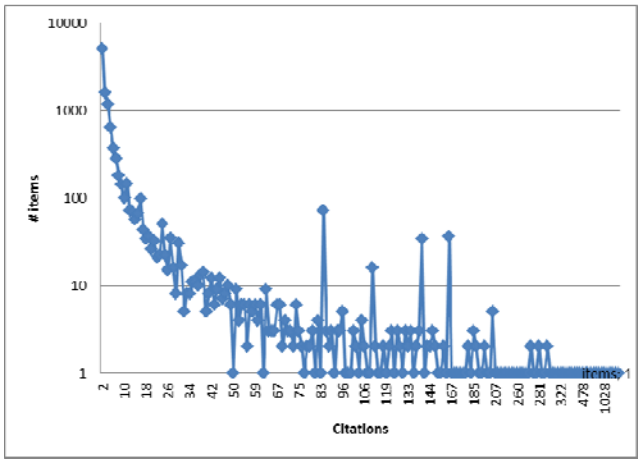

Figure 1. Citation distribution of Sample 1 (logarithmic scale).

Results for Sample 1

Table 3 shows the citation distribution of Sample 1 (10,934 items with at least two citations in DCI) for items with DOI or URL only separated according to the three main DCI document types (data set, data study, and repository[13]). The results reveal that almost half of the data studies have a DOI (48.9%) but only few data sets do so. Data studies are on average more often cited than data sets (17.5 vs. 3.2 citations per item), and data studies with a DOI attract more citations (mean values) than those with a URL (20 vs. 14 citations per item).

There were only few repositories (51) in the data set; it is the document type, which attracts the most citations per item. This finding is in line with the results of Belter (2014) who also found aggregated data sets – Belter calls them "global-level data sets" – to be more cited. However, such citing behaviour has a negative side effect on repository content (i.e., the single data sets) since it is not properly attributed in favour of citing the repository as a whole.

The high values of the standard deviation and variance illustrate the skewness of the citation distribution (see Figure 1). Almost half of the research data (4,974 items; 45.5%) have only two citations. Six items, two repositories and four data studies, from different decades (PY=1981, 1984, 1995, 2002, 2011, and 1998, sorted by descending number of citations) had more than 1,000 citations and account for almost 30% of the total number of citations.

[13] Table 3 includes repositories as document type to illustrate the citation volume in DCI.

Table 4 shows the top 10 repositories by the number of items. Considering the number of citations, there are three other repositories which account for more than 1,000 citations each: Manitoba Centre for Health Policy Population Health Research Data Repository (29 items; 1,631 citations), CHILDES - Child Language Data Exchange System (1 item; 3,082 citations), and World Values Survey (1 item; 3,193 citations). Interestingly, although "figshare" accounts for almost 25% of the DCI, no item from "figshare" was cited at least twice in DCI. We also noted that the categorization of "figshare" items is missing. All items are assigned to the Web of Science category (WC) "Multidisciplinary Sciences" or the Research Area (SU) "Science & Technology/Other Topics" preventing detailed topic-based citation analyses. Furthermore, only nine items from Sample 1 were related to an ORCID, three data sets with a DOI, and three data sets and data studies with a URL.

Table 4. Analysis of Sample 1 by sources (repositories) (n=10,934 items).

Sources (with DOI)	*# items*	*# citations*	*Sources (with URL)*	*# items*	*# citations*
Inter-university Consortium for Political and Social Research	2530	53041	miRBase	3456	10209

GigaDB	2	5	nmrshiftdb2	219	445
			Finnish Social Science Data Archive	183	913

Considering their origin, considerable differences were reported in Sample 1 for items with or without a DOI (see Table 4). All twice or more frequently cited research data with a DOI are archived in nine repositories, while 92 repositories account for research data without a DOI.

Table 5 shows that there are big differences between the most cited data types when considering research data with a DOI or with a URL. Survey data, aggregate data, and clinical data are the most cited ones of the first group (with a DOI), while sequence data and numerical and individual level data are the most cited data types of the second group (with a URL). Apart from survey data, there is no overlap in the top 10 data types indexed in DCI. Similar results were obtained when considering data sets and data studies separately.

Disciplinary differences become apparent in the citations of DOIs and URLs as well as in the use of certain document types. As shown in Table 6 it is more common to refer to data studies via DOIs in the Social Sciences than in the Natural and Life Sciences, where the use of URLs for both data studies and data sets is more popular. Torres-Salinas, Jimenez-Contreras and Robinson-Garcia (2014) also report that citations in Science, Engineering and Technology citations are concentrated on data sets, whereas the majority of citations in the Social Sciences and Arts & Humanities refer to data studies. Table 6 suggests that these differences could be related to the availability of a DOI.

Table 5. Analysis of Sample 1 by data types (manually merged), top 10 types (n=10,934 items).

Results for Sample 2

Sample 2 comprises all items from DCI satisfying the following criteria: two or more citations in DCI, a DOI or a URL and at least one altmetrics score in PlumX (n=301 items). Table 7 shows the general results for this sample. The total number of altmetrics scores is lower than the number of citations for all document types with or without a DOI. Furthermore, the mean altmetrics score is higher for data studies than for data sets.

Tables 8 and 9 show the distributions of data types and subject areas in this sample. Most data with DOI are survey data, aggregate data, event over transaction data, whereas sequence data and images are most often referred to via URL only (see Table 8). Microdata with DOI and spectra with URL only are the data types with the highest altmetrics scores per item. Concerning subject areas the results of Table 9 are very similar to the results of Table 6. Given the small sample size it is, however, notable that in some subject areas, e.g. Archaeology, research data receive more interest in social media (i.e. altmetrics scores), than via citations in traditional publications. This is confirmed by the missing correlation between citations and altmetrics scores for this sample (see Figure 2). Both cases clearly demonstrate that altmetrics can complement traditional impact evaluation. Nevertheless, coverage of

research data in social media is still low, e.g. from the nine repositories whose data studies and data sets were cited twice in DCI and had a DOI (see Table 4), only five items had altmetrics scores in PlumX, and only one DOI item of Sample 2 included an ORCID.

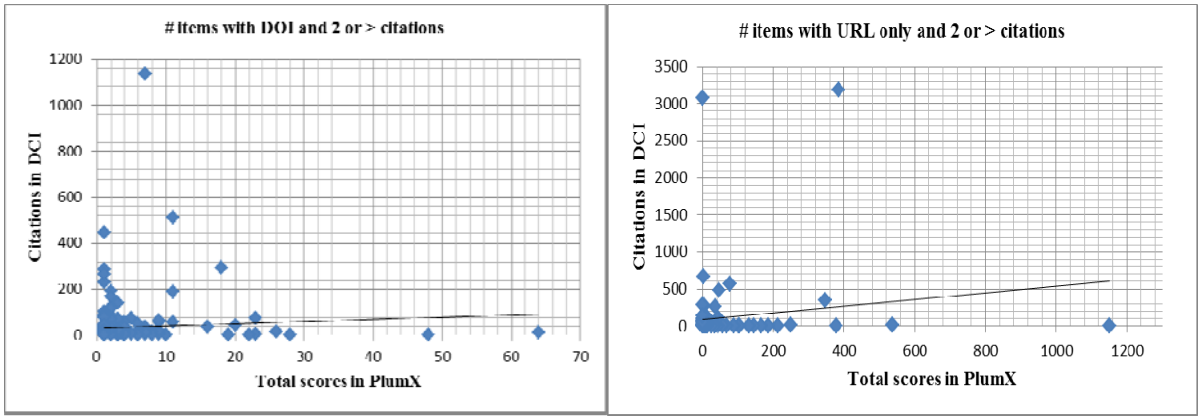

Figure 2. Citations DCI versus scores in PlumX for items with (left) and without (right).

Selected altmetrics scores and comparison of the results of three altmetrics tools

Table 10 shows the general results obtained in PlumX according to PlumX's aggregation groups (i.e., captures, social media, mentions, and usage) for all document types and with or without DOI. While DOIs for data sets seem to be important in order to get captures (mainly in Mendeley), a URL is sufficient for an inclusion in social media tools like Facebook, Twitter, etc.

The top 10 research data-DOIs attracting two or more citations and with at least one entry in PlumX are shown in Table 11. We can observe that cited research data attracts more citations than altmetrics scores, and that there is no correlation between highly cited and highly scored research data.

The comparison of altmetrics aggregation tools also revealed that ImpactStory only found Mendeley reader statistics for the research data: 78 DOIs had 257 readers. Additionally, ImpactStory found one other DOI in Wikipedia. ImpactStory found five items, which have

not been found by PlumX, although they all solely relied on Mendeley Data. The Mendeley data scores were exactly the same in PlumX and in ImpactStory. On the other hand, PlumX found 18 items that were not available via ImpactStory. These research data were distributed on social media platforms (mostly shares in Facebook) and one entry has been used via click on a Bitly-URL (Usage:Clicks:Bitly).The tool Altmetric.com found only one from 194 items.
As already reported in Jobmann et al. (2014), PlumX is the tool with the highest coverage of research products found on social media-platforms. Whereas Mendeley is well covered in ImpactStory, no other altmetrics score were found for the data set used in this study.

General Conclusions

Most of the research data still remain uncited (approx. 86%) and total altmetrics scores found via aggregation tools are even lower than the number of citations. However, research data published from 2007 onwards have gradually attracted more citations reflecting a bias towards more recent research data. No correlation between citation and altmetrics scores could be observed in a preliminary analysis: neither the most cited research data nor the most cited sources (repositories) received the highest scores in PlumX.
In the DCI, the availability of cited research data with a DOI is rather low. A reason for this may be the increase of available research data in recent years. Furthermore, the percentage of cited research data with a DOI has not increased as expected, which indicates that citations do not depend on this standard identifier in order to be processed by the DCI.

Nevertheless, data studies with a DOI attract more citations than those with a URL. Despite the low number of research data with a DOI in general, surprisingly, the DOI in cited research data has so far been more embraced in the Social Sciences than in the Natural Sciences.
Furthermore, our study shows an extremely low number of research data with two or more citations (only nine out of around 10,000) related to an ORCID. Only three of them had a DOI

likewise. This illustrates that we are still a far cry from the establishment of permanent identifiers and their optimal interconnectedness in a data source.

The low percentage of altmetrics scores for research data with two or more citations corroborates a threefold hypothesis: First, research data are either rarely published or not findable on social media-platforms, because DOIs or URLs are not used in references thus resulting in a low coverage of items. Second, research data are not widely shared on social media by the scientific community so far, which would result in higher altmetrics scores[14]. Third, the reliability of altmetrics aggregation tools is questionable as the results on the coverage of research data on social media-platforms differ widely between tools. However, the steadily increasing percentage of cited research data with DOI suggests that the adoption of this permanent identifier increases the online visibility of research data and inclusion in altmetrics tools (since they heavily rely on DOIs or other permanent identifiers for search).

A limitation of our study is that the results rely on the indexing quality of the DCI. Our analysis shows that the categorisation in DCI is problematic at times. This is illustrated by the fact that all items from figshare, which is one of the top providers of records, are categorised

into “Miscellaneous”. Also, the category “repository” is rather a source than a document type. Such incorrect assignments of data types and disciplines can easily lead to wrong interpretations in citation analyses. Furthermore, it should be taken into account that citation counts are not always traceable.

Finally, citations of research data should be studied in more detail. They certainly differ from citations of papers relying on these data with regard to dimension and purpose. For example, we found that entire repositories are proportionally more often cited than single data sets, which was confirmed by a former study (Belter, 2014). Therefore, it will be important to study single repositories (such as figshare) in more detail. It is crucial to further explore the real meaning and rationale of research data citations and how they depend on the nature and structure of the underlying research data, e.g., in terms of data curation and awarding of DOIs.

[14] figshare lately announced a deal with Altmetric.com which might increase the visibility of altmetrics with respect to data sharing: http://figshare.com/blog/The_figshare_top_10_of_2014_according_to_altmetric/142

Also, little is known about how data citations complement and differ from data sharing and data usage activities as well as altmetrics.

Stopped Sum Models for Citation Data

Abstract
It is important to identify the most appropriate statistical model for citation data in order to maximise the power of future analyses as well as to shed light on the processes that drive citations. This article assesses stopped sum models and compares them with two previously used models, the discretised lognormal and negative binomial distributions using the Akaike Information Criterion (AIC). Based upon data from 20 Scopus categories, some of the stopped sum models had lower AIC values than the discretised lognormal models, which were otherwise the best. However, very large standard errors were produced for some of these stopped sum models, indicating the imprecision of the estimates and the impracticality of the approach. Hence, although stopped sum models show some promise for citation analysis, they are only recommended when they fit better than the alternatives and have manageable standard errors. Nevertheless, their good fit to citation data gives evidence that two different, but related, processes drive citations.

Conference Topic
Citation and co-citation analysis

Introduction

Fitting statistical models to citation data is useful both to understand the citation process itself (de Solla Price, 1976) and to identify the factors that affect the citedness of academic papers (Bornmann, Schier, Marx, & Daniel, 2012; Didegah & Thelwall, 2013). For example, negative binomial regression previously has been used to analyse factors underlying patent citations (Maurseth & Verspagen, 2002). The choice of statistical model is not straightforward (Bookstein, 2001), however, because citation data is typically highly skewed (de Solla Price, 1976) with a heavy tail (i.e., with particularly many articles having high citation counts) which makes it difficult to identify and fit the best distribution (Clauset, Shalizi, & Newman, 2009). Nevertheless, it has recently been shown that the distribution of citations to articles from an individual Scopus category and year follows a hooked power law or a discretised lognormal distribution substantially better than a power law (Thelwall & Wilson, 2014a) and that, on this basis, (discretised) ordinary least squares regression on the log of the citation data, after adding 1 to cope with the problem of uncited articles, is applicable and is probably the best available regression method (Thelwall & Wilson, 2014b). It should be noted that although the data is well fitted by the discretised lognormal distribution, it should not be assumed that it was derived from that distribution, as models should not be regarded as literal descriptions of nature (Hesse, 1953). Moreover, it is useful to assess additional statistical models in case a more powerful model can be found as well as to shed light on the processes underlying citation, which are still far from fully understood. This paper investigates stopped sum models for citation data for the first time. These have very different underlying assumptions to the lognormal distribution but can result in similar shaped distributions.

Hence, should citation data fit them well, the results would have both practical and theoretical implications for citation analysis.

Stopped sum distributions

Stopped sum distributions were initially developed by Neyman to model the number of larvae in a field (Neyman, 1939). Neyman viewed the distribution of larvae as resulting from two population waves. The first 'parent' (or primary wave) distribution was followed by a distribution of 'offspring' (or secondary wave), whereby the numbers in the secondary wave would be dependent on the numbers in the primary wave; the overall population being the sum of the populations from the two waves (Johnson, Kemp, & Kotz, 2005, pp. 381–382). The two waves can have completely different statistical distributions. If, for example, the primary wave distribution is Poisson and the secondary wave distribution is negative binomial, the overall distribution is known as a *Poisson stopped sum negative binomial (NB) distribution*. Here stopped sum models are explored due to their potential to model citation data as two waves, the primary wave and secondary wave. Given that the overall number of citations that an article receives might come from a similar two waves process, the primary wave representing citations received shortly after a journal article has been published, and the secondary wave, perhaps overlapping with the first to some extent, representing the citations received as a result of scientists discovering an article because of its previous citations, either directly by following citations or indirectly because more cited articles are ranked more highly in some citation databases.

The stopped sum models for citation counts could also be appropriate if the two waves occurred simultaneously instead of sequentially. For example, for the Poisson stopped sum negative binomial model, one of the wave distributions follows the Poisson distribution and the other wave follows the negative binomial distribution at the same time.

The original model proposed by Neyman (1939) assumed that zero counts in the primary wave will automatically be followed by zero counts in the second wave. Hence, if X follows the Poisson stopped sum NB distribution, P(X=0) is just P(X=0) under the Poisson distribution.

For citation counts of one or more, the stopped sum assumes that this can only be a result of a non-zero citation in the primary wave. For example, a citation count of 3 can only arise as a result of one of the three combinations:

- 3 citations in the primary wave, 0 citation in the secondary wave; or
- 2 citations in the primary wave, 1 citation in the secondary wave; or
- 1 citation in the primary wave, 2 citations in the secondary wave.

The Poisson stopped sum NB distribution will therefore have the following probability mass function (p.m.f.):

$$P(X=y)=\begin{cases} e^{-\lambda} & if\ y=0 \\ \sum_{j=1}^{y}\frac{e^{-\lambda}\lambda^{j}}{j!} * \binom{y-j+\alpha-1}{\alpha-1} p^{\alpha}(1-p)^{y-j} & if\ y\geq 1, \text{and } p=\frac{\alpha}{\mu+\alpha} \end{cases}$$

The other stopped sum distributions that are considered include the NB stopped sum Poisson distribution:

$$P(X=y)=\begin{cases} p^{\alpha} & if\ y=0 \\ \sum_{j=1}^{y}\binom{y+\alpha-1}{\alpha-1}p^{\alpha}(1-p)^{y}*\frac{e^{-\lambda}\lambda^{y-j}}{(y-j)!} & if\ y\geq 1 \end{cases}$$

and the NB stopped sum NB distribution:

$$P(X=y)=\begin{cases} p^{\alpha} & if\ y=0 \\ \sum_{j=1}^{y}\binom{y+\alpha-1}{\alpha-1}p^{\alpha}(1-p)^{y}*\binom{y-j+\theta-1}{\theta-1}q^{\theta}(1-q)^{y-j} & if\ y\geq 1 \end{cases}$$

where $p=\frac{\alpha}{\mu+\alpha}$ in all cases.

The Poisson stopped sum Poisson distribution was considered but because very large AICs were obtained indicating a poor fit for citation data we do not discuss it further here.

Modified stopped sum distributions

In the study made by Neyman in 1939, the restriction of having zero counts in the primary wave resulting in zero counts in the secondary wave was necessary, but in the case of citation analysis, it is feasible that a zero citation count in the first population wave could be followed by a non-zero count in the second. This can occur due to the limitations of the citation database used to analyse the citations. For example, an article may be uncited in Scopus, but cited in Google Scholar, and its Google Scholar citations could attract new second wave citations. Hence a modified stopped sum is also considered, where, for example, 3 citations could arise from 0 citations in the primary wave and 3 citations in the secondary wave. The modified Poisson stopped sum NB distribution for this case has p.m.f.:

$$P(X=y)=\sum_{j=0}^{y}\frac{e^{-\lambda}\lambda^{j}}{j!}*\binom{y-j+\alpha-1}{\alpha-1}p^{\alpha}(1-p)^{y-j} \quad where\ y\geq 0 \text{ and } p=\frac{\alpha}{\mu+\alpha}$$

Using similar adjustments, the modified NB stopped sum Poisson distribution has p.m.f.:

$$P(X=y)=\sum_{j=0}^{y}\binom{y+\alpha-1}{\alpha-1}p^{\alpha}(1-p)^{y}*\frac{e^{-\lambda}\lambda^{y-j}}{(y-j)!} \quad where\ y\geq 0 \text{ and } p=\frac{\alpha}{\mu+\alpha}$$

Whilst the modified NB stopped sum NB distribution has p.m.f.:

$$P(X=y)=\sum_{j=1}^{y}\binom{y+\alpha-1}{\alpha-1}p^{\alpha}(1-p)^{y}*\binom{y-j+\theta-1}{\theta-1}q^{\theta}(1-q)^{y-j}$$

$$where\ y\geq 0 \text{ and } p=\frac{\alpha}{\mu+\alpha}$$

Note that the modified Poisson stopped sum Poisson distribution is equivalent to a Poisson distribution, and hence is not considered here.

Research Questions

1. Do stopped sum models fit citation count data better than discretised lognormal and negative binomial models?
2. If so, which stopped sum model produces the most consistent results?

Methods

Data from 20 different subject areas were selected from Scopus in order to assess the models for a wide range of different disciplines. This is important because citation patterns are known to vary considerably between disciplines. This data has previously been analysed in Thelwall and Wilson (2014). Each subject area is a single Scopus category and consists of all documents of type article that were published in 2004, giving ten years for the articles to attract citations.

Fitting statistical models

The models were fitted using the R software (R Core Team, 2014). The MASS package (Venables & Ripley, 2002) was used to fit the negative binomial distribution. As there are no known statistical packages readily available to model the proposed stopped sum distributions, the parameters of the distributions were estimated by maximum likelihood estimations methods. AIC is a commonly used statistic for model selection, the model with the lowest AIC usually being regarded as the model that best fits the data (Bozdogan, 2000).

$$AIC = -2 \times \log(L) + (2 \times p)$$

Hence the AIC may be regarded as a penalised version of the loglikelihood, where L is the likelihood of the model and p is the number of parameters estimated. For example, both the Poisson stopped sum NB and NB stopped sum Poisson will have p=3, as there is one parameter (λ) in the Poisson wave and two parameters (NB mean, μ and size, α) in the NB wave. The NB stopped sum NB model will have p=4 as two parameters (μ and α) are estimated in each of the NB waves. Whilst opinions differ, when selecting the 'best' model, it has been suggested that a difference of 6 between the AICs will be large enough to imply a significant difference between the models (Burnham & Anderson, 2003).

Standard errors

Standard errors were computed to reflect the precision with which the proposed statistical models estimate the relevant parameters (Dodge, 2003, p. 386). For the negative binomial models, standard errors were obtained directly from the model fitting software. For the discretised lognormal, the standard errors were obtained by bootstrapping.

For other models the standard errors were calculated using the Hessian matrix, which is the matrix of the second derivatives of the log-likelihood function. The Hessian matrix can also be obtained whilst estimating the parameters for the corresponding distributions using the optim function in R (R Core Team, 2014). Suppose that L represents the log-likelihood function of a stopped sum distribution with two parameters, say λ and μ, then the Hessian matrix is given by $\begin{pmatrix} \frac{\partial^2 L}{\partial \lambda^2} & \frac{\partial^2 L}{\partial \mu \partial \lambda} \\ \frac{\partial^2 L}{\partial \mu \partial \lambda} & \frac{\partial^2 L}{\partial \mu^2} \end{pmatrix}$, and the standard errors for λ and μ are calculated as the square root of the main diagonal of the inverse of the negative Hessian matrix (Ruppert, 2011, pp. 166–167). At 95% confidence interval can be computed by parameter estimate ± 1.96*standard error.

Results

The modified negative binomial stopped sum negative binomial distribution (NBNB) produced the lowest AIC for 13 out of 20 subjects. The next most successful models are the NB stopped sum NB and the discretised lognormal. The Poisson stopped sum NB and the modified NB stopped sum Poisson each fitted 'best' for only one subject (see Table 3 in Appendix).

Parameter estimates for stopped sum distributions

The estimated parameters for Tourism and Soil will be discussed for the proposed stopped sum distributions. These subjects were selected as they are examples of subjects, which return parameter estimates and errors for all the fitted distributions. From Table 1, when Tourism is fitted with the Poisson stopped sum NB model, one wave follows the Poisson distribution with mean, λ=3.22, whilst the other wave follows a negative binomial distribution with mean, μ=18.77 and size, α=0.57; thus the negative binomial wave has a variance of 640.19, since the negative binomial variance equals $\frac{\mu^2}{\alpha} + \mu$. However, when fitted with the NB stopped sum Poisson model, one wave follows a negative binomial distribution with mean, μ=21.53, size, α=0.98, and variance=495.77, whilst the other wave follows a Poisson distribution with mean, λ=0.01. The estimated means (μ) in both negative binomial waves are relatively larger than the estimated means (λ) in the Poisson waves, suggesting that the majority of citation counts for Tourism derive from the negative binomial wave. This supports the interpretation that the two waves occur simultaneously, instead of sequentially, as mentioned above. It is also interesting to note that the sum of the estimated means from the Poisson waves and negative binomial waves of these stopped sum models are approximately equal to the estimated mean when Tourism is fitted solely with the negative binomial model.

When fitted with the NB stopped sum NB model, the estimated mean for Tourism in the primary NB wave (13.48) is larger than that of the secondary NB wave (8.25), suggesting that the majority of citation counts for Tourism derive from the primary wave. Furthermore, the sum of the estimated means from the NB stopped sum NB model for Tourism is also approximately equal to the estimated mean when Tourism is fitted with the negative binomial model only.

Similar results were obtained for Soil. When citation counts for Soil are fitted with the Poisson stopped sum NB model and NB stopped sum Poisson model, the mean estimates in the NB waves are much larger than those of the Poisson waves, suggesting that the majority of citation counts from Soil derive from the NB wave. Moreover, the sum of the estimated means for the stopped sum models is approximately equal to the estimated mean for the negative binomial model only (which is 16.93).

Table 1. Estimated parameters for the NB, Poisson stopped sum NB, NB stopped sum Poisson and NB stopped sum NB models.

	Negative binomial		*Poisson stopped sum NB*			*NB stopped sum Poisson*			*NB stopped sum NB*			
Sub.	*mu*	*size*	λ_1	*mu2*	*size2*	*mu1*	*size1*	λ_2	*mu1*	*size1*	*mu2*	*size2*
Tour.	21.53	0.98	3.22	18.77	0.57	21.53	0.98	0.01	13.48	1.30	8.25	0.10
Soil	16.93	0.74	2.27	16.09	0.56	16.87	0.74	0.06	13.78	0.82	3.46	0.04

Table 2 compares estimated parameters for the NB distribution against those of the modified stopped sum distributions. For the modified versions, the estimates of the Poisson stopped sum NB are similar to those of the NB stopped sum Poisson distributions. Similarly to the stopped sum distributions, Tourism and Soil depends largely on the wave that derives from

the NB distribution, as the λ estimates are relatively lower than the mu estimates. Furthermore, the sum of the two mu estimates for the modified NB stopped sum NB distributions (21.533 and 16.931) are also similar to the estimates from the NB distribution.

Table 2. Estimated parameters for the NB, modified Poisson stopped sum NB, modified NB stopped sum Poisson and modified NB stopped sum NB models.

	Negative binomial		*Modified Poisson stopped sum NB*			*Modified NB stopped sum Poisson*			*Modified NB stopped sum NB*			
Subj.	*mu*	*size*	λ_1	*mu2*	*size2*	*mu1*	*size1*	λ_2	*mu1*	*size1*	*mu2*	*size2*
Tour.	21.53	0.98	1.41	20.12	0.75	20.12	0.75	1.41	14.75	0.35	6.79	1.17

Standard errors for stopped sum distributions

Figures 1 and 2 show the mean and size estimates for the primary and secondary waves of the modified NB stopped sum NB distributions. Visual, Literature and Rehab were excluded as standard errors could not be obtained as a result of a singular hessian matrix.

Although the modified NB stopped sum NB distribution gave the lowest AIC, the model produced very large standard errors, resulting in large confidence intervals, as shown in Figures 1 and 2, indicating that this modified NB stopped sum NB model is impractical. This result could possibly be due to the nature of citations, which differs from that of the larvae studied by Neyman. With larvae and their offspring it is clear which wave of population a larvae originates from, this is not the case with citations – usually it will be far from clear cut which wave a given citation might belong to, which in turn leads to difficulty estimating the mean number of citations for that wave, and hence the large associated standard errors.

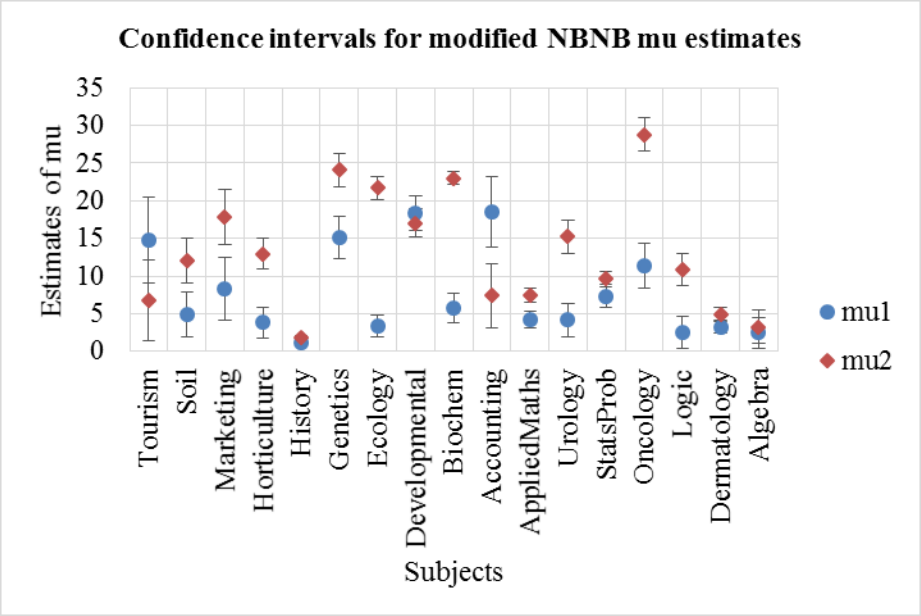

Figure 1. Mean (mu) estimates for the modified NB stopped sum NB distribution for both primary and secondary waves with 95% confidence intervals.

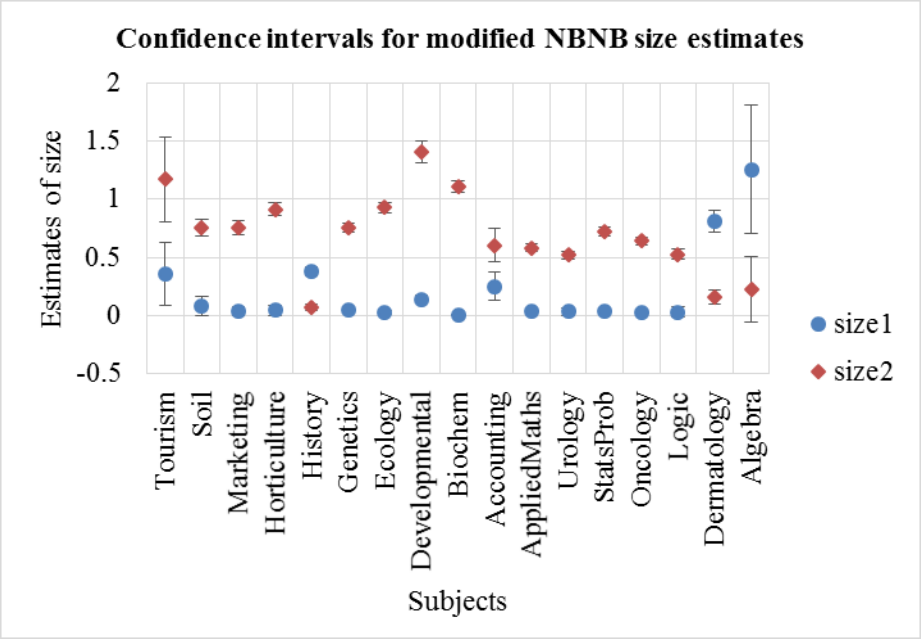

Figure 2. Size estimates for the modified NB stopped sum NB distribution for both primary and secondary waves with 95% confidence intervals.

A further examination of the modified NBNB stopped sum model was carried out with simulations using some known fixed parameters, and similar results were obtained. Moreover, simulations were carried out on all the other stopped sum models and similar results were also obtained for the NBNB stopped sum distribution. Hence it can be concluded that both the stopped sum and modified NBNB stopped sum models are impractical when modelling data with no covariates. Further studies should be conducted to see if adding covariates would change the reliability of the model.

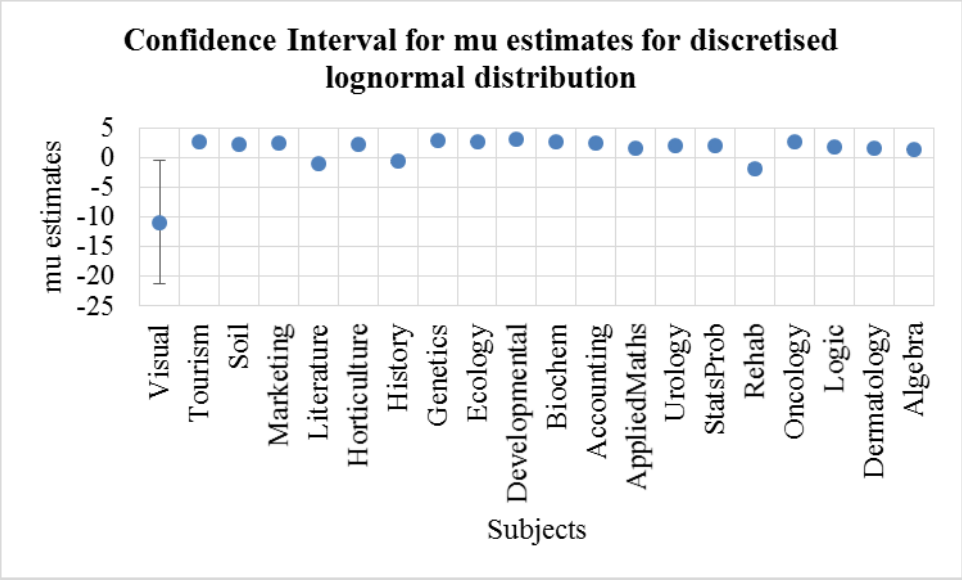

Figure 3. Mu estimates for the discretised lognormal distribution with 95% confidence intervals.

On the other hand, the 95% confidence interval for all subjects except Visual for the discretised lognormal distribution (Fig. 3) are much narrower compared to that of the

modified NB stopped sum NB distribution. This indicates that the discretised lognormal distribution is more suitable in practice.

Conclusions

This paper tested stopped sum distributions for modelling citation data for the first time and also introduces a modification to allow the 'waves' to occur simultaneously rather than sequentially. However, given that the standard errors for the stopped sum distribution tend to be very large it is doubtful whether these distributions are useful for citation data even though they produce the lowest AIC. For example, out of all the tested distributions, the modified NB stopped sum NB distribution produced the lowest AIC, but the large standard errors suggests that it is an unsuitable model as its parameter estimates are too unreliable for predictions or conclusions based upon the model to be meaningful.

Overall, the results suggest that for covariate free data, the discretised lognormal distribution is much more suitable for regressing citation data from a single subject and year. Nevertheless, on a theoretical level, the good fits found for some of the stopped sum models give evidence that there are (at least) two important and separate processes that govern the citing practices of authors. For one of these processes, existing citations are irrelevant for new citations, and for the other, they are relevant.

Abstract
We analyse and compare the difference in discipline level of the received citations over a period of time and across fields in China by implementing the diachronous methods of bibliometrics. The citations of 896,645 papers from the Chinese Citation Database (1994 to 2013) that comprised four disciplines, namely, Philosophy, Library and Information Science (LIS), Physics, and Mechanical Engineering, are collected. Results indicate the following conclusions. First, the received citations strongly differ across various fields and over time. Second, the average of the received citations after a given year has an identical change. The number initially increases rapidly, and then declines slightly in the recent years. Uncitedness rate decreases in the early stage of the study period, whereas the rate stabilises or increases slightly in the recent years. Third, the average of the received citations peak after seven and nine years in mechanical engineering and philosophy, respectively, whereas both physics and LIS peak after three years. The span from the year of publication to the cited peak is relatively stable in LIS for 20 years. However, the span decreases in the early stage of the study period, and then stabilizes in the recent years for the other three disciplines. Recently, all four disciplines indicate relatively consistent citation trends. These results highlight the recent evolution of Chinese research systems towards relatively steady states.

Conference Topics
Citation and Co-citation Analysis; Country-level Studies

Introduction
Citing is a fundamental academic behavior among scholars. Citing shows the use of previous research, presents the processes of scientific inheritance and communication, and manifests respect for other scientific researchers (Yang et al., 2010). In the 20th century, citing other works became common in writing scholarly or scientific papers (Kaplan, 1965). Analysis of citing behavior is an important field and method in information science. At present, citation analysis is widely used to evaluate scientific works, initiate scholarly communication, analyse academic behavior, and process information retrieval (Hirsch, 2005; Hammarfelt, 2011; Ketzler & Zimmermann, 2013; Ding et al., 2014).

Information scientists have extensively investigated the distributions and changes of citing behavior (Finardi, 2014). According to the general theory of human behavior, we design the framework of citation behavior analysis. Figure 1 shows a four-dimensional model of citing behavior analysis. This model integrates analytical dimensions in terms of level (who), method (how), perspective (when), and content/topic (what and why). The combination of different dimensions can display the citing behavior in multiple functions and aspects. According to the analysis perspective, citing behaviors mainly include synchronic and diachronic distributions that fundamentally designate and refer to completely different characteristics of scientific literature (Nakamoto, 1988). Synchronic analysis is generally more common than other analytical approaches to citing behaviors (Heistermann et al., 2014). Line and Sandison (1974) proposed the diasynchronous analysis, a kind of synchronous analysis, which studies the synchronous distribution of cited documents at different time periods. Larivière et al. (2008) studied the evolution of yearly synchronous scores computed from 1900 to 2004. Their study showed the increase in average and median ages of cited literature, whereas the price index decreases over time. However, Egghe (2010) argued that

"Larivière' results do not have a special informetric reason but that they are just a mathematical consequence of a widely accepted simple literature growth model."

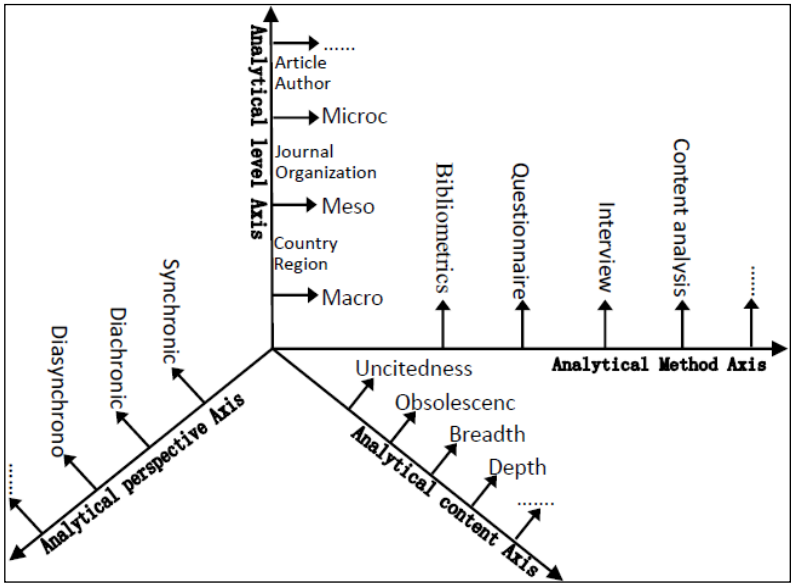

Figure 1. Four-dimensional model of citing behavior analysis.

Diachronic analysis consists of analyzing the distribution of citations gained over time by a publication within a given year by subsequent literature. However, this analysis is generally ignored because of the unavailability of data and the difficulty in implementation. Nevertheless, diachronic analysis has certain advantages, including its appropriateness for citation distribution (Bouabid & Larivière, 2013). Some papers focused on citation distribution and its evolution based on diachronic analysis. First, Finardi (2014) plotted the mean received citations against the time gap (in years) between the publication of the cited article and received citations. Afterwards, he established that citations follow different trends in various fields or disciplines. Some scholars studied the time gap between the publication of a scientific work, as well as the first citation it received (Bornmann & Daniel, 2010). Egghe et al. (2011) proposed a first-citation-speed index, which is utilised for a set of papers, based on the number of publication times and the initial citation. Bouabid and Larivière (2013) recently used a diachronous model to study life expectancy changes and to identify variations in life expectancy between countries and scientific fields based on the citations received by papers.

Second, studies focused on one intriguing aspect of citation analysis, which is the distribution of uncitedness. Schwartz (1997) defined uncitedness as the inability of papers to be cited in citation indexes within five years after their publication. Stern (1990) claimed that although most papers are eventually cited, a number of papers in various scientific disciplines are never cited. Pendlebury (1991) established that the lowest rates of uncitedness occurred among physics and chemistry papers. Garfield (1998) opined that knowing the number of uncited papers and clearly defining these prior to interpretation are important. Egghe et al. (2011) discovered that Nobel laureates and Fields medalists cover a large fraction (10% or more) of uncited publications. A positive correlation was found between the h-index and the number of uncited articles as well.

Lastly, some researchers investigated changes in citing behavior in the context of the overall situation. Larivière et al. (2008) studied the evolution of the aging phenomenon, particularly on how the age of cited literature has changed in over 100 years of scientific activity. They discovered that the average and median ages of cited literature underwent several changes during the period. Evans (2008) showed that as more journal issues are offered online, fewer

journals and articles are cited, and a large part of these citations refer to a small number of journals and articles. Larivière et al. (2009) challenged the conclusion of Evans (2008) and argued that the dispersion of citations is, in fact, increasing. Yang et al. (2010) studied citing behavior by employing three measures of citation concentrations using the Chinese Citation Database (CCD). The concentration of citations was claimed to be declining, and cited papers are broad and diverse. In our view, the diachronic analysis of citation behaviour has two main aspects: the citation change of papers **published** in different years and the citation change of papers **cited** in different years. However, scholars have yet to analyse received citations over a long period of time and across various fields in China.

Since 1978, when the reforms and opening up policies were implemented, China has experienced unprecedented changes. Chinese science exhibited remarkable progress as well. With the popularity of the Internet and development of computer networks in recent years, social environment and scientific research underwent significant changes (Zhou et al., 2009; Yang, 2010). In China, What is the exact general distribution of citation? What are the advancements in citation behaviour in Internet era? Are there differences in citation behaviour across various scientific fields in China?

Our research aims to discover the citation distribution trends over time in different scientific fields in China. Specifically, we focus on the following: (1) the general differences of citation distributions among disciplines, (2) the citation or uncitedness characteristic of papers **published** in different years (For example, papers published in 2000, 2001, 2002... are cited respectively after 5 years, that is, 2004, 2005, 2006...), and (3) the citation characteristic of papers **cited** in different years (For example, a paper published in 2000 is cited in 2000, 2001, 2002...).

Methods and data

Data sample

China has the following citation databases: Chinese Science Citation Database, Chinese Social Sciences Citation Index, Chinese Humanities and Social Science Citation Database, Chinese Science and Technology Paper Citation Database, CQVIP Citation Database, and CCD. In this study, we used CCD as our data resource. CCD collects all references for the China National Knowledge Infrastructure (CNKI) and performs deep data excavation on the citation relationship between studies. Furthermore, CCD provides a citation statistical analysis function based on authors, institutions, publishers, and journals. CCD is one of the products of CNKI (http://www.cnki.net/), and the database covers 6,642 journals while its web version has more than 8200 journals. CCD only contains Chinese journals. Tsinghua University and Tsinghua Tongfang Holding Group first launched CNKI in June 1999. CNKI is the key project of the national informatization construction in China, which established the most comprehensive system of academic knowledge resources (CNKI, 2014). CNKI comprises more than 90% of the knowledge resources in China, which is the broadest in titles and type coverages, as well as the most in-depth in years of coverage in the country. The oldest paper dates back to 1979. This database is updated daily.

We analysed publications and citations from 1994 to 2013, which spans 20 years, to identify publishing and citing patterns at the discipline level. This period was chosen because it is recent and 20 years is sufficiently long in performing the comparisons. All papers from 1994 to 2013 were collected in July 2014. The papers covered four disciplines based on the classification system of CNKI: philosophy, library and information science (LIS), physics, and mechanical engineering. These disciplines, respectively, represent the humanities, social sciences, science, and engineering. The LIS is somewhat peculiar given its evolution towards forms of publication and citation that are closer to the hard sciences. However, we are highly

familiar with this subject because many related research also use LIS as an example. We considered citation types including journals, books, dissertations, meetings, and newspapers. To verify the consistency of the data, we downloaded the data again after a week. We consulted the database provider several times regarding data access issues (i.e., the exact time of database upgrade per day and the range and scope of the citation database). The database is only appropriate for a country, and only reflects the situation in China. Thus, results may differ when international databases are used for comparison.

Methodology

Three aspects of related indicators of received citations across fields and over time are presented. The three aspects involve six equations.

Generally, the papers published in year *i* were cited in year *j*. Both *i* and *j* are from 1994 to 2013, and *j*>=*i*. P_j represents the number of papers published in year *i*. C_j represents the number of citations in year *j*, which were obtained from the papers published in year *i*. We analyse the general situation of the papers cited and published every year and analysed them using the following equations.

1) The average number of citations obtained by each paper from the published year to year *m* (*m* equals to 2013 in this study), and the average number of citations obtained by each paper in each year.

F1: $\frac{\sum_{j=i}^{m} C_j}{P_i}$ expresses the average number of citations obtained by each paper from the published year to year *m*.

F2: $\frac{F1}{n}$ expresses the average number of citations obtained by each paper in each year, where *n* represents the distance between published years *i* and *m*, that is, *n* = *m*-*i*+*1*.

2) Percentage of uncited papers within a given time period.

F3: $(1 - \frac{P^c}{P_i}) \times 100$, P^c is the number of papers cited at least once within a given time period after publication. The time span of one, two, or all years are set. In the case of three years, all papers published in 2003 are referred to as P_{2003}. We attempted to determine how many of the papers are uncited after three years (between 2003 and 2005). The time period ends in 2005 for the three-year perspective (including the publication year).

3) Time evolution of the average received citations.

We obtain Equation 4 by the methodology described in Finardi (2014).

F4: $MEAN_k = \frac{C_j}{P_i}$ expresses the average number of citations in year *j*, which were obtained by the papers published in year *i*. That is, the received citations of each paper in year *j* after being published for *x* (*x*=*j*-*i*+*1*) years (including the published year). At a constant value of *x*, which can be changed or assigned between 0 and 19 in the empirical analysis, we can obtain a series of $MENN_k$. For example, if we set *x* equals to 3, then we have $MEAN_1 = \frac{C_{1996}}{P_{1994}}$, $MEAN_2 = \frac{C_{1997}}{P_{1995}} \ldots MEAN_{18} = \frac{C_{2013}}{P_{2011}}$, where *k* is from 1 to *N* and *N* is dependent on *x* that equals to 2013-1993-*x*+1(*x* is the time distance between the published and cited years *i* and *j*, respectively).

F5: $AMEAN_x = \frac{\sum_{k=1}^{N} MEAN_k}{N}$ expresses the average of means among different occurrences from papers published in several years. By this equation, any possible bias because of the use of citations received in a single year may be avoided. The final result is the plot of $AMEAN_x$ vs. x.

F6: $CAC_x = \frac{\sum_{j=i}^{i+x} C_j}{P_i} \Big/ x$ expresses the cumulating average number of citations that each paper has received during x years, beginning its publication in year i (including the published year). For example, if i equals 2000 and x equals 3, the number of citations received at 2000, 2001, and 2002 from the papers published in 2000 will be summed, and then the cumulating average values of received citations of each paper per year will be calculated.

Result and discussion

Overview

A total of 896,645 papers in philosophy, LIS, physics, and mechanical engineering that were published from 1994 to 2013 were collected. The upper left curve in Figure 2 shows that 41,793,391 papers were published across all fields in CCD for the past 20 years (1994 to 2013). The number of papers steadily increased each year, from 927,684 in 1994 to 3,478,490 in 2013. The curve shows that the growth pattern is an S-shape and has three stages (i.e., slow, rapid, and slow growth). The growth of scientific papers slowed down after 2008. The progress of LIS and philosophy papers remains consistent with those of the other fields. However, a downward trend in physics and a highly irregular trend in mechanical engineering in the recent years are observed. Instead of using typical journals, we selected sample papers in the selected disciplines by an artificial category classification of the database. Numerous papers in China are being published in international journals, especially those in the science and technology field, resulting in changes in the growth rate in Chinese journals.

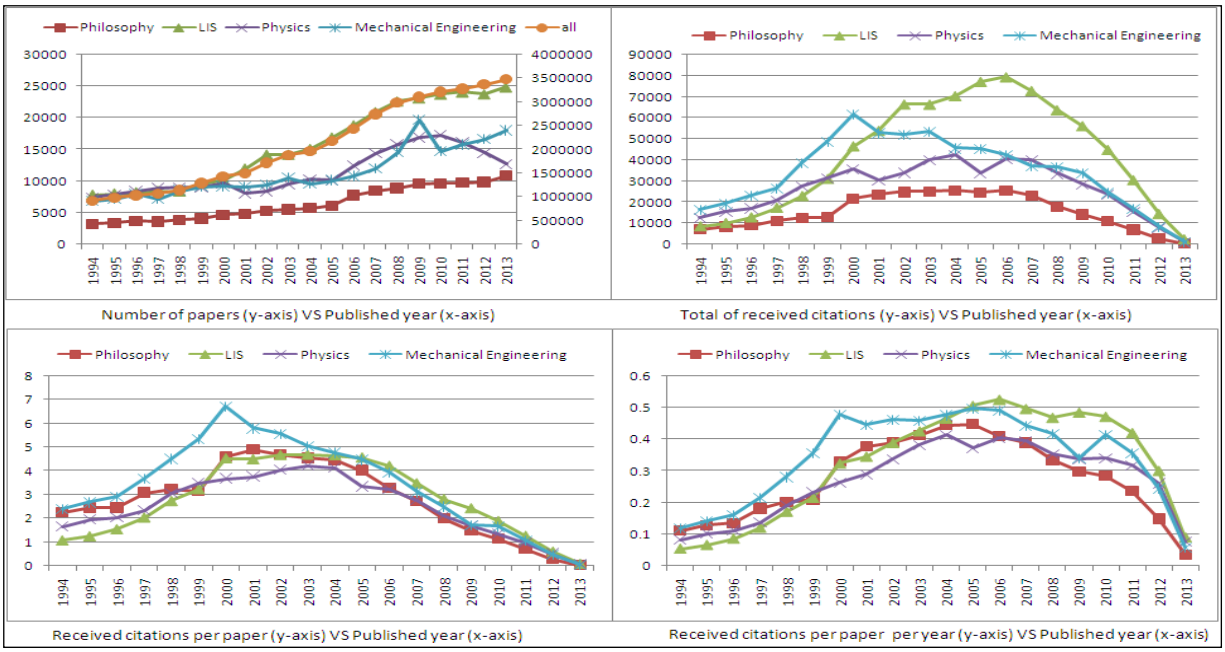

Figure 2. Overall situations of received citations across four disciplines.

Figure 2 shows the overall situations of received citations across four disciplines in CCD. The curves of the received citations exhibit an arch shape (i.e., the middle is high and the end is low). A paper published a long time ago generally has increased chances of receiving citations because of the cumulative phenomenon. However, Figure 2 exhibits the trend of received citations in all four subjects as from increasing in the early periods of the study period to decreasing in the recent years. This phenomenon is caused by two reasons. First, the number of published papers and references for each paper increases each year. The rapid updating of information and the increase in the received citations of each paper can lead to the increase in the number of citations (Price, 1965). Therefore, the cumulative effect of received citations is weakened. Second, people are generally interested in and use the latest research as reference. Researchers strive to make their papers novel. Thus, papers published in previous years have become irrelevant. Figure 2 also exhibits that the received citations of each paper each year (bottom right corner of the figure) eliminate the accumulation phenomenon and display the advantages of papers published in the recent years. The curves of the total received citations and the number of papers published in a specific year are generally consistent. LIS indicated the largest number of papers and received citations in the recent years, whereas philosophy recorded the lowest.

Citation and uncitedness characteristics of papers published in different years

Figures 3 and 4 show the average of the received citations after a paper is published in a given year. In the case of five years window, all papers published in 2000 were taken as the research sample; we determined the average number of times that these papers were cited in 2004. For clarity of presentation, Figure 3 displays only the received citations in four fields after 1, 2, 5, and 10 years. The curves exhibit an identical change (i.e., an initial rapid increase and then a slight decline in the recent years) and indicate that the average of the received citations (published in the recent years) failed to increase. The rapid growth of the average of the received citations in the early stages of the study period changes to a relatively stable development phase because of the slow growth in the number of published papers, the development of the Internet, and the widespread use of open-access and e-print materials. However, whether a special informetric reason or merely a mathematical consequence of a simple literature growth model exists, this phenomenon requires further validation and

investigation (Egghe, 2010). The average of the received citations exhibits significant differences among the four disciplines in various time spans. The maximum value was attained by LIS after one, two, and three years compared with the other three disciplines in each publication year. However, this value slowly decreased, and LIS attained the minimum value each year after 10 years. Physics and mechanical engineering show the exact opposite of LIS. That is, after 10 years, the maximum value of the average of the received citations was achieved.

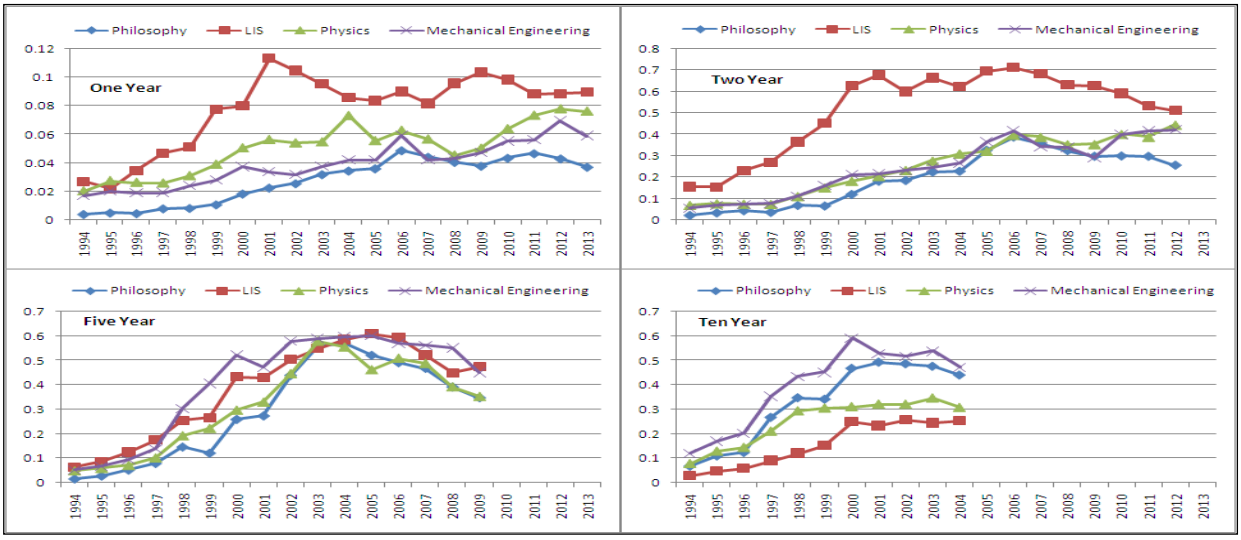

Figure 3. Received citations of each paper each year (y-axis) vs. published year (x-axis) (Part I).

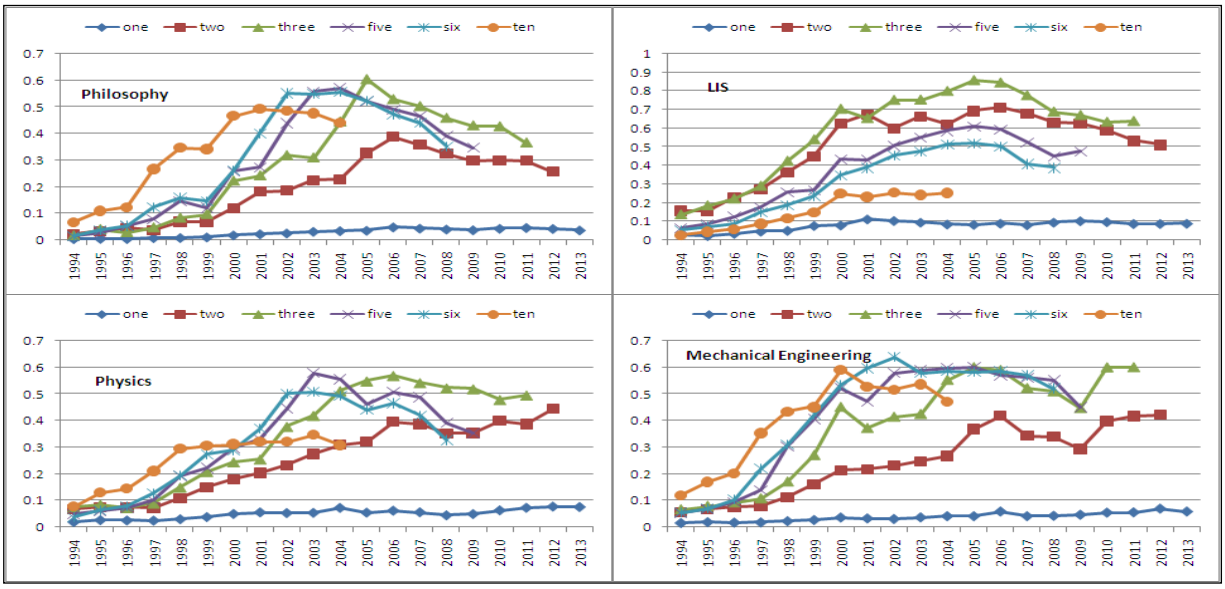

Figure 4. Received citations of each paper each year (y-axis) vs. published year (x-axis) (Part II).

Figure 4 illustrates the received citations by discipline and clarifies the situations of various time spans in each field. Philosophy, physics, and mechanical engineering papers published in the early stages of the study period received more citations in six and ten-year windows than in the recent years. Generally, recently published papers have more citations of papers published from the last three years, which implies that the life expectancy of scientific

literature is generally becoming shorter. Papers on LIS (published almost all year) received more citations in two and three-year windows.

The uncitedness results are presented in four citation windows representing one, two, five, and all years after the publication year. Figures 5 and 6 show that the uncitedness rate generally decreases in the early stages of the study period, and then stabilises or increases slightly in the recent years. This phenomenon is due to the following reason. First is the emergence of databases and networks that provided researchers with additional opportunities to find articles for citation and that allowed equal access to all documents. However, the development of databases has entered a period of relative stability in recent years and the uncitedness rate changes slowly as well. Second, the steady increase in the number of published articles and references for each paper decreases the uncitedness rates in the early stages of the study period. However, the rates of both published articles and references relatively stabilised in the recent years. Third, CCD, which is used and promoted in a wide range of areas, was established in 1999. As CCD became increasingly stable, its data updates became timely in recent years. After the reform, the opening up, and the development of science and technology, research conditions and environments significantly improved. The state of scientific research has become steady in recent years in China.

A number of studies showed that the uncitedness rate is lowest in the sciences, high in the social sciences, and highest in arts and humanities (Hamilton, 1991). However, Figures 5 and 6 display contrasting results. The uncitedness rates in LIS are significantly lower than the other three disciplines in the one-, two-, and five-year citation windows in almost all publication years. A possible reason for this phenomenon is the privileges and required expertise in accessing and using documents (especially online information retrieval) in LIS. Papers published in the recent year exhibit high uncitedness rates for Philosophy in the one-, two-, and five-year citation windows. However, the low uncitedness rates in the all-year citation window showed more documents being cited in this discipline.

Figure 6 shows the uncitedness situation by discipline. The curves exhibit the same trend for all four disciplines. The uncitedness rates in the one-year window are relatively stable, while in the two-year window, the uncitedness rates decrease rapidly and decline sharply in the five-year window. However, the all-year window is special because different results were obtained for papers in different publication years. For example, papers published in 1994, 2000, and 2008 are in the all-year citation window, particularly 20, 14, and 6, respectively. Consequently, the two curves of the five- and all-year windows move gradually closer.

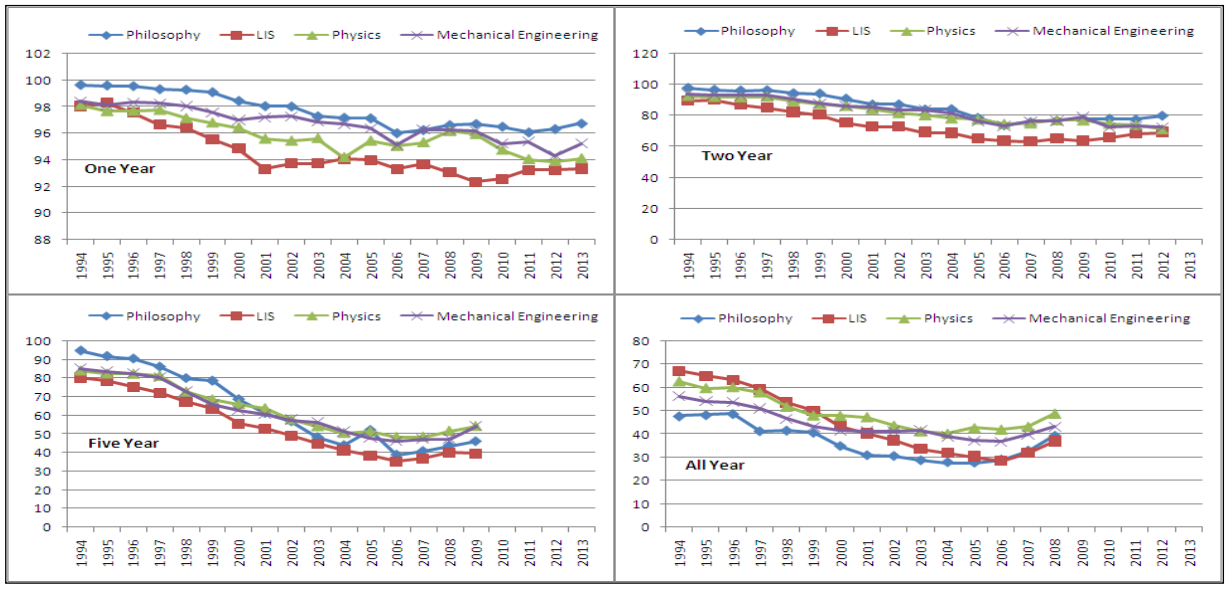

Figure 5. Number of uncited articles (y-axis) vs. published year (x-axis) (Part I).

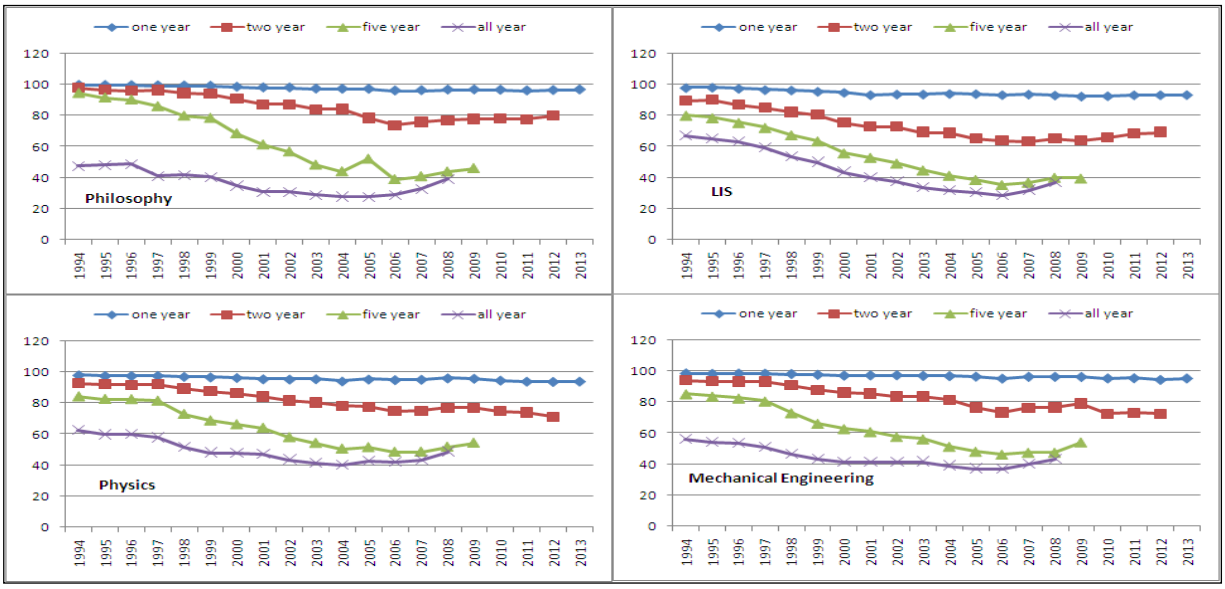

Figure 6. Number of uncited articles (y-axis) vs. published year (x-axis) (Part II).

Citation characteristics of papers cited in different years

Figure 7 shows the mean of the received citations of each paper after a given time period using Equations 5 and 6. The average value avoids possible biases that are caused by using the received citations in a single year. The curve shows the values from 1 to 20 years after publication.

Figure 7 presents the average of the received citations over time. The typical citation curve starts with a rapid increase during the initial years followed by a peak, and then a slow but steady decrease (Larivière et al., 2008). LIS and physics had a similar trend in terms of the average of the received citations. These disciplines peaked at three years after publication, as observed by Finardi (2014) and Bouabid & Larivière (2013). However, physics steadily decreases and LIS rapidly decreases, which created a steep curve. The times of cited peak values are distinct among different disciplines. The trend of mechanical engineering presents a peculiar behaviour because a peak is not exhibited. Instead, the received citations increase in the first three to five years and then stabilise at high values. Citations of mechanical engineering papers continue for a long time after their publication. Figure 7 also suggests that philosophy has a different citation path, with the continuous growth from one to eight years, peak at nine years, and a subsequent slight decrease. This trend is because philosophy information can be accessed and used for a long time, with slow obsolescence.

Figure 7 shows that notable differences exist between the trends of the mean of the received citations in different fields. Consequently, we can conclude that clear differences exist among other specific fields of natural and social sciences. However, further evidence must be obtained by using longer time periods and increasing the number of disciplines compared with that in this study. The maximum values of the average of the received citations peaked after seven years in mechanical engineering and nine years in philosophy. The journal impact factor (IF) only considers citations received in the first two or five years after publication (i.e., 2-years IF or 5-years IF). Thus, high citation values are not captured in the IF computation. The following reasons can explain the particular trends in mechanical engineering and philosophy. Papers published in both disciplines increased from 1994 to 2013, resulting in a parallel growth in the number of citations. Moreover, referring to old literature is preferred in both disciplines, resulting in stable citation curves.

The curves at the right of Figure 7 represent the cumulating value. The curves of the right and left categories in Figure 7 are relatively consistent. However, the curves on the right are smoother than the curves on the left, and the corresponding peaks lag for several years because of the average cumulative effect. For example, in the case of x=3 (x-axis) in Equation 6, we calculated the number of received citations published after one, two, and three years, and then calculated the average values of the received citations of each paper each year.

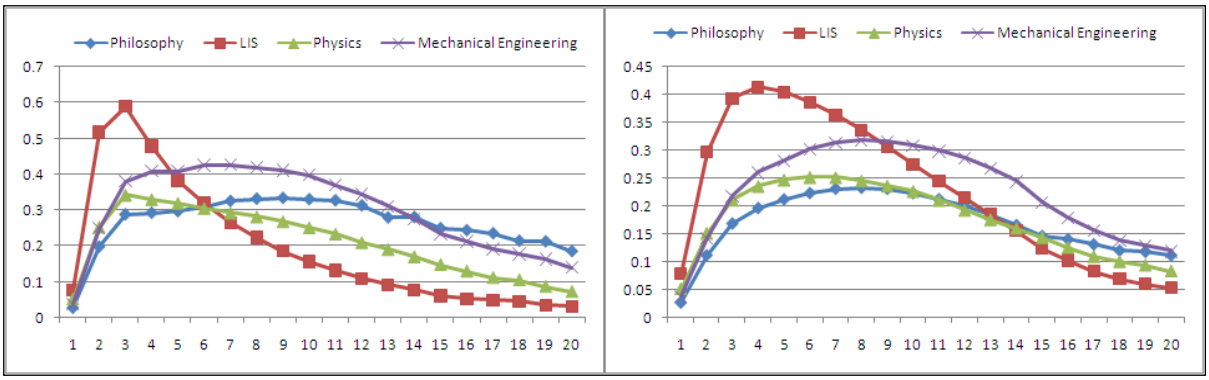

Figure 7. $AMEAN_x$ **(y-axis) vs.** x **(x-axis).**

Figure 8 shows the received citations of each paper each year within the identified time period. We selected the publication years of 1994, 1998, 2002, and 2008 as representatives. The data for the other years of publication showed the same trends. However, these were not included in this paper. The trend in LIS is completely different from those of the other three disciplines. LIS presents a peak at two or three years, which slightly decreases in all cited years. The curves of the other three disciplines are relatively consistent. The received citations of papers published in 1994, 1998, and 2002 increase tremendously and peak in 2006 before slightly decreasing. However, a big difference is observed in the received citations for papers published in different years (i.e., 1994, 1998, and 2002). We can conclude that the early publication years tend to have late citation peaks. For example, the received citations of philosophy papers published in 1994 exhibited their peak 14 years after publication (2007), whereas papers published in 2002 exhibited their peak six years after publication (2007). In general, all four disciplines possess a relatively consistent citation trend in recent years.

Figure 9 shows the situation of the received citations by discipline. Philosophy papers published in the early part of the study period still received many citations. These old papers are not excluded from the science system. Thus, they remain to have a relevant contribution. The citation curves in LIS are consistent in the different cited years. However, the curves of the other three disciplines exhibit a similar trend; papers in these three disciplines became more quickly obsolete in general in recently. Furthermore, many curves peak between 2006 and 2008.

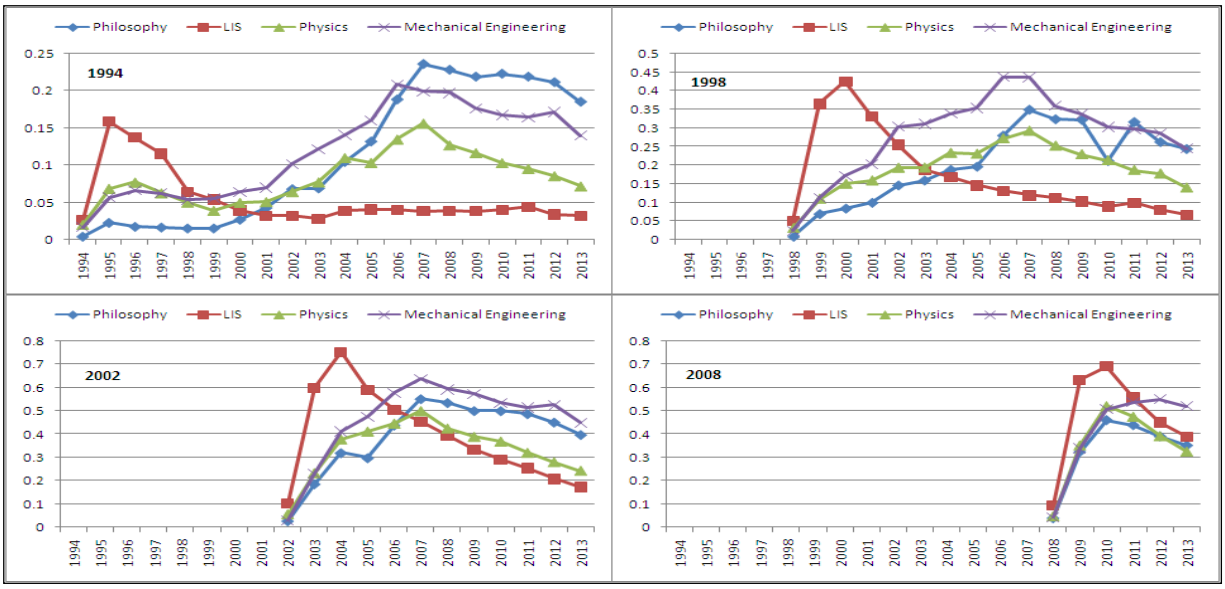

Figure 8. Received citations of each paper each year (y-axis) vs. cited year (x-axis) (Part I).

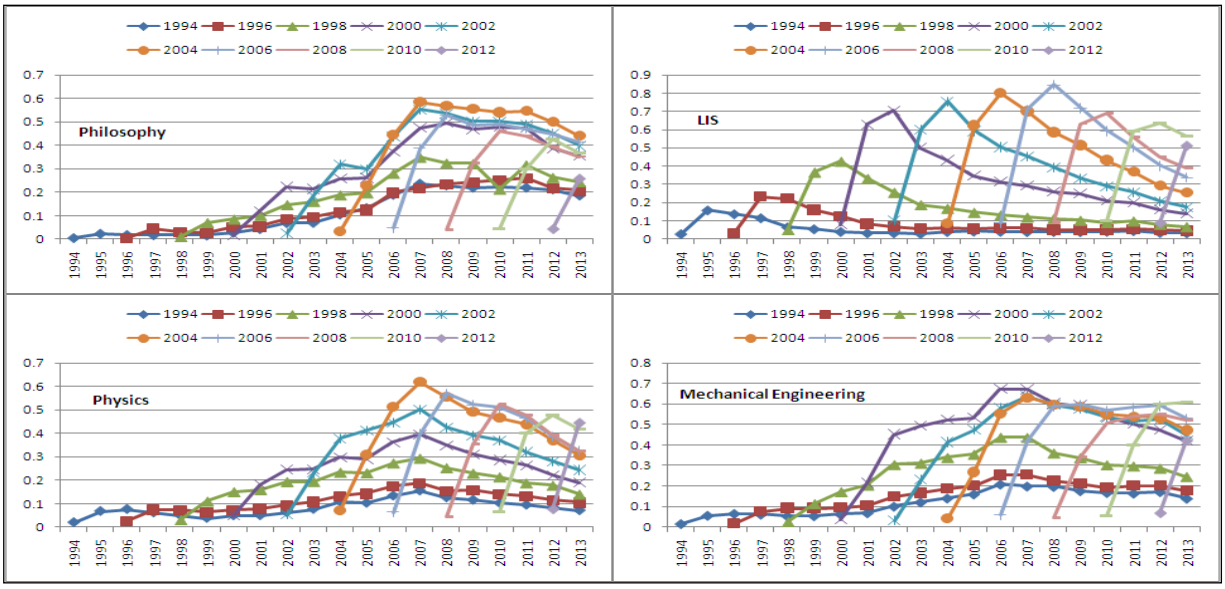

Figure 9. Received citations of each paper each year (y-axis) vs. cited year (x-axis) (Part II).

Conclusion and further research

A total of 896,645 papers on philosophy, LIS, physics, and mechanical engineering, which were published from 1994 to 2013, were collected. This study analysed the differences of these papers in terms of the received citations across fields and over time in China. The following conclusions were derived from the results. First, the growth of published papers is generally S-shaped and undergoes three stages (i.e., slow growth and rapid growth). The curves of the received citations of each paper exhibit an arch shape (i.e., the middle is high and the end is low). The cumulative phenomenon of received citations is not obvious. Second, the average of the received citations in a given year window changes identically, initially increases rapidly, and then slightly decreases in the recent years. The average of the received citations exhibits significant differences among the four disciplines in various time spans. In one-, two-, and three-year windows, a maximum value is observed in LIS in each published

year. The value slowly decreases until the LIS obtains a minimum value within the 10-year windows. However, physics and mechanical engineering exhibit an exactly opposite change. Third, the uncitedness rate generally decreases in the early stages of the study period, but stabilises or increases slightly in recent years. The uncitedness rates in the one-year window are relatively stable, but decreases rapidly in the two-year window and drops sharply in the five-year window. Fourth, notable differences exist among the trends of the mean of the received citations of the different fields. The maximum values of the average of the received citations peak after seven years for mechanical engineering, nine years for philosophy, and three years for both physics and LIS. These results are similar to those obtained by Finardi (*2014*) and Bouabid & Larivière (*2013*). Lastly, citation characteristics of papers cited in different years. LIS citations are completely different from those of the other three disciplines. LIS citations peak at two or three years and then slightly decrease in all cited years. The curves of the other three disciplines are similar. Papers published in the early stages of the study period have a later cited peak. In the recent years, all four disciplines possess a relatively constant citation trend. Generally, Chinese research systems evolve into a relatively steady state from a rapid growth and then change in the early period.

This study has analysed comprehensively the received citations across fields and over time in a systematic manner. As a result, consistent conclusions are drawn. For future research, we intend to perform the following. First is we will measure the received citations at the discipline level by implementing diachronous methods. We will consider synchronic methods and combine the two methods. Aside from the discipline level, other levels (e.g., journals, authors, countries, papers, agencies) will also be analysed. We intend to study citations based on literature units and analyse large-scale samples using probability statistics. Second is we will increase the number of disciplines. We will choose additional representative samples from other disciplines for a comprehensive statistical analysis. Furthermore, we will select other document databases such as international document databases, to verify the pattern and characteristic changes in the received citations. Third is we will increase the level of examination and improve the measured indicators of distribution and evolution of the received citations. The measurement methods of the received citations can be enhanced, and an in-depth analysis of the specific distribution of highly cited papers will be conducted. Lastly, a detailed and in-depth study will be implemented to check the factors that affect citation evolution and examine the cause and effect of these changes (e.g., the effect of the growth in number of papers on received citations). Furthermore, we will determine how to handle the trend and changes in the distribution of the received citations.

Danish Centre for Studies in Research & Research Policy, Department of Political Science, Business and Social Sciences, Aarhus University, Denmark.

Abstract
This paper examines the rise in co-authorship in the Social Sciences over a 33-year period. We investigate the development in co-authorship in different research areas and discuss how the methodological differences in these research areas and changes in academia affect the tendency to co-author articles. The study is based on bibliographic data about 4.5 million peer review articles published in the period 1980-2013 and indexed in the 56 subject categories of the Web of Science's (WoS) Social Science Citation Index (SSCI). Results show that in the majority of the subject categories we can document a rise in the mean number of authors and that there are disciplinary differences in how much the number of authors has increased. The most substantial rise in the mean and median number of authors has happen in subject categories, where the research often is based on the use of experiments, large data set, statistical methods and/or team-production models.

Conference Topic
Citation and Co-citation Analysis

Introduction
This paper explores the rise in co-authorship in the social sciences. The study is based on all the articles registered from 1980-2013 in the Web of Science's (WoS) Social Science Citation Index (SSCI). Several studies have examined the rise in the number of authors in different research fields. The studies vary in design, but the majority of the bibliometric studies can be categorized as studies either based on bibliographic data from a national database (Lariviere, Gingras, & Archambault, 2006; Ossenblok, Verleysen, & Engels, 2014) or a selection of journals (Cronin, Shaw, & La Barre, 2003; Fisher, Cobane, Vander Ven, & Cullen, 1998; Hudson, 1996; Norris, 1993; White, Dalgleish, & Arnold, 1982). The study by Wuchty, Jones, and Uzzi (2007) is one of the few studies, that examined the increase in research collaboration by using bibliographic data about research articles from multiple fields collected from the subject categories in WoS. However, their study is based on a sample of research articles and not an exhaustively data collection of the research articles indexed in WoS. Furthermore, Wuchty et al. (2007) do not clarify how many articles in their study that are indexed in either Science and Engineering, Social Sciences or Arts and Humanities. This paper is the first study of the rise of co-authorship in the social sciences to use a large sample of time series data based on all of the publications in SSCI, thus the study cover multiple fields of the social science. The study is therefore not bias by national publication tendencies or the selection of journals. The disadvantage of a data set restricted to articles from SSCI is that other publication types and a substantial share of journals are excluded (Hicks, 2005; Ossenblok et al., 2014; Piro, Aksnes, & Rørstad, 2013). However, we believe that the larger data sample compensate for these data limitations. Hence, the objective of this

paper is to document the rise in co-authorship in the social sciences and discuss the factors that could have influenced this evolution.

The increasing focus on authorship can partly be attributed to the growing importance of and attention paid to a researcher's publication record, which is influential in the considerations for employment, promotion, funding and increases in salary (Biagioli, 2012; Costa & Gatz, 1992; Weingart, 2005). Thus, there is a tendency to measure and assess researchers' based on their quantitative research output instead for the content of this output. This creates incentives to "game" the system to improve one's resume by co-producing publications. This is especially the case, when the performance-based research funding systems use whole counts instead of fractionalizing (Butler, 2003; Ossenblok et al., 2014), so the reward for producing a publication does not have to be shared. Hence, the instrumental uses of performance-based funding systems affect the researchers' publishing behavior, including their definitions, perceptions and practices of authorship (e.g. Ossenblok, Engels, & Sivertsen, 2012). However, the rises in co-authorship and research collaboration are also affected by other factors that influence the research community. The rise can be a result of the increasing tendency to perform large scale research projects executed as team-production models. These projects require greater human and financial resources, a larger data collection effort and often more advanced technical and statistical analyses, hence leading to more specialization and division of labor in the research process (Beaver, 2001; Birnholtz, 2006; Cronin et al., 2003; Fisher et al., 1998; Hudson, 1996; Moody, 2004; Rennie, Yank, & Emanuel, 1997; White et al., 1982). These types of projects are often associated with natural and medical sciences, where there is a strong tradition for working in the fore mention team-production model. However, the increasing tendency to work with large scale data set, the rise in using quantitative methods and in some cases experiments have generated a similar team-production model in the social sciences (Cronin et al., 2003; Hudson, 1996; Moody, 2004). Furthermore, studies have found that researchers in the more quantitative research areas of social science is more likely to collaborate (Fisher et al., 1998). Others have pointed at the increasing mobility of researchers that has made it possible and desirable to expand inter-institutional collaborations (Melin, 2000; White et al., 1982) while the development of communication and information technology have enabled geographically disperse researchers to collaborate, by making it easier to communicate, analyze and exchange data (Beaver, 2001; Fisher et al., 1998; Melin, 2000). Furthermore, the growing number of people working in academia has created more collaboration opportunities (Fisher et al., 1998; Lee, 2000; Melin, 2000), especially the increase in PhD students have created more opportunities for research advisors to collaborate and co-author with their students (Fisher et al., 1998; Price, Dake, & Oden, 2000). However, this tendency has given rise to issues regarding honorary or gift authorship in academia and some studies suggest that research advisors may be inappropriately demanding co-authorship with their students (Rennie et al., 1997). This is disputed by Costa and Gatz (1992), who found that students willingly are giving their advisors inappropriate authorship credit even though the advisors do not fulfill the journal guidelines and requirements for co-authorship. However, they do suggest that the willingness to offer co-authorship can be affected by a power imbalance between advisors and advisees, especially because of the increase in PhD students being subsidized by grants held by their advisors. In this paper we will document the evolution of co-authorship and research

collaboration by presenting evidence for the increase in the number of authors per publication.

Method

The bibliometric data used in this study were collected from the Centre for Science and Technology Studies (CWTS) enhanced version of Thomson Reuters' WoS database in December 2014. We collected bibliographic information for 4,466,134 articles from 99,752 journal issues published in 1980 to 2013 and registered in WoS' SSCI 56 subject categories. These 56 subject categories have in our analysis been grouped into 6 overall subject categories. The grouping of the categories is based on the topics of each subject category described in the SSCI scope notes (SSCI, 2012). Hence, there are differences in how many categories there has been group together, and the similarity of the research areas. The Social Sciences, Interdisciplinary group consist of a variety of subject categories and do not have the similar thematic relationship as the other groups.

- **Management, Planning & Geography** (Geography, Planning & Development, Urban Studies, Environmental Studies, Management, Transportation)
- **Political Sciences, Business and Law** (Criminology & Penology, Business, Business, Finance, Economics, Public administration, International Relations, Law, Political Science
- **Psychology** (Psychology, Mathematical, Psychology, Psychoanalysis, Psychology, Experimental, Psychology, Social, Psychology, Educational, Psychology, Applied, Psychology, Biological, Psychology, Clinical, Psychology, Developmental, Psychology, Multidisciplinary, Psychiatry
- **Social Health Sciences** (Public Environmental & Occupational Health, Substance Abuse, Gerontology, Health Policy & Services, Rehabilitation, Education, Special, Nursing, Ergonomics)
- **Social Sciences, Interdisciplinary** (Social Sciences, Biomedical, Family Studies, Information Science & Library Science, Social Sciences, Interdisciplinary, Hospitality, Leisure, Sport & Tourism, Industrial Relations & Labor, Social Sciences, Mathematical Methods, Communication, Linguistics, Ethics, History & Philosophy of Science, History of Social Sciences, History)
- **Sociology & Anthropology** (Anthropology, Area Studies, Social Work, Education & Educational Research, Women's Studies, Demography, Social Issues, Sociology, Ethnic Studies, Cultural Studies)

Our study limits the relevant types of publications to journal articles, though we know that the publication pattern in the social sciences is more varied (Lariviere et al., 2006; Ossenblok et al., 2014), thus letters, book chapters and books are an essential part of the scholarly communication in some fields of the social sciences. Unfortunately, the Thomson Reuters Book Citation Index (BCI), part of the WoS core collection, do not have as systematic and exhaustively bibliographic information about books compared to the SSCI's information about journal articles. The BCI do only cover the time period from 2006-present, while SSCI have bibliographic data from 1900 to present, so by choosing to only include journal articles we can set a larger time frame for this study.

Results

In the follow subsections we will present the data showing the increase in number of authors per publication. For each group we will present a figure demonstrating the development in the different subject categories[1]. Our data show that the fields of social sciences have experienced a mean 114 percent increase in the number of authors during the last 33 years, hence there have been added 1,2 authors more to each publication. However, there are large differences in how much the number of authors has risen, with the lowest increase being in the History subject category with a minimal change (0.1 authors) to the highest mean increase in Psychiatry (3 authors).

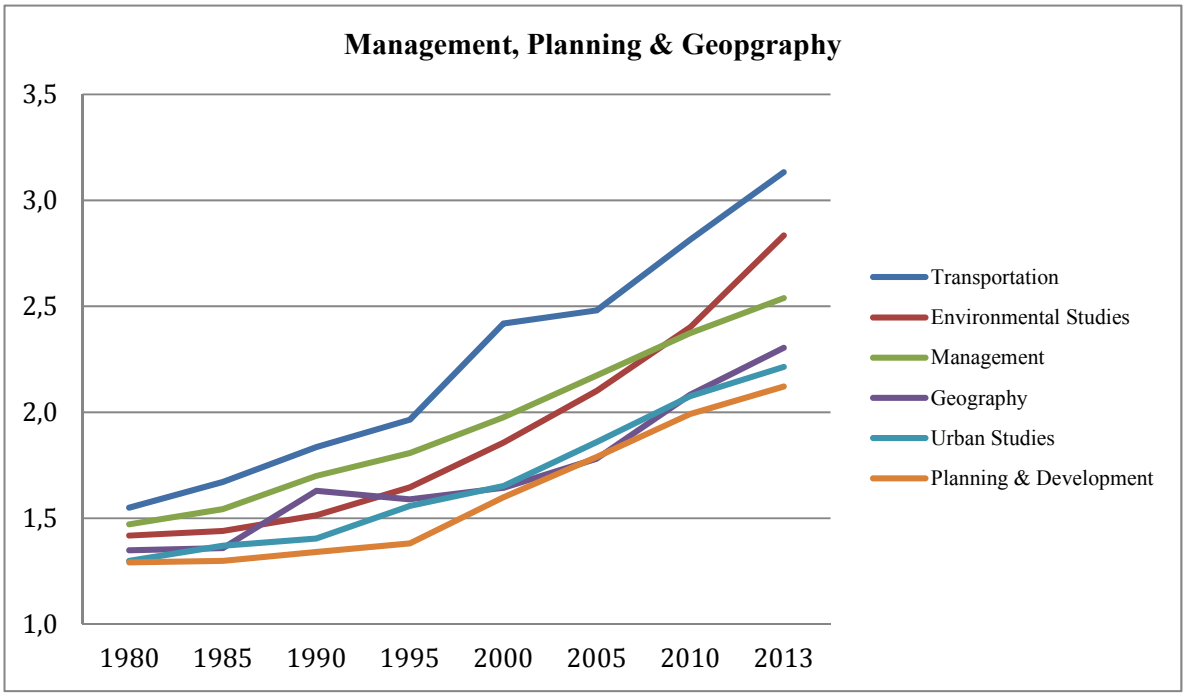

Figure 1. The mean number of authors per publication from 1980-2013 of the group Management, Planning & Geography.

The six categories group as Management, Planning & Geography consist of 373,372 publications. Figure 1 shows the evolution in numbers of authors. The mean numbers of author have increase 71% to 102% or 0.8 – 1.6 authors during the 33 year time period. The mean numbers of authors in 1980 are in the range of 1.3-1.6 authors and have increased in 2013 to 2.1-3.1 authors. The median number of authors is 1 in all categories in 1980. In 2013 the median number of authors has risen to 3 in the category Transportation, while the remaining categories have a median of 2. Even though the category Transportation does not cover civil engineering per se, the close relation with the above mentioned research field can explain some of the increase in co-authorship in this category. The subject categories in this group have all similarities to research fields

[1] We have in this article, because of the space limit, decided to present the development of co-authorship in six figures. The data behind the study will be presented in more details at the conference and are also available if requested.

in science and technology, and are probably influenced by collaboration and publication tendencies dominating these fields.

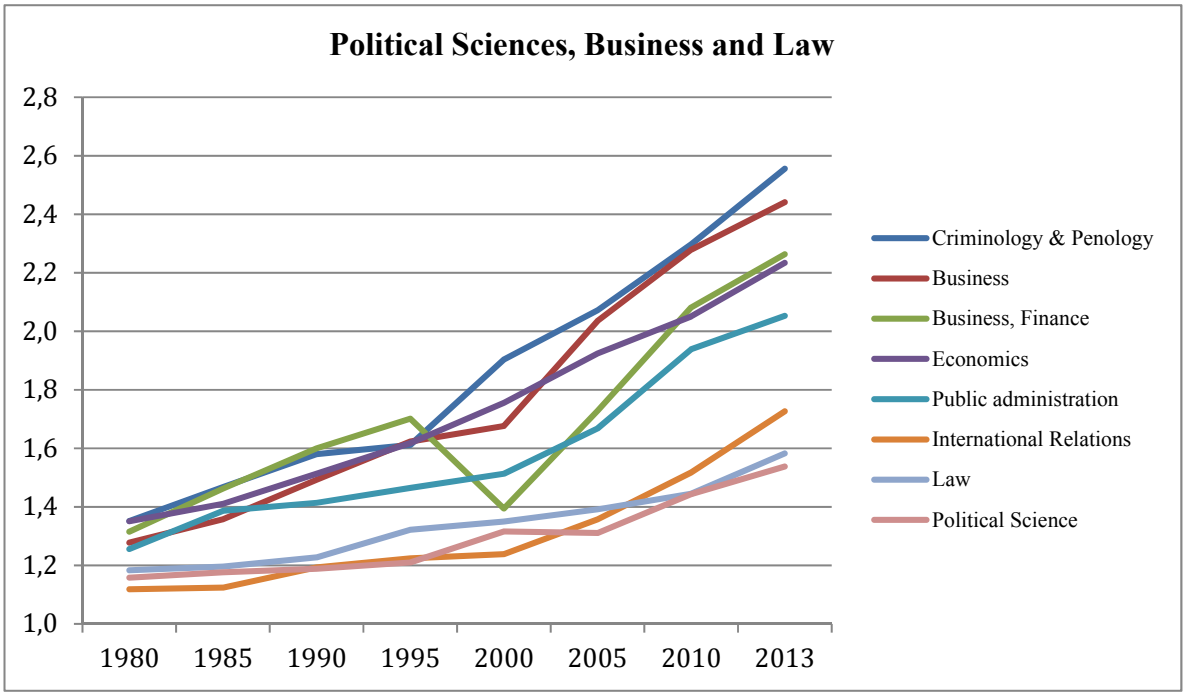

Figure 2. The mean number of authors per publication from 1980-2013 of the group Political Sciences, Business and Law.

The 1,011,725 publications belonging to the Political Sciences, Business and Law show a rise between 38% to 89% in the mean numbers of authors. The mean numbers of authors are between 1.1 - 1.4 in 1980 to 1.5 - 2.6 in 2013 (see figure 2). In Business, Business, Finance, Economics, Criminology & Penology and Public Administration have the median number of authors increase from 1 to 2 authors during the 33 years, while in the remaining categories the median number of authors is 1 during the time period. The greater rise in mean number of authors in the categories Criminology & Penology, Business, Business, Finance, Economics, and Public Administration could be because of the greater use of statistics and register/survey data (Fisher et al., 1998; Hudson, 1996). Political Science is the category in this group with the highest amount of publications (n = 172,625) and covers a broad range of research, thus the lower increase and mean number of authors is probably because areas of Political Science have similarities with research fields in the humanities. The same is the case for the category Law that draws on methods often associated with humanities, such as text analysis.

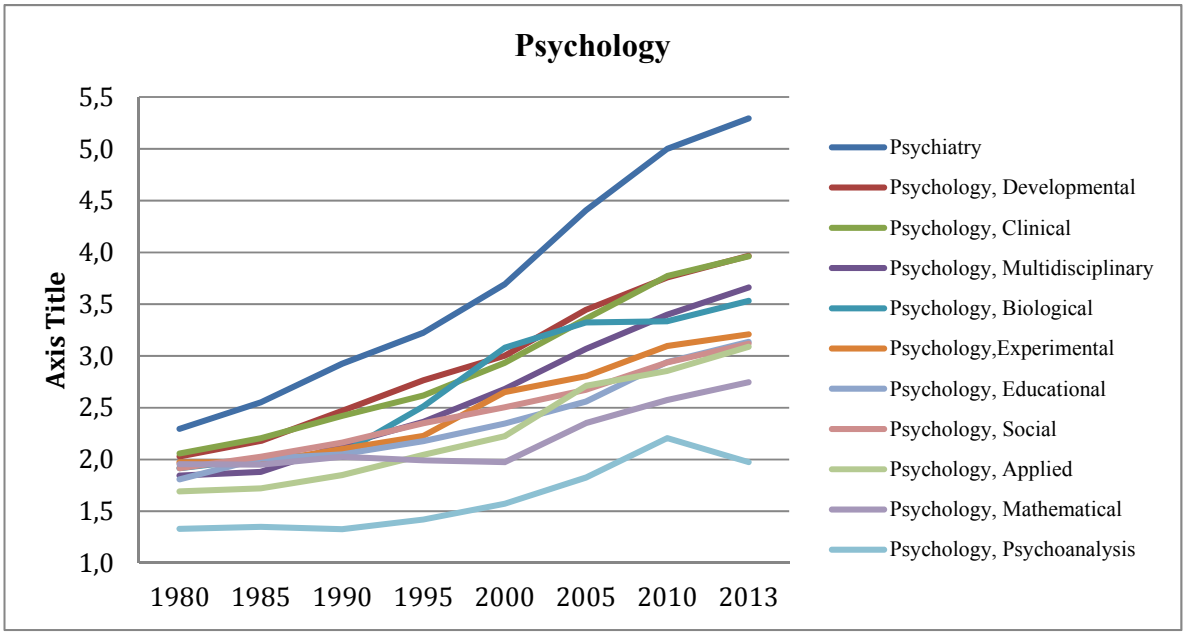

Figure 3. The mean number of authors per publication from 1980-2013 of the group Psychology.

We have collected 1,101,234 publications categorized as Psychology. During the 33 years the mean increase in number of authors is in the range from 0.6 to 3 authors or from 40 % to131%. The mean numbers of authors in 1980 are between 1.4-2.3 authors, this have in 2013 increased to between 2-5.3 authors. The categories of Psychology have all increased the number of authors in the byline during the 33 years, though it is not a constant increase as can been seen in figure 3. The category with the lowest increase is Psychoanalysis, the subject category with a publication and collaboration behavior closest to the humanities, and a mean number of authors in 2013 at 2 authors. Psychoanalysis is the only subject category in the Psychology group where the median have remain constant at 1. In the other end of the scale we have Psychiatry, a subject category with close relations to the medical research fields and therefore a similar collaboration and publication pattern. The mean number of authors in this category is 5.3 authors and the median is 5. Psychology, Mathematical have constantly had a median at 2, while Psychology, Applied have had an increase in the median number of authors from 1 to 3 and Psychology, Clinical have had an increase in median authors from 2 to 4. Psychology, Experimental, Psychology, Social, Psychology, Educational, Psychology, Development, Psychology, Biological and Psychology, Multidisciplinary have had an increase in the median number authors from 2 to 3 authors.

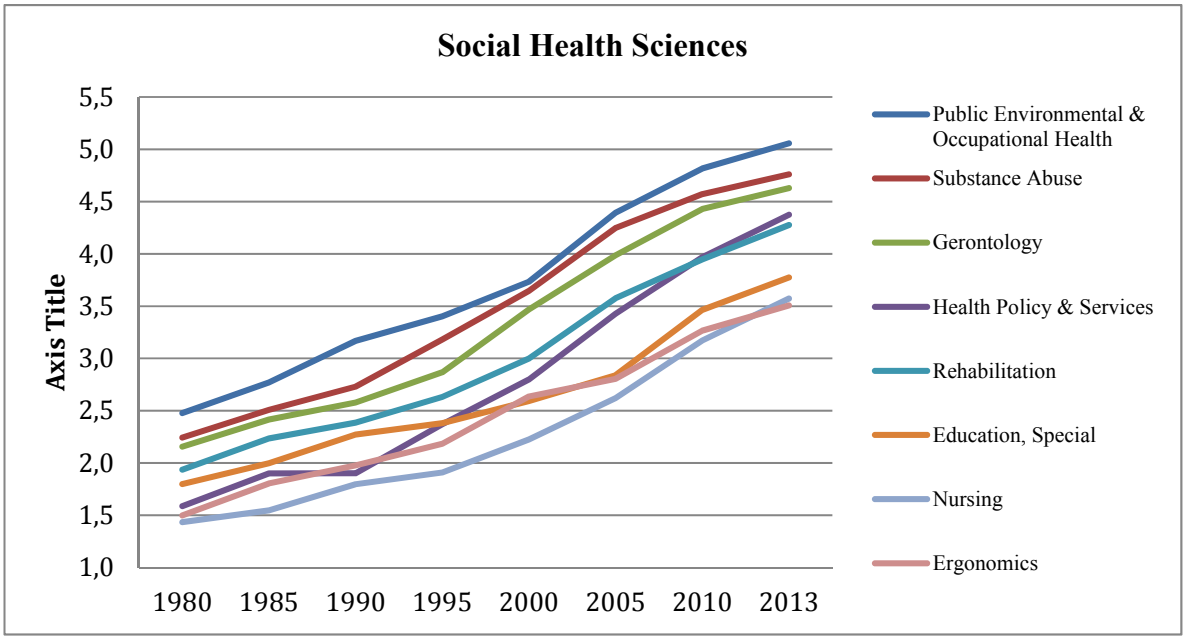

Figure 4. The mean number of authors per publication from 1980-2013 of the group Social Health Sciences.

The data of the categories Social Health Sciences is based on 824,125 publications. The mean number of authors per publication in the Social Health Sciences categories has risen between 104% to 176% or 2-2.6 authors. Figure 4 shows how there have been a substantial increase in all seven subject categories during the 33 years. The median number of authors in 1980 is 1 in the categories Ergonomics, Health Policy & Services and Nursing and 2 in the categories Rehabilitation, Public Environmental & Occupational Health, Substance Abuse, Gerontology and Educational, Special. In 2013 the median numbers of authors have risen to 3 authors in Ergonomics, Nursing and Education, Special and to 4 in the remaining categories. The mean numbers of authors in the Social Health Sciences are between 1.4-2.5 authors in 1980 and have risen to 3.5-5.1 authors in 2013. The average numbers of authors are general quite high in Social Health Sciences compared to other subject categories in the Social Sciences and the subject categories have a publication and collaboration pattern similar to the health and life sciences.

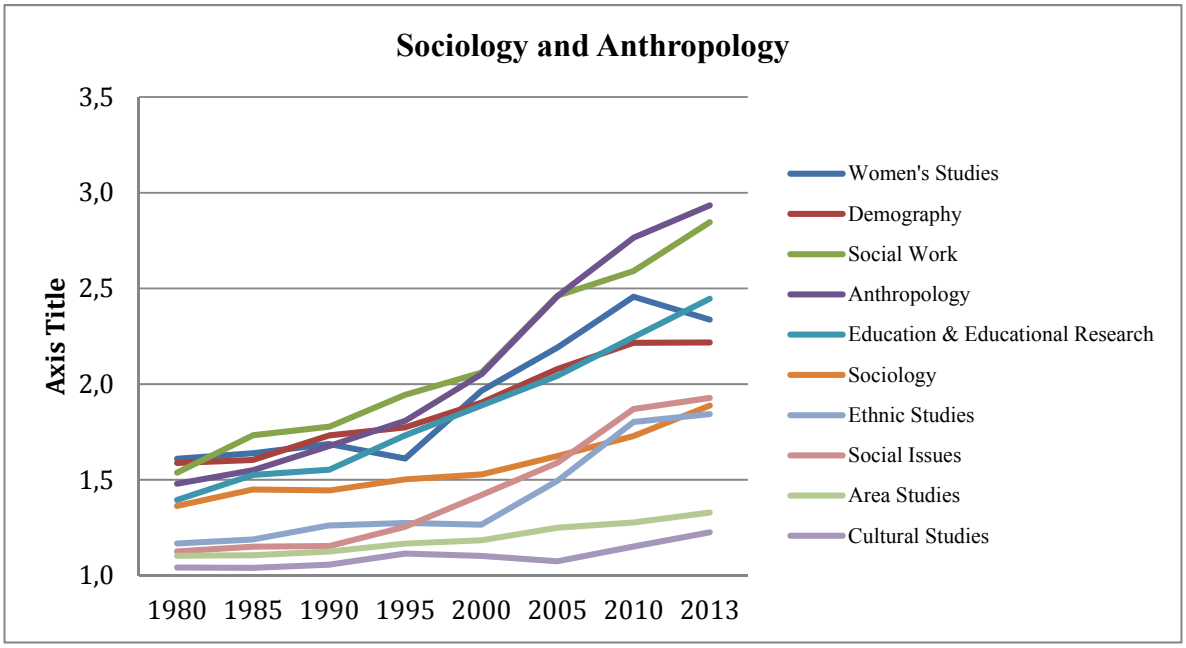

Figure 5. The mean number of authors per publication from 1980-2013 of the group Sociology and Anthropology.

In our data set we have 514,504 publications categorized in the 10 subject categories of Sociology and Anthropology, and the mean percentage increases in numbers of authors are between 17% to 98%. In Figure 5 is the increase in number of authors demonstrated. There have been minimal changes in the mean number of authors in the subject category Cultural Studies and Area Studies, while the categories Social Issues and Ethnic Studies have increased with 0.6-0.8 authors. All of these fore mention categories have a median at 1 in the whole time period. The median has risen to 2 authors for Education & Educational Research, Anthropology, Social Work, Sociology, Women's Studies and Demography. These categories, except Sociology, have a mean number of authors between 1.4-1.6 authors in 1980, which has increased to 2.2-2.9 in 2013. The mean number of authors has only increased with 0.5 for Sociology.

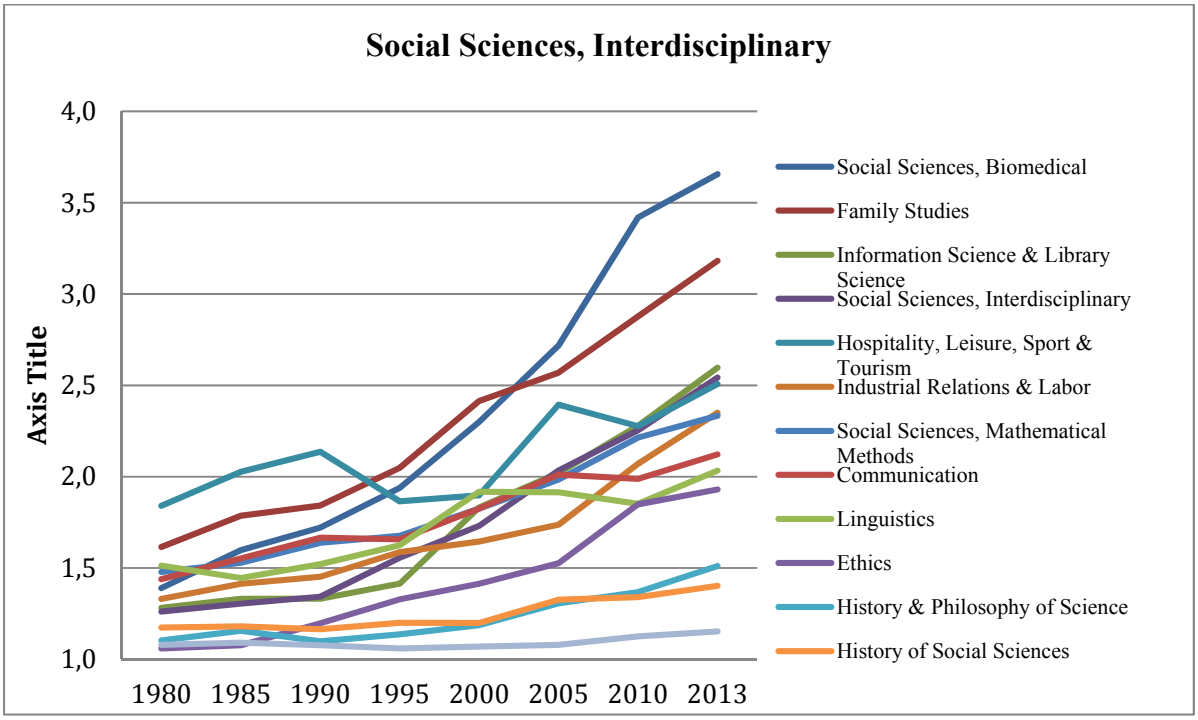

Figure 6. The mean number of authors per publication from 1980-2013 of the group Social Sciences, Interdisciplinary.

694,752 publications are indexed in the categories in the group Social Sciences, Interdisciplinary. The mean increases in numbers of authors are between 6.8%-163% or between 0.1-2.3 authors. Figure 6 demonstrates how much the increase in the numbers of authors varies from 1980 to 2013. The category History hardly had any changes in the mean number of authors and the median remain constantly at 1 during the time period. The median also remains at 1 author in the categories History of Social Science, History & Philosophy of Science and Ethics, while the mean rises from 1.1-1.2 authors in 1980 to 1.4-1.9 authors in 2013. The median increases from 1 to 2 authors in the categories Communication, Information Science & Library Science, Industrial Relations & Labor, Linguistics, Social Sciences, Interdisciplinary and Social Sciences, Mathematical Methods and the mean numbers of authors increases from 1.3-1.5 authors to 2-2.5 authors. The median is constant at 2 authors in Hospitality, Leisure, Sport & Tourism, where mean number of authors rise from 1.8 authors to 2.5 authors. The median increases from 1 author in 1980 to 3 authors in 2013 in the categories Family Studies and Social Sciences, Biomedical and the mean numbers of authors rises from 1.4-1.6 authors to 3.2-3.7 authors. In this very mixed group we can see how the categories with research closest to the humanities such as History, History of Social Science, History & Philosophy of Science and Ethics have a lower rise in the number of mean authors, while the categories Family Studies and Social Sciences, Biomedical, that both are methodological close to the life and medical sciences have had a substantial high rise in number of authors.

Discussion

In this study we document the evolution of co-authorship in the social sciences and find that the majority of research fields have had substantial increases in the numbers of authors per publication. During the 33 years the increase is equal to one author or more in

31 out of 56 subject categories, and in further five subject categories, the increase is nearly 1 author (0.9). We detect a similar increase when we include the median increase in the number authors, where the median number of authors has increased by one or more authors in 42 out the 56 subject categories. The increases in the number of authors have not happened in the same degree in all areas of the social sciences and illustrate how heterogeneous the research fields of social sciences are. The articles indexed in the four subject categories History, Cultural Studies, Area Studies and History of Social Sciences have only had a mean increase in the number of authorship between 0.1-0.2, and could be categorized as status quo during the 33 years. The percentage increases in the mean number of authors in the subject categories varies from 6.8% (History) to 175.6% (Health Policy & Services).

The results of this study confirm that there is an increasing tendency to co-author and collaborate and is in line with the tendency detected in previous studies of co-authorship and collaboration (e.g. Bebeau & Monson, 2011; Fisher et al., 1998; Ossenblok et al., 2014). Namely that the number of authors per publication has increased in the social sciences and that the largest increases have occurred in the fields with use of experiments, large data set, statistical methods and/or team-production models, such as the Social Health Sciences and parts of Psychology. A good example in our study of how the methodological differences affect the collaboration patterns is the subject categories group as Psychology. The subject categories Psychology, Psychoanalysis and Mathematical are both examples of research domains dominated by theory building and abstract concepts and with methodological relationships to research fields often defined as belonging to the humanities. The opposite are Psychiatry and Developmental Psychology, where the research are more experimental and empirical, and often sampled in collaboration with other researchers. Hence, the greatest rises in number of authors have occurred in subject categories containing research fields using quantitative methods and with a close relationship to the medical and life sciences or the natural sciences. An additional explanation for the rise in co-authorship in the majority of the subject categories is the increasing tendency for supervisors to co-author with students (Costa & Gatz, 1992; Fisher et al., 1998; Price et al., 2000).

Conclusion

As mentioned in the introduction, most of the bibliometric studies about co-authorship and research collaboration in the social sciences have been focusing on the trends and patterns in particular research fields or countries and have been based on data collected from a selection of journals in one or few research fields or national databases. In this study we use a larger sample of articles to confirm there is a rise in co-authorship in the majority of the research fields in the social sciences, and that in more than half of the subject categories the mean number of authors has increased by one or more authors.

Few of these studies undertake a deeper investigation of the rise of co-authorship and research collaboration (Costa & Gatz, 1992; Fisher et al., 1998), and the explanations offered for the rise is often speculative and anecdotal or borrowed from the “hard” sciences. We have discussed some of the factors that influence the researchers’ collaboration behavior and the rise in co-authorship. However, our explanations are based on the fore mention studies, and we therefore suggest that the next step is a thoroughly

investigation of the effects of these factors in the fields we have documented a rise in co-authorship.

The Recurrence of Citations within a Scientific Article

Abstract
Although listed at the tail of a scientific article only once, a reference is usually cited repeatedly inside the full text of the article. In this research, we investigated the universality of recurring citations in Journal of Informetrics. About 1/4 references are repeatedly cited. For these repeatedly cited references, their citation location and citation context for the first and subsequent times are examined separately. Normally, recurring citations of a same reference tend to be located in the same section instead of different ones. It proves that, even if a reference is cited for multiple times in a single citing paper, it is still focus on the same topic in the same section most of the time. We also explored the reason why recurring citations are happening. By comparing the contexts of two kinds of citations, the first-time citations and the succeeding citations, we found that, for a specific reference, its first-time citation is usually not as intentional as the succeeding citations. Just because of the relative importance of the succeeding citations compared to the first-time citation, recurring citations are reasonable and necessary.

Conference Topic
Citation and co-citation analysis

Introduction
Citations are essential components for scientific articles. Traditional citation analysis is more like reference analysis, since only references listed at the tail of the article are researchers' concern. Citations, which indicate the locations and context where references are cited, are almost ignored in previous research. The reference analysis is much easier and effective most of the time, but in the meanwhile, some important information might be neglected. For example, where are these references are cited inside the citing papers? How are the citations distributed among different sections? By investigating the citation location and the citation context, however, we can understand not only the pattern how references are cited, but also the reason why authors cite it like that.

Nowadays, full-text citation analysis, which is about how references are cited in the body of citing papers, is just beginning (Ding, Liu, Guo, & Cronin, 2013; Hu, Chen, & Liu, 2013; Liu, Zhang, & Guo, 2013; Zhang, Ding, & Milojević, 2013). During to the increasingly availability of structured full texts such as XML-formatted articles, researchers began to turned their attention from references to citations in the body of articles. For example, Ding et al. have examined the distribution of references across text and find that most highly cited works appear in the Introduction and Literature Review sections of citing papers (Ding et al., 2013). Hu et al. visualize the location distribution of citation instances, especially those to highly-cited references. The results show that citations are usually distributed very uneven inside the full texts of scientific articles (Hu et al., 2013).

In full-text citation analysis, recurring-citation is an interesting issue. Recurring-citation refers to the phenomenon that a reference is cited more than once in a citing paper. Take this paper for example, we cite the reference of (Hu et al., 2013) in the first sentence of last paragraph for the first time, and then cite it again in the last sentence of the same paragraph for the second time. In this paper, we call this reference a repeatedly cited reference, or a reference with recurring citations. Recurring-citation is a common fact in citation behaviour. In our previous research, we find that, sometimes, a reference might be repeatedly cited as many as nine times in a single paper (Hu et al., 2013).

In this research, we will investigate the phenomenon of recurring citations. Our concern is the universality and the pattern of recurring-citations, including: (1) how common recurring citations are in scientific articles? (2) where the recurring citations of a single reference are usually located inside the paper? (3) what the difference is between its first-time citation and the succeeding ones? In the end, the reason why recurring-citation is necessary will also be discussed.

Data and Methods

To detect recurring citations of a reference inside a citing paper, the full text of the citing paper need to be observed. There are two types of full texts: one is in unstructured format such as PDFs, which is human-friendly; the other is in structured format such as XMLs/HTMLs, which is machine-friendly. Compared with PDFs, structured full texts, e.g., XMLs, are much easier to process by computer. For example, XML-formatted full texts can be parsed directly using an existing function: *xml_parse()* in PHP. Thus, it is very straightforward to identify citations inside a citing paper. Nowadays, structured XML-formatted full texts are available and downloadable in almost every bibliographic database, such as Elsevier, Springer, John & Wiley, and especially, the open access online journals like PLoS ONE. In this study, the data of full texts was sourced from Elsevier ConSyn (http://consyn.elsevier.com), a content syndication system developed by Elsevier. Since 2011, Elsevier ConSyn provided downloadable articles in XML format.

In Elsevier ConSyn, we retrieved and downloaded all the full texts of 350 articles published in Journal of Informetrics (JOI) from 2007 to 2013. Journal of Informetrics is chosen as the case in this study because it is published by Elsevier and belongs to the field of library and information science. By our own developed program, we parsed these XML-format full texts and extract all the citations inside them. Since each citation instances is clearly marked with a XML tag, i.e. <*ce:cross-ref*>, they can be recognized and extracted easily. All the attributions of each citation, including its location and its citees, were recorded and import into database tables.

By looking into citations' citees, we achieved the cited times of each reference inside each citing paper. If the cited times is equal to one, it means the reference is one-time cited inside this citing paper. While if cited more than once, the reference is considered as repeatedly cited or recurrently cited. In this research, we will count the frequency of each type of reference, e.g., once-cited, twice-cited, triple-cited, etc. In this way, the universality and intensity of recurring-citation can be estimated accordingly.

For repeatedly cited references, their citation locations will be studied. The location of citation can be measured by, from macro to micro scales: character, word, sentence, paragraph and section. In this study, we chose the measurement at the largest scale: section. We will calculate the count of citations in each section and see how citations are

distributed in different sections. Generally, a scientific article is made up of four sections, namely *Introduction*, *Data and Methods*, *Results,* and *Discussion and Conclusions*. It is called IMRaD structure usually (see e.g. Agarwal & Yu, 2009; Swales, 1990) To some extent, citation location can reveal the citation motivation. If we are aware of the section where a citation is located, the role of the citation can be figured out to some extent. For instance, if a reference is cited in the section of *Data and Methods*, usually section II, it is probably a helpful citation relevant in the aspect of methodology; while if it located in the section III or the section of *Results*, the citation is more likely about comparable results.

Besides the location distribution of recurring citations, we also examined the difference between a reference's first-time citation and the succeeding ones. We extracted the context when a reference is cited for the first time and when it is cited again in the following parts. The first-time and the succeeding citation contexts will be compared in terms of the count of their citees inside. The more citees/references a citation contains, the less important each citee/reference is. The citation with many citees/references, such as the one in the first sentence of the second paragraph, is called perfunctory citation (Cano, 1989; Oppenheim & Renn, 2004; Pham & Hoffmann, 2003; Voos & Dagaev, 1976), which means authors decide not to cite the citees/references seriously in an excluded way. In this research, we are interesting in which one, the first-time citation or the succeeding citation, is more likely to be perfunctory citation for a multiple-cited reference.

Results and Discussion

The universality of recurring citations

Firstly, we examined how common recurring citations are in the Journal of Informetrics. Among all the 11,327 references inside the 350 articles, 8,417 (74.3%) of them were cited once in a single citing article. The other 2,910 references (account for 25.7%) were cited twice or more, including 1,726 (15.2%) twice-cited references, 613 (5.4%) triple-cited references, and 571 (5.0%) references cited for four times or more. Although one-time citation is the main citation pattern undoubtedly, the phenomenon of recurring-citation cannot be ignored in both frequency and intensity.

Figure 1 shows the frequency distribution of references of each kind, companied with a distribution graph in double logarithmic coordinates. As it shown in the best fitting line, the frequency distribution of multiple citations follows a power law ($y= 21557\ x^{-3.479}$, $R^2=0.9679$), which is a very common law in the field of bibliometrics, such as the distribution of scientific productivity (Lotka, 1926) or keywords (Zipf, 1949). Obviously, it is not accidental that the frequency distribution of recurring citations is in this pattern.

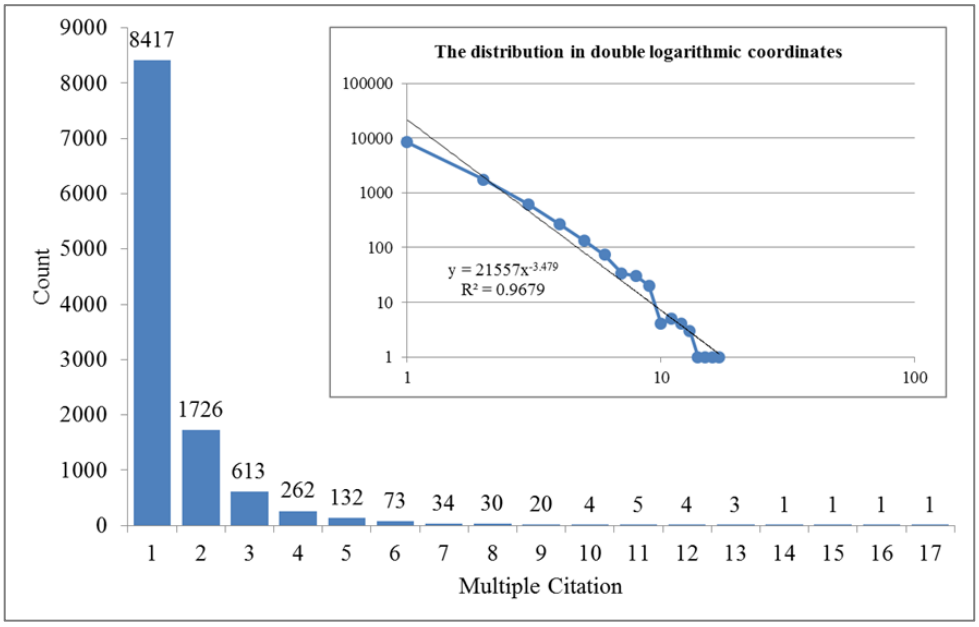

Figure 1. The count of references by their multi-citation times.

The locations of recurring citations

The location pattern of recurring citations is the focus of this research. In this part, we will investigate the location distribution of multi-citation by section. In Journal of Informetrics, 92 articles (26.3% of all) adopt IMRaD structure, which is most used form to organize articles in our research. Thus, we selected all these 92 four-section articles in IMRaD structure as cases, and explored how citations are distributed in the four different sections.

As shown in Figure 2, among all the 3035 citations in these 92 articles, 1238 (40.8%) citations are located in Section I, or the section of *Introduction*; 760 (25.0%) of them are located in Section II (or *Methods*); 769 (25.3%) citations is in the sections of *Results*; and 268 (8.8%) in *Discussion and Conclusions*. This mode of section distribution of citations meets our expectation on citation locations, since it is the widely accepted fact that authors are likely to cite most in the section of *Introduction*.

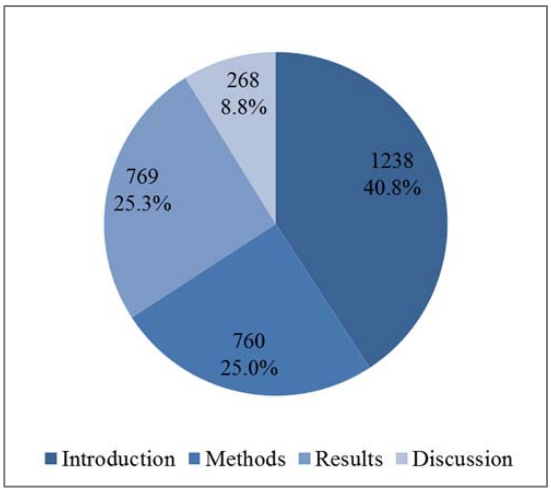

Figure 2. The count of citations in each section.

Based on the section distribution of citations, we are then able to investigate the section combination distribution of a reference's recurring citations. For each repeatedly cited reference, its recurring citations could be located in any sections, either the same section or the different sections. Since twice cited references are the simplest and most common (59.3%) types of repeatedly-cited references, they were chosen for calculating combined-section distribution.

For each twice-cited reference, we recorded the located sections of both citations. The counts of the 10 types of section combinations are shown in Table 1. Among all the 796 twice-cited references, the most common ones are those cited in Section I for both the first and the second time. 224 (28.2% of all) references belong to this type. 124 (15.6%) references are cited in Section I for the first time and Section II for the second time. References that are cited in section IV twice are least common (18 or 0.8%). Totally, 444 (55.8%) references are cited in the same section twice, while 350 (44.2%) ones are cited in the difference sections.

Table 1. The combined section distribution of the twice citations of references

Located Section of the second citation / Located section of the first citation	*Sec I*	*Sec II*	*Sec III*	*Sec IV*
Sec I	**224** 28.2%			
Sec II	**124** 15.6%	**90** 11.3%		
Sec III	**68** 8.6%	**42** 5.3%	**112** 14.1%	
Sec IV	**64** 8.1%	**24** 3.0%	**28** 3.5%	**18** 2.3%

Although more twice cited references are cited in the same section, we cannot say that a reference's multiple citations tend to be located in the same sections except that the expected proportion of the multiple citations located in the same section is calculated and compared. Thus, we assume that a reference's twice citations are located independently and randomly, just like two arbitrary citations in the article. Under this hypothesis, the expected distribution of section combinations of twice citations can be calculated as follow:

(Sec I, Sec I) : (Sec I, Sec II) : (Sec I, Sec III) : (Sec I, Sec IV)

: (Sec II, Sec II) : (Sec II, Sec III) : (Sec II, Sec IV)

: (Sec III, Sec III) : (Sec III, Sec IV)

: (Sec IV, Sec IV)

= 40.8%×40.8% : 40.8%×25.0%×2 : 40.8%×25.3%×2 : 40.8%×8.8%×2
: 25.0%×25.0% : 25.0%×25.3%×2 : 25.0%×8.8%×2
: 25.3%×25.3% : 25.3%×8.8%×2
: 8.8%×8.8%

=16.6% : 20.4%: 20.7% : 7.2% : 6.3% : 12.7% : 4.4% : 6.4% : 4.5% : 0.8%

Figure 4 shows the expected and observed proportions of the section combinations of each kind. If the expected values match the observed well, it means the twice citation are located independently and randomly indeed; otherwise, it means that there is a certain tendency in how to cite a reference twice. In Figure 4, we have not seen the match between the expected and observed values. For example, based on our initial hypothesis, the proportion of (Sec I, Sec I) should be 16.6%, not even closed to 28.2% as observed; the proportion of (Sec I, Sec III) should be 20.7%, while the observed value is 8.6%, which is much lower. Neither of them presents the match as assumed.

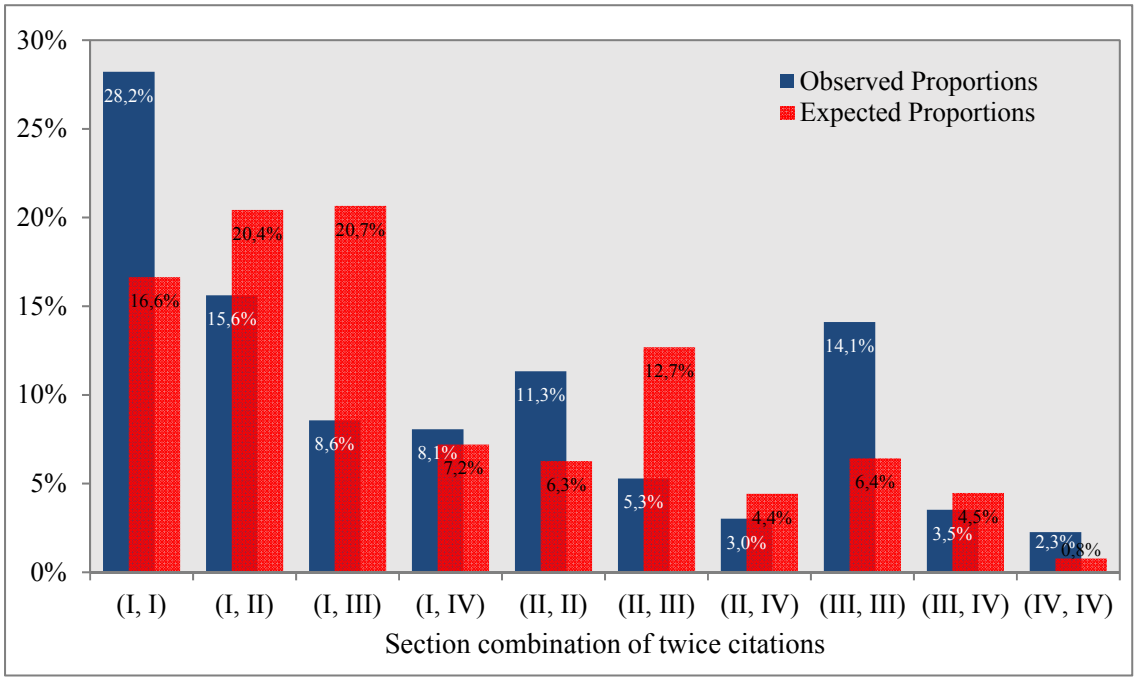

Figure 3. The distribution of the expected and observed proportions of located section combinations of twice citations.

According to the comparison between the expected and observed values, these 10 combinations can be divided into two classes: the above-expectation combinations and the below-expectation ones. The combinations of (Sec I, Sec I), (Sec II, Sec II), (Sec III, Sec III), (Sec IV, Sec IV) and (Sec I, Sec IV) belong to the former. Their observed proportions are higher than expected significantly. The other 5 combinations, i.e., (Sec I, Sec II), (Sec I, Sec III), (Sec II, Sec III), (Sec II, Sec IV) and (Sec III, Sec IV), belongs to the latter. From this division, we can see that, the references with twice citations located in the same section are preferable to those with twice citations located in different sections. The only exceptions are the references cited inside (Sec I, Sec IV), which have an above-expectation proportion (2.3% v.s. 0.8%), though its twice citations located in the different sections.

Why do authors tend to cite a reference multiple times inside the same section? The explanation could be simple. Normally, a reference is only helpful for a single topic, usually existing in a concentrated part of an article, such as a section. Few references are necessary for several different topics, or in different sections. That is why references are

preferred to be cited in a single section. This explanation also interprets why the combination of (Sec I, Sec IV) is an exception. The first and the fourth section, although farthest away with each other, are actually discussing about the same topic at the same level, i.e., the hindsight and foresight of research questions.

The context of recurring citations

We have revealed how common recurring citations are and where these recurring citations are usually located, and now we will examine their contexts. Firstly, the citation contexts of repeatedly cited references for the first and the succeeding times were extracted separately. There are totally 11,448 first-time citation contexts and 5,469 succeeding ones extracted. We will explore the difference between these two groups of citation contexts in terms of citation intensity, which can be estimated by how many citees they contained.

The count of citees contained in each citation context is calculated one by one. Averagely, a citation contains 1.94 citees, or put it another way, authors cite 1.94 references once at a time. As it shown in Figure 6, although most citations (64.2% of all) cite only one single citee/reference, there are still more than 1/3 of citations contain two or more citees/reference. 1457 (8.7%) citations cite even five or more references once.

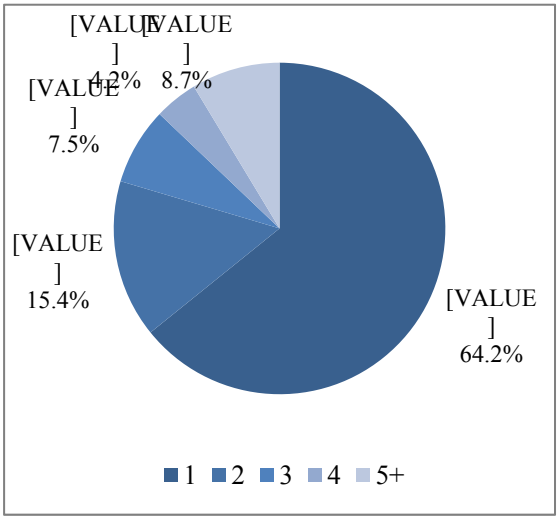

Figure 4. The distribution of citations by the count of contained citees.

Separately, the counts of citees contained by the first-time and succeeding citations are investigated. The first-time citations contain 2.13 citees on the average, while the succeeding citations contain 1.94 citees. Figure 5 shows the specific distribute of both of them by their count of contained citees. For the first-time citations, totally 38.5% of citations cited two citees or more; while for succeeding citations, only 30.1% did. It means the first-time citations are more likely to be perfunctory citations than the succeeding citations. In other words, authors normally cite a reference more casually and perfunctorily for the first time; and then cite it again in the following paragraphs more formally and solemnly. In other words, usually, authors just mention a reference in the beginning, and then seriously use it when citing it later again.

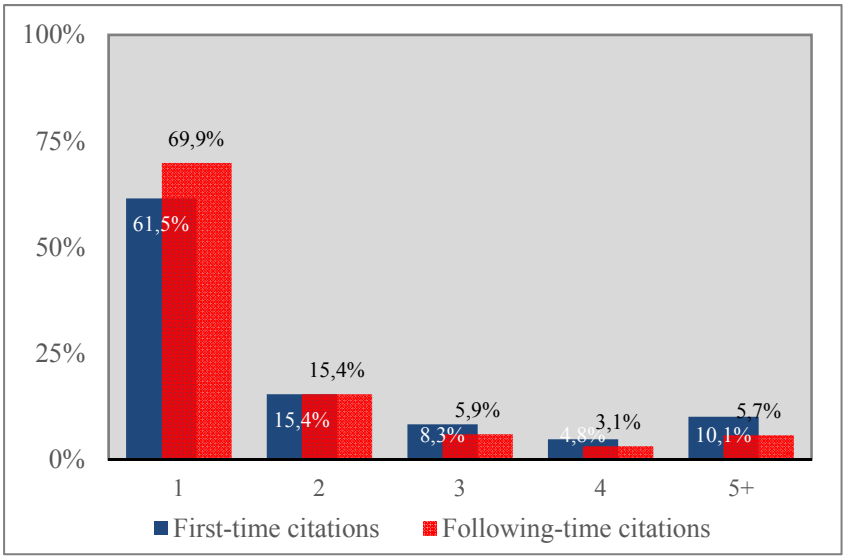

Figure 5. The distribution of the first-time and succeeding citations by their count of contained citees.

Conclusions

Recurring citations are common in scientific publications. In Journal of Informetrics, about 1/4 references are repeatedly cited in citing papers. Although not the mainstream of citation pattern, recurring-citation is undoubtedly a phenomenon that cannot be ignored in full-text citation analysis, an increasing hot research field in recent year.

In this study, we investigate the recurring-citation phenomenon in two perspectives: the citation location and the citation context. In citation location analysis, we find that a reference's recurring citations tend to be located in the same section or closely with each other. It shows that a reference is only cited in a single topic normally. When the topic switches, the reference has little chance to be cited again.

The context of recurring citations contexts are also examined in terms of their citation intensity. As it shown in the result, for a repeatedly cited reference, its first-time citation is usually kind of perfunctory. The reference is always cited accompanied with other references together. When it is cited another time in the following part of the citing paper, the citations are more exclusively and solemnly. Precisely because the succeeding citations are usually more importantly, recurring citations are reasonable and necessary inside scientific articles.

Abstract
Author bibliographic coupling is extended from bibliographic coupling concept and holds the view that two authors with more common references are more related and have more similar research interests. This study aims to examine the association between author bibliographic coupling strength and citation exchange in Information Science & Library Science and more specifically, in imetrics. The results show that there is a positive and significant association between these two factors in Information Science & Library Science and also in imetrics; however, the correlation is more significant among imetricians. This confirms the Merton's norm of universalism versus constructivists' particularism. A closer investigation of bibliographic coupling and citation networks among thirty highly cited imetricians shows that Thelwall, M. is in strong bibliographic coupling and citation relationships with the majority of authors in the network. He and Bar-Ilan have the strongest ABC and citation relationships in the network. Rousseau, R., Glänzel, W., Bornmann, L., Bar-Ilan, J., and Leydesdorff, L. are also in strong ABC relations with each other as well as other authors in the network.

Conference Topic
Citation and co-citation analysis

Introduction
Bibliographic coupling (BC), first introduced by Kessler in 1963, refers to the number of common references between two articles. The more the number of common references between two articles, the more intellectually related they are.

In contrast with co-citation analysis (CA) requiring strength signals (number of citations), BC could help in research fronts detection even with weak signals (Glänzel & Czerwon, 1996). Kuusi and Meyer (2007) claimed that BC has never been used for exploring technology foresight and rare studies used it for research evaluation purposes. However, they used BC for anticipating technological breakthroughs. Yan and Ding (2012) compared different types of networks, including citation based and non-citation based networks at institutional level, and found that BC and AC networks have high similarity and also found that AC has a high similarity with citation networks. Boyack, Börner and Klavans (2009) applied BC to mapping the structure and evolution of research publications in Chemistry. Soó (2014) proposed age-sensitive BC, so if two documents share recent references, they are more related than those sharing older references. Hence, not only the number of common references, but also their age, influences the extent of relatedness between two research works. Van Raan (2005) also reported that intellectual relatedness between two documents could be better obtained through using common

references that are more recent. BC is an effective way for science mapping, research fronts detection and information retrieval (See Jarneving, 2007, 2005; Morris, Yen, Wu, & Tesfaye, 2003; Qiu, 2007). Peters, Braam and van Raan (1995) investigated chemical engineering publications and found that publications with common citations to highly cited papers are more related. White et al. (2004) claim that intellectual ties based on shared references could serve as a better predictor for citations between authors than social ties.

Author bibliographic coupling (ABC), first proposed by Zhao and Strotmann (2008), is extended from BC concept and holds the view that two authors with more common references have more similar research interests. They mentioned that BC is fixed when two articles are published but ABC is constantly evolving over time as the two authors' oeuvre grows. Ma (2012) stated that ABC has an advantage in providing a more comprehensive and concrete map of intellectual structure of the fields and detecting their research fronts in comparison to author co-citation analysis (ACA). The very few studies on ABC did only an author coupling analysis of intellectual structure of few subject fields. For example, using a combination of ACA and author bibliographic coupling analysis (ABCA), Zhao and Strotmann (2014) sought to predict future research trends in information science (IS). They studied research fronts and knowledge bases of IS and also the structural evolution of IS between two 5-year periods (2001-2005 and 2006-2010). They found ABCA an appropriate method to investigate authors' specific research interests in IS and suggested using ACA and ABCA together to better investigate intellectual structure of a subject domain. The same combined method was used in Byun and Chung (2012) to study the research trends of authors in social welfare science; they also suggested using both ACA and ABCA together to investigate traditional and future research trends of a specific domain.

The extent to which two authors are coupled through common references is measured by ABC strength which has different methods to calculate it: Simple, minimum and combined methods (Ma, 2012). Rousseau (2010) also proposed a simple method for calculating the relative ABC by dividing the number of common references between two authors by the total number of their references. Frequency of common references was simply used to measure ABC strength in this study.

No research on the association between ABC strength of two authors and number of citations exchanging between them is found, so this study seeks to examine this relationship in Information Science & Library Science (IS&LS) and more specifically, in imetrics. Therefore it aims to examine the correlation between ABC strength measured by the number of common references between two authors and the number of citations exchanged between them.

Research questions

According to the normative theory of citation, citations are indicators of the cognitive or intellectual influence of a scientific work (Merton, 1973). In a scientific paper, citations can be concept markers (Small, 1978), however, and can transfer knowledge and help with its enlargement (Merton, 1988). As a result, methods like CA have been used for mapping intellectual structure in science (Small, 2004), where BC is used for the same purpose. Hence, common references between pairs of documents, authors, journals or institutions show the extent to which they are related. For instance, two authors who

share a larger number of common references are likely to do research on a narrow area and exchange a high number of citations. Counting citations between two authors with different BC strengths, not only could support Robert K. Merton's norm of universalism versus constructivists' particularism, but also shows any possible difference by the number of common references as a measure of relatedness and types of authors (i.e. highly cited vs. less cited authors).

The theories of citation, normative view vs. social constructivist view, will be examined through answering these questions. The normative theory of citation holds that citations reflect the scientific quality and merits of research outputs because citers use them to reward the works of their colleagues (Small, 2004; White, 2004; MacRoberts & MacRoberts, 1987; Merton, 1973) whereas the social constructivist theory holds that authors use the references to support their own claims and points made. This latter theory emphasises factors affecting citations other than the quality and content of the cited article (White, 2004; Baldi, 1998; Gilbert, 1977).

Given that BC shows relatedness, a positive association between the number of common references and number of citations between two authors will confirm that citations are made for the matter of 'relatedness' and are not perfunctory.

To reach the research goals, this study seeks to answer these questions:

1. Do two authors with a higher number of common references cite each other more often?
2. Is the above association stronger for highly cited authors than other authors?

Methodology

Data collection:

Documents published during 1990-2012 in the journals of Information Science & Library Science (IS&LS) were extracted from Thomson Reuters Web of Science (WoS). This time period is current and consists of a reasonable number of years for investigating the relationship between number of common references and citations exchanged between authors. WoS indexes the mainstream of research and the most prestigious journals in different fields of science; however, a large number of journals in WoS come from a small number of international publishers (Didegah & Gazni, 2011).

Author names disambiguation:

The author names were disambiguated by improving Gazni & Thelwall (2014) method, resulting in 98.2% precision and 92.7% recall. The co-authorship network of authors was used for the improvement. For example, A is a disambiguated author and B is his/her co-author. The papers written by both A and B as co-authors were appended to A's articles. Author names' disambiguation will improve the accuracy of research on author level analysis by distinguishing one name that belongs to several different people and conflating the name variants of a single person.

Calculations:

To make the processing manageable, a random sample of 385 authors with any properties out of all authors who have at least one paper in the journals of IS&LS during 1990-2012

was chosen. The number of common references between these 385 authors and all other authors in the field were counted, where the joint papers were eliminated either for counting the number of common references or for counting the number of citations made and received between each pair of authors. Only citations made and received from the journals in the field were processed for either counting the number of citations between authors or counting the number of common references among them. A list of authors who have at least one common reference with the authors in the sample, and also exchanged citations with them, was created for each author in the sample. For a closer investigation of the association between the number of common references and citations between pairs of authors and also of ABC networks, a sample of highly cited authors in imetrics was taken into account. For this purpose, thirty highly cited imetricians introduced in Abrizah and colleagues (2014) were selected for further analysis. The main reason for taking this sample into account is that these are prolific authors in a specific domain, publishing for a long time and have an excellent knowledge of the domain, its publications and researchers. This is while in the sample of authors from IS&LS, there may be less prolific authors, such as students who publish for a short period of time and then disappear from the research area, and their unfamiliarity with the area will affect their reference and citation behaviours. Therefore, a sample of thirty highly cited imetricians is a consistent sample for showing the association between ABC strength and citation exchange between pairs of authors.

Results

The association between number of common references (BC strength) and number of exchanged citations between pairs of authors in IS&LS

Spearman correlation was tested for the association between the number of common references and the number of citations exchanging between pairs of authors. The results show positive significant correlations between the number of times two authors cited each other and the number of common references between them. The correlation was tested for different groups of pairs of authors with one to 300 common references; it is stronger for the groups of authors with 300 common references than those with a single common reference (Table 1). Therefore, as the number of common references between two authors increases, the number of citations between them also increases. Table 1 shows the increase trend; however, the correlation fluctuated as the number of common references increases but tends to increase. To put it in another way, when the bibliographic coupling strength is stronger between two authors, they tend to cite each other more often. Author bibliographic coupling strength shows how strongly two authors are intellectually related. So, more intellectually related authors cite each other more often. This result confirms the normative theory of citation holding the view that authors cite relevant works, and citations reflect scientific merit and quality.

ABC strength and citation relationship among thirty highly cited authors in imetrics

Thirty highly cited authors in imetrics identified in Abrizah and colleagues (2014) were chosen for a closer investigation of research goals. The main research question on the association between ABC strength and number of exchanged citations was also examined for this group of highly cited authors. Spearman correlation test shows a strong positive association between the number of common references and the number of citations between the authors (Spearman's rho= 0.771, p-value< 0.001), once more confirming the significance of content relevance in citation behavior and normative view of citations.

Moreover, all ABC relations are mapped between each pair of highly cited authors (See Fig. 1). Based on the results, all thirty authors are in BC relationships with all or some of other authors in the network except for Griffith, BC. During 1990-2012, he has published 4 papers in imetrics and has no common references with any of the highly cited authors.

Thelwall, M. is in strong BC relationships with all other authors except with Vanleeuwen, T.N. (only one common reference) and VanRaan, A.F.J. (three common references). He and Bar-Ilan, J have shared the highest common references in the network (4,527 common references) and they have exchanged a large number of citations in the network (118 citations). Thelwall, M. has more than 100 common references with 18 authors in the network. He is also in a strong BC relationship with Vaughan, L. (2,725 common references). Thelwall, M. has also exchanged the highest number of citations in the network with Vaughan, L. (195 citations). He has also strong BC ties with seven others, Leydesdorff, L., Ingwersen, P., Rousseau, R., Cronin, B., Glänzel, W., and Egghe, L., respectively.

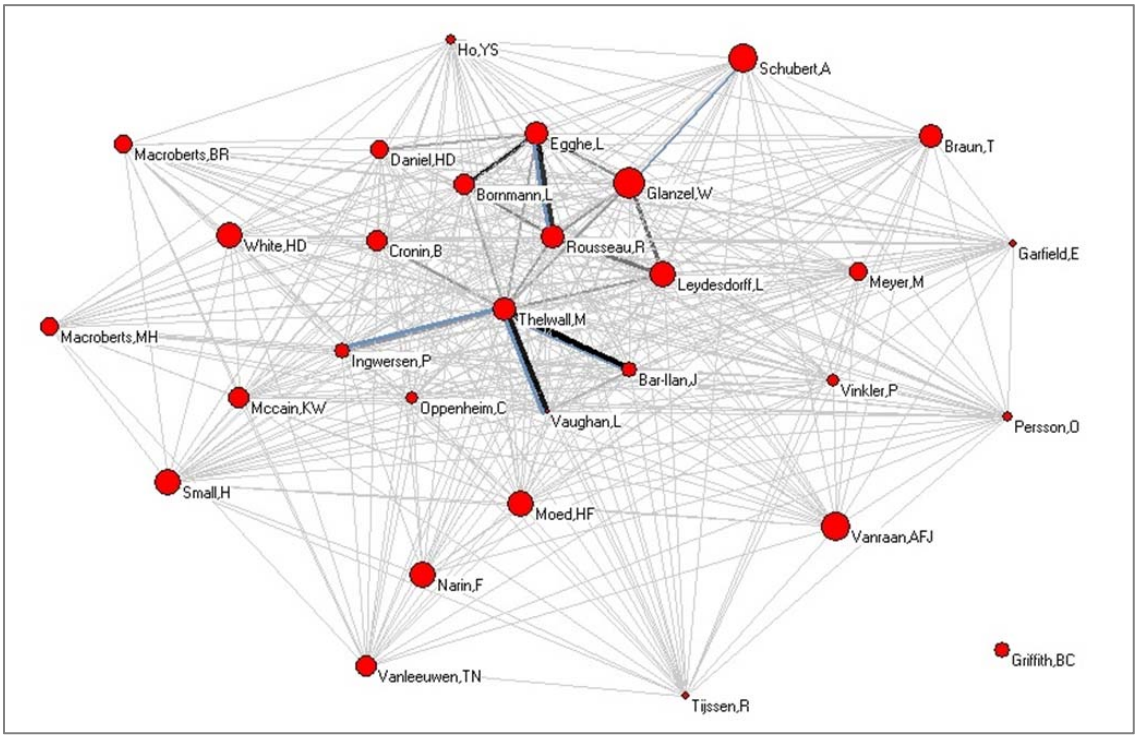

Figure 1. ABC among highly cited authors in imetrics; the black lines show ABC relations and the width of the lines shows ABC strength between pairs of authors; the blue lines show the strongest citation relations in the network and the width of the lines shows the number of citations exchanged between pairs of authors; the size of vertices shows the number of other highly cited authors in the network that each author is in an ABC relation with.

Another strong ABC relationship, and also citation relationship, is seen between Rousseau, R and Egghe, L. (2,270 common references and 175 exchanged citations). Rousseau, R is also in strong BC relationships with other authors in the network. He has strong BC ties with Leydesdorff, L., Bornmann, L., Glänzel, W., and Thelwall, M., respectively.

Glänzel, W., Bornmann, L., Bar-Ilan, J., and Leydesdorff, L. are also in strong BC relationships with other authors in the network. They also have strong citation relationships with each other as well as other highly cited authors.

The correlation between ABC strength and citation exchange in imetrics in comparison with IS&LS

The correlation between the number of common references and the number of citations for top thirty imetricians was examined first amongst themselves and then between them and all other authors in IS&LS with whom they are in BC or citation relationships. As shown in Figure 2, a stronger relationship exists between the authors in the first group than in the second one and regarding the top thirty imetricians, the correlation varies from one author to another one.

For each highly cited imetrician, the proportions of common references with each in-group authors was estimated. Fig. 3 shows that each highly cited author is in a BC relationship with 27 other in-group authors. For example, about 24% of references of

each author are common with one other author. The author distribution of the number of common references with other authors demonstrates a core-scatter shape.

Core references in imetrics

We tried to go further than author couples for common references and identified a number of common references between three and more authors. The thirty highly cited authors in imetrics were examined for this purpose.

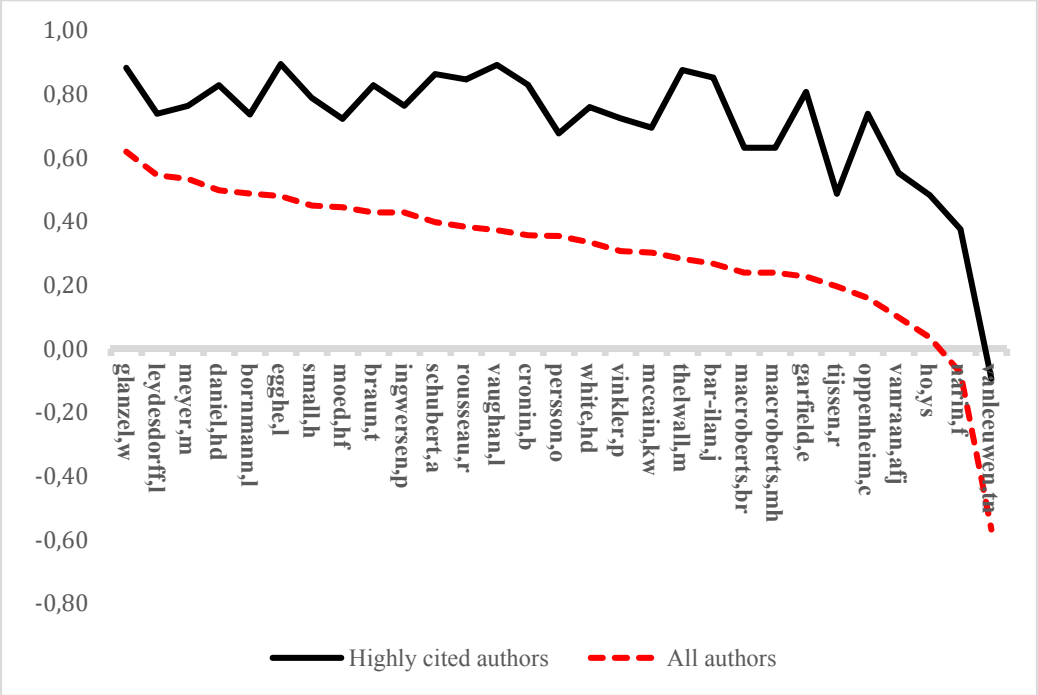

Figure 2. ABC strength and citation correlation between highly cited authors and all authors in IS&LS.

The interesting result is that seventeen highly cited imetricians have one reference in common. The common reference is Hirsch's paper on H-index (Hirsch, J.E. (2005): An index to quantify an individual's scientific research output. *Proceedings of the national academy of sciences of the United States of America*, 102 (46)). Egghe, L., Rousseau, R., and Bornmann, L. have cited this paper more than thirty times in their publications showing that the H-index is one of their common research interests. It is interesting to note that Egghe, L. and Rousseau, R also have the strongest citation relationship with each other in the network (seventeen5 citations have been exchanged between them) and these two imetricians are also in a strong citation relationship with Bornmann, L. with Bornmann, L. being the fourth top author in citation relationships with both Egghe, L. and Rousseau, R. The strong citation relationships between these authors are mainly due to their similar research interests, one of which is H-index. Twelve highly cited authors have simultaneously five references in common which are listed in Table 2. Eleven authors have nine references and ten authors have eleven references in common.

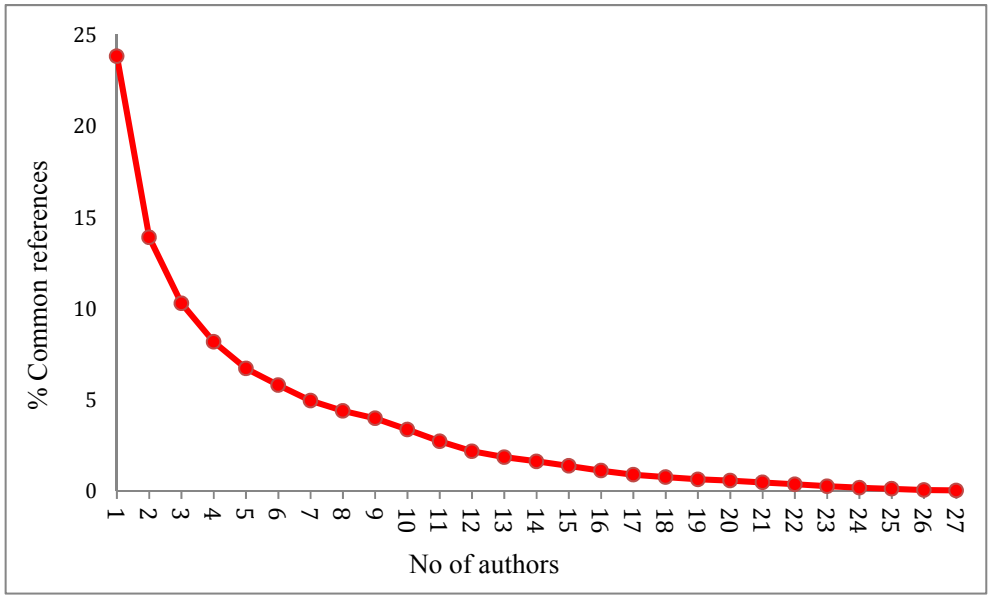

Figure 3. The proportion of common references between each of thirty highly cited imetricians and other in-group authors.

Table 2. Five common references between twelve highly cited imetricians.

Discussion and conclusion

This study examined the association between author bibliographic coupling strength and the number of times authors cited each other. The results of the study on authors in IS&LS showed that there is a positive and significant correlation between ABC and exchanged citations between two linked authors confirming that authors are citing related authors and relevant research works in their field (Table 1). This finding opposes the social constructivist view holding that authors cite others for some other reasons than relevance or rewarding the cited author, but it confirms the normative theory of citations. A group of thirty highly cited authors in imetrics were also examined for this purpose. The result of the association between ABC and the number of citations shows a positive strong correlation between ABC and exchanged citations between imetricians. Therefore, highly cited authors in imetrics are in strong BC relationships with whom they also have strong citation relationships.

The number of common references between pairs of authors was accepted as a measure of relatedness between them. Therefore relatively, the higher number of common

references between two authors, especially in a long-term period, could show the extent to which they are working in similar research areas; however, authors may change their research interests over time due to changes in the research fields. The higher number of citations between two authors with higher number of common references, when they are not co-authors, could probably show that they cite each other since they may work on similar research areas and also for the matter of relevancy.

ABC relations between the thirty highly cited imetricians were examined and mapped and strong relationships were determined. Thelwall, M. and Bar-Ilan, have the strongest ABC relationship in the network; they are also in a strong citation relationship. Rousseau, R., Glänzel, W., Bornmann, L., Bar-Ilan, J., and Leydesdorff, L. are also in strong ABC relations with each other as well as other authors in the network. In an investigation of the number of common references in groups of two and more imetricians, smaller groups have a larger number of references in common while larger groups have fewer numbers of common references. For example, seventeen imetricians have only one reference in common while some two-author groups have more than a thousand common references. The latter groups presumably work on narrow research areas. Larger groups with fewer number of common references suggest membership in a wider research area. The results show that a maximum of seventeen authors have one reference on H-index in common. Authors citing this single paper are also in strong citation relationship with each other.

Comparing the correlation between number of common references and number of exchanged citations for highly cited imetricians and all authors in IS&LS related to Fig. 2 shows that number of common references between imetricians increases the probability of higher citations between them more than that of IS&LS. Moreover, ABC relationship or common references with each single author may result in different number of citations with him/her.

Intuitively, considering the core-scatter distribution of citations to papers in the science network, an author probably has common references with a large number of other authors, while he/she probably has more common references with a fewer number of other authors (Fig. 3). The author presumably has more related research interests with the latter group of authors where some of them may belong to the same research community.

The number of common references and citations between pairs of authors could be also influenced by the number of papers published by the authors. For example, two authors may have five common references whilst the first author only published a single paper during his/her entire research life and the second one published more than twenty papers. The first author will have fewer common references with any other authors in the field than the second author and he/she will have less opportunity to cite other authors due to his/her short research life. So authors' research lifetime in the science network (e.g. newcomers, students, faculty members and professional researchers) does matter. Authors with a longer research life have more chances to know other researchers in similar research fields and they also have extra opportunities to focus on more specific and narrow research topics, compared to authors with a shorter research lifetime. Hence, a stronger association between the number of common references and citations exchanged between authors is found for the former group.

Science network and its attributes are continuously changing over time and a research specialty may appear or disappears after a while; authors may also change their research interests during their research lifetime. In the current study, a longer time span is used to

show that clustering authors, based on more recent common references, may be replaced by a shorter one, which could result in a stronger relationship between the bibliographic coupling network and the citation network. According to the results of current studies, authors with a longer research lifetime and more citations demonstrate a stronger relationship between their number of common references and citations. However, even weak ties in bibliographic coupling networks could also be used for research front detection purposes. Bibliographic coupling is not enough for mapping intellectual structure of science and measuring relatedness by itself. Thus, as with previous studies, it is better to be combined with other methods, such as co-citations, to realise better results.

Abstract
Citation context was used to measure the influence of highly cited papers. The themes of citation context were analyzed with bibliometrics methods. The citation context was classified into three categories as positive, negative and neutral. And the neutral citations were also classified into three sub categories, related work in background or introduction, theoretical foundation, and experimental foundation. The citation contexts of a highly cited paper of O'Keefe were extracted as the experiment data set. The results showed that the co-occurrence method was very useful for describing the themes of the citation contexts. The citation contexts of the selected paper were divided into five themes. The classification of citation contexts could provide more information about how and why a paper was highly cited. There was no negative citation in this experiment, and more than 10% citation contexts were positive citation. About 50% of the neutral citations were belonging to related work in background or introduction. The detailed influence of the target paper was also illustrated in our research.

Conference Topic
Citation and co-citation analysis

Introduction
Citation frequency is a commonly used indicator to measure the importance of a paper. Recently, *Nature* asked Thomson Reuters, which now owns the SCI, to list the 100 most highly cited papers published from 1900 to 2014. The results revealed some surprises, many of the world's most famous papers do not rank in the top 100 (Van Noorden, Maher, & Nuzzo, 2014). John P. A. Ioannidis and colleagues surveyed the most-cited authors of biomedical research for their views on their own influential published work. The results showed that the most important paper was indeed one of author's most-cited ones. But they described most of their chart-topping work as evolutionary, not revolutionary (Ioannidis, Boyack, Small, Sorensen, & Klavans, 2014). Although the citation frequency is an important indicator to measure the influence of a paper, it is hard to reveal why others always cited this paper and what influence it makes. Citation context refers to the text surrounding the references (Henry Small, 1982). It could provide more detailed information about citation.

In this paper, we take John O'Keefe's (Nobel Prize winner in Physiology or Medicine 2014) most influence paper as instance. The influence of this paper will be analyzed based on citation context. Our analysis will provide a richer understanding of which knowledge claims made by O'Keefe have had the greatest impact on later work.

Related work

Citation context analysis

Citation context can be defined as the sentences that contain the citation of a particular reference. For example, the sentence "This comparison is made using BLASTX [18]" is the citation context of reference [18].

Citation content can be used to identify the nature of a citation. The attributions and functions of a cited paper can be identified from the semantics of the contextual sentences (A. Siddharthan, Teufel, S., 2007). Nanba and Okumura (Nanba, 1999, 2005) collected citation context information from multiple papers cited by the same paper and generated a summary of the paper based on this citation context information. They also extracted citing sentences from citation contexts and generated a review. Elkiss et al. (Elkiss, 2008) generated the citation summarization based on citation context to describe the topic of cited paper. Mei (Mei, 2008) and Mohammad (Mohammad, 2009) found that the summarization of citation contexts is very different from the abstract of the cited reference. Liu and Chen(Liu & Chen, 2013) studied the differences between latent topics in abstracts and citation contexts. The results showed that topics from citing sentences tend to include more specific terms than topics from abstracts of citing papers. Nakov (Nakov, 2004) referred to citation contexts as citances – a set of sentences that surrounding a particular citation. Citances can be used in abstract summarization and other Natural Language Processing (NLP) tasks such as corpora comparison, entity recognition, and relation extraction. Small (H. Small, 1979) studied the context of co-citation and analyzed the context in which the co-citation paper mentioned. In addition, he analyzed the sentiment of the co-citation context (H. Small, 2011).

Anderson (Anderson, 2010) analyzed the citation contexts of a classic paper in organizational learning which was published by Walsh and Ungson in the Academy of Management Review. The results provided a richer understanding of which knowledge claims made by Walsh and Ungson have been retrieved and have had the greatest impact on later work in the area of organizational memory, and also what criticisms have been leveled against their claims. Chang(Chang, 2013) compared the citing topics of *Little Science*, *Big Science* in natural sciences and humanities and social sciences through citation context. He found that the citing topics in natural sciences and humanities and social sciences were very similar, but the cited motivation had some differences.

The classification and function of citation context

Citation context contains the direct related information between cited paper and citing paper. It could be used to reveal the nature of a citation. The cited motivation of each citation is different, so the value of each citation will be different. For example, some of the citation contexts support the claims in the cited paper, and some of them may take the opposite opinion about the views or methods in the cited paper. Spiegel-Rösing (Spiegel-Rösing, 1977) studied the citation context of Science Study in 1977 and classify the citation context into 13 categories, including use the data of cited paper, use the method of cited paper, compare the work of cited paper and citing paper and so on. In order to provide more information for literature management, Teufel reclassified the above 13 categories into four categories, (1) Explicit statement of weakness, (2) Contrast or comparison with other work, (3) Agreement /usage /compatibility with other work, (4) A

neutral category(Teufel, Siddharthan, & Tidhar, 2006) . Cue phrases were used to identify the category of each citation context. The similar method was also employed in Liu's (Liu et al.) work in which the citation context was classified as positive citation, negative citation, and neutral citation. Other people like Small (Henry Small, 1982), McCain (McCain & Turner, 1989), Siddharthan (A. Siddharthan & Teufel, 2007), Swales (Swales, 1990) also did some work about citation context classification.

Data and Method

Our procedure consists of three major components, 1. Data collection and preprocessing, 2. Theme analysis of citation context, and 3. The classification of citation context. Details are explained in corresponding sections.

Data collection and preprocessing

The 2014 Nobel Prize in Physiology or Medicine is awarded to Dr. John M. O'Keefe, Dr. May-Britt Moser and Dr. Edvard I. Moser for their discoveries of nerve cells in the brain that enable a sense of place and navigation. The scientific background was introduced in the document "The Brain's Navigational Place and Grid Cell System" . The keywords this document were selected manually and used to retrieve the award field in Web of Science. The search query was shown as follows：

TI=(hippocamp* AND (place OR Position* OR spatial)) OR (("grid cell*" OR Position* OR Navigation* OR spatial OR place) And ("entorhinal cortex" OR brain OR cerebral))

The time period was from 1945 to 2014, and 4441 papers were collected.

The citation context collection was built through three steps. First, the paper with the first author O'Keefe and the highest citation frequency was selected. Second, the papers which cited the chosen paper were downloaded with full text. Actually, we could just find less than 20% full text papers. Last, the citation contexts of the chosen papers were extracted from the full text for further analysis. The extraction method has been introduced in our previous work (Liu & Chen, 2013).

The theme analysis of citation context

The theme analysis includes two tasks. One is counting the frequency of noun phrases appeared in citation contexts. Another is mapping the co- occurrence network of noun phrases.

Part-of-speech is needed before extract noun phrases. There are many tools to label part-of-speech, such as PosTagger, CLAWS POS tagger. Stanford Log-linear Part-Of-Speech Tagger (Toutanova & Manning, 2000) was employed in this work, which was developed by NLP group of Stanford University. The noun phrase formation rules was designed with the same method described in Wang's paper (Wang, Liu, Ding, Liu, & Xu, 2014). When counting the frequency of noun phrases. If one citation context contains two same noun phrases, it will count once.

In bibliometrics analysis, co-occurrence method was often used to detect subjects/themes (Hofer, Smejkal, Bilgin, & Wuehrer, 2010; Lee, 2008; Zhang et al., 2012). But few of the related works use this method to detect the theme of citation context. Pajek software was employed to mapping the noun phrases co-occurrence network of citation context. We expect to identify the citing themes through drawing the co-occurrence map.

The classification of citation context

Following the work of Spiegel-Rösing (Spiegel-Rösing, 1977) and Teufel (Teufel et al., 2006), citation contexts will be classified into three categories as positive, negative and neutral. Table 1 shows the description of each category. We divided the positive category into three sub categories and the negative category into two sub categories.

Table 1. The description of each category

Category		Description
Positive	(1)	Affirm or praise the cited work
	(2)	Apply the methods, tools or databases of the cited paper
	(3)	Comparison of methods and results
Negative	(1)	Point out the weakness of the citation
	(2)	Contain negative cue words
Neutral	(1)	Contain no cue words

To our knowledge, the proportion of neutral citations occupy more than others. So we will classify the neutral citation into three sub categories based on the citation motivation.

(1) Related work in background or introduction. Introduce the related work with no comments.
(2) Theoretical foundation. Concepts, principles, methods, or results which will be used in citing paper.
(3) Experimental foundation. Including experimental conditions, processes, environment, and results.

Results and discussion

Target paper detecting

Table 2 shows top ten highly cited papers in Nobel Prize award field. The highest cited paper was "PLACE NAVIGATION IMPAIRED IN RATS WITH HIPPOCAMPAL - LESIONS" which published in *Nature* in 1982. It has been cited 3589 times. Although this paper got highly cited in Nobel Prize award field, it did not appear in "Scientific background" document, which was the instruction of why the winner got this prize. The author Morris R.G.M did not get Nobel Prize. The Nobel Prize was given to the author of the second highest cited paper "HIPPOCAMPUS AS A SPATIAL MAP - PRELIMINARY EVIDENCE FROM UNIT ACTIVITY IN FREELY-MOVING RAT". The result is similar to the work of Van Noorden (Van Noorden et al., 2014) that the Nobel Prize winner's paper did not get the highest citation frequency.

O'Keefe who is the Nobel Prize winner had three papers ranked in top ten high cited papers in Nobel Prize award field. The highest cited paper had been cited 1812 times. This paper was selected as the target paper. The seminal work of this paper was the discovery of "place cell".

It is hard to download all the 1812 citing papers. So 200 citing papers with full text were selected in our experiment. There were 228 citing sentences. The target paper was average cited 1.14 times in each citing paper.

Table 2. Top ten high-cited papers in Nobel Prize award field.

Author	Title	Journal	Year	Cited frequency
Morris, R. G. M., P. Garrud, et al	PLACE NAVIGATION IMPAIRED IN RATS WITH HIPPOCAMPAL-LESIONS	Nature	1982	3589

Okeefe, J	PLACE UNITS IN HIPPOCAMPUS OF FREELY MOVING RAT	Experimental Neurology	1976	657

The themes of citation context

299 noun phrases were extracted from the citation contexts. Table 3 listed twenty high frequency noun phrases. The term “place cell” got the highest frequency of 76, because the most contributing work of the target paper was the discovery of place cell. Hippocampus, environment, rat, fire, neuron were all the important terms in target paper. Some of the terms were not mentioned in the target paper, such as cognitive map and ca3.

Table 3. Top twenty high cited papers in Nobel Prize award field.

No.	Noun phrase	Frequency	No.	Noun phrase	Frequency
1	place cell	76	11	discovery	17
2	hippocampus	74	12	place field	15
3	environment	55	13	rodent	13
4	rat	44	14	ca3	13
5	animal	40	15	space	12
6	cell	31	16	ca1	12
7	location	29	17	position	11
8	fire	25	18	pyramidal cell	9
9	cognitive map	19	19	region	9
10	neuron	18	20	navigation	9

Figure 1 showed the co-occurrence map of the noun phrases. Each node represents a noun phrase. The size of the node was proportional to the number of terms co-occurred with it. We set the co-occurrence threshold as more than once and got 71 nodes in the map.

The map could divide into five parts manually based on the relationship of terms. Part A was mainly involving navigation, which was not mention too much in cited paper. It was the following research of place cell. Part B was related to neuron region, including CA1 and CA3. CA1 was discussed in the cited paper, but CA3 was found in the later work. Part C was related to experimental process about firing pattern of rat. Part D was the experimental environment. The definition of place field was widely cited. Part E was about the concept of place cell.

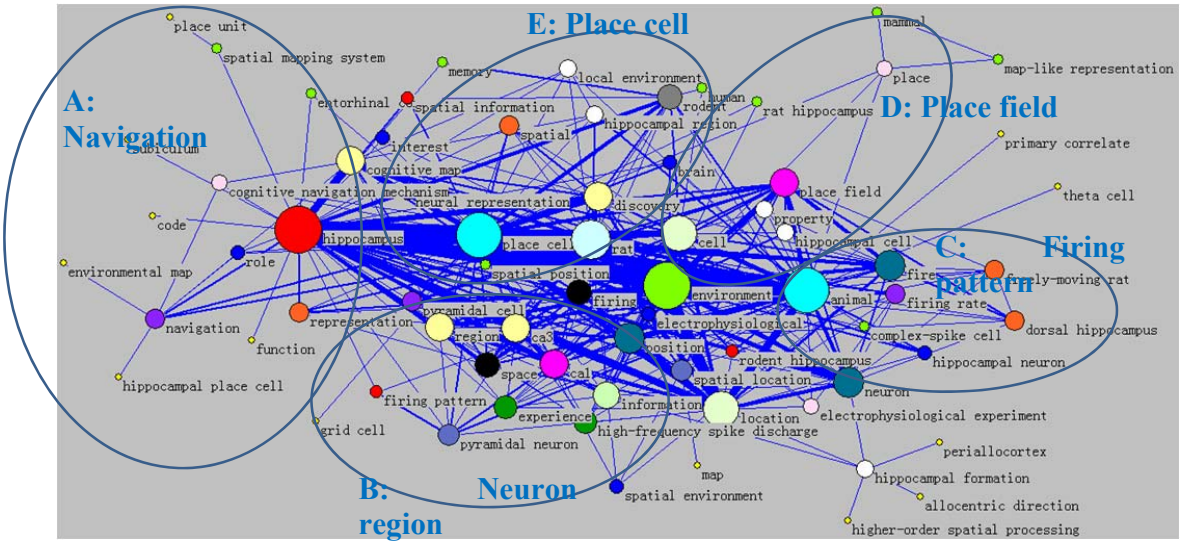

Figure 1. Co-occurrence map of the noun phrases.

Table 4. Example of positive citations

No.	Positive citation
1	The discovery of place cells [1]-[5] in the hippocampal regions of rats **consolidated** the idea that hippocampus probably represents a cognitive map of the local environment of an animal……
2	The concept of cognitive map for navigation, carried out mainly by Tolman [10], was **fuelled** by the discovery of the so-called place cells in the hippocampus of the rat and has widely increased our understanding of cognitive navigation mechanisms [11]
3	The **breakthrough** came in 1971 with the discovery of the rat s cognitive map in the cells of the hippocampus [16]……
4	The idea of the formation of a cognitive map was first proposed by Tolman [45] in the late 40s and was later **supported by the discovery** of place cells by o keefe and dostrovsky [35]
5	The **striking discovery** of place cells in the rat hippocampus [51] has triggered a wave of interest on spatial learning that holds until today

Table 5. Sub categories distribution of neutral citations

Category	Related work	Theoretical foundation	Experimental foundation
Counts	114	49	41

The classification results

The classification results showed that most of the citations were neutral citation. There was no negative citation in our datasets. 24 of 228 citation contexts were positive citations and 204 citations were neutral citations. Table 4 listed some examples of positive citations.

The sub categories distribution of neutral citations was shown in table 5. Nearly half of the citations were cited as related work. Theoretical foundation had 49 citations, and most of them were related to place cell or place field. 41 of 204 neutral citations were classified into experimental foundation, including ca1 neuron fire experiment, rodent studies and so on.

Conclusion and discussion

Citation context was used to measure the influence of paper in this research. The influence was identified from two aspects, the theme of the citation context and the classification of the citation context. The results showed that the traditional bibliometrics methods could be utilized in identify the themes of citation context. The citation contexts were divided into five themes in our experiment. The classification results showed that there were no negative citations of O'Keefe's most influential paper. More than 10% citation contexts were positive citations.

Through the citation context analysis of the influence paper, the detailed influence of the high influence paper could be revealed. The influence themes are more wide than the abstract of the target paper and the proportion of the positive citations takes more account than it appears in some journals (Liu et al., 2014).

There is only one case study in this paper. Although we could get some insightful results from this case study, comparative experiments are still needed in our future work.

Acknowledgments

This research is supported by National Natural Science Foundation of China (grant number 61272370), the specialized research fund for doctoral tutor (20110041110034), and the ISTIC-THOMSON REUTERS Joint Laboratory Open Foundation (IT201002). Part of the research was conducted during Shengbo Liu's visiting doctoral studentship at the iSchool at Drexel University. Thanks to the reviewers for the kindly suggestions.

Time to First Citation Estimation in the Presence of Additional Information

Abstract
We are interested in modelling the time to first citation, that is how long does it take for a publication to be cited for the first time after it has been published in a journal. We argue that both cited and uncited publications should contribute to the distribution of the time to first citation. Moreover, our objective is to model the time to first citation nonparametrically, hence under no parametric assumption. Due to the similarities with the observed data in survival analysis, we employ the techniques based on censored data and describe the distribution of the time to first citation in terms of the hazard rate, that is the instantaneous rate of being firstly cited. We find that publications receive their first citation at increasing rates in the first 24 months after their publication date and at decreasing rates afterwards. Moreover, we observe that the hazard rate and hence the time to first citation is influenced by the document type, number of authors and collaboration type and field. We also investigate the difference in the time to first citations for publications grouped by their collaborative status or the assigned field.

Conference Topic
Citation and co-citation analysis

Introduction
The first citation a publication receives is an important event in the bibliometric data, as it is not only a simple citation count, but also marks a change in the status of the publication, i.e. from being uncited the publication becomes cited. Certainly, observing the first citation of a publication depends on the considered time frame. Regardless the period of analysis, certain publications will never receive their first citation, in other words we will not observe the first citation received by some publications for any finite time period we consider.

Another important aspect concerns the time it takes for a publication to receive its first citation. For some publications it takes a small amount of time, such as 1-2 months, while for others it can even take more than 10 years. Due to overlong reviewing and publication procedures, some publications might even have negative times to first citation, meaning that the publication has been cited before it has been published.

The event that a publication received its first citation, as well as the time to the first citation received considerable attention over the years, starting with Schubert and Glänzel (1986), Glänzel (1992), Rousseau (1994), Glänzel and Schoepflin (1995). Since 2000, Egghe (2000), Egghe and Rao (2001), Burrell (2001), and Glänzel et al. (2012) continued to model the first citation data. Additionally, we acknowledge the work of van Dalen and Hekens (2005) and Bornmann and Daniel (2010), that is specifically close to the present research and will be referred to later on. Most of the previous work relies on the parametric modelling of the time to first citation distribution, such as the double exponential model (Rousseau, 1994), mixtures of non-homogeneous Poisson process

(Burrell, 2001), etc. The modelling in the existing literature focuses only on publications in certain journals or fields and the uncited publications do not always contribute to the time to first citation distribution, yet they emerge as a consequence of the model (Burell, 2001). Additionally, in Egghe (2000), the proportion of the uncited documents emerges from the model.

It should be stressed however that the time to first citation distribution derived from a set of publications that contains both uncited and cited documents does not coincide with the time to first citation distribution of the publications that receive a citation. From a probabilistic perspective, the first distribution is the sub-distribution of the latter. Furthermore, not accounting for the uncited publications can lead to biases in the estimation of the distribution of the time to first citation.

Our present study aims to continue and extend the research on the time to first citation analysis. We consider all the publications, regardless the document type and field, that appeared in Web of Science (WoS) in 2000 and their first citations received until the end of 2013. The time to first citation is registered in months. Additional data is recorded for each publication, such as document type, the number of authors, institutions and countries, and information on collaboration.

We propose an approach that aims to model the time to first citation distribution by accounting for all observations (both uncited and cited publications). Our approach assumes that the event of interest is the first citation, which is time dependent and we are interesting in modelling the time to this event of interest, namely the time to first citation. The time to event analysis has been employed in many fields. In sociology, it is known as event history analysis, in economy as duration analysis and in engineering is called reliability theory. Nevertheless, it is best known in biostatistics, where most research has been performed and where it is called survival analysis.

Consequently, the terminology employed in survival analysis is ubiquitous. In biostatistics, a frequent event of interest is death and the time to the event is then expectedly called survival time. Different functionals of the distribution of the time to the event of interest are successively termed survival function, hazard or cumulative hazard function. We will employ this unfortunate terminology in the analysis of the time to first citation.

A typical feature of the data in survival analysis is that not all events of interest are observed within the period of analysis. These observations are referred to as censored observations. The uncited publications are therefore regarded as censored observations. The uncited publications are in fact right censored observations, since their first citation is conditioned to take place after the period of analysis ended, i.e. at the right of the period of analysis. This approach circumvents the issue of not having a time to first citation for the uncited publications.

In survival analysis, the distribution of the time to event data is usually characterized by its survival function, as well as its hazard rate. The hazard rate provides information on the evolution in time of the event rate, in our case first citation rate. An attractive feature of the hazard rate compared to the density function, for example, is that the hazard rate accounts for the aging effect, while the density does not. Based on our data, we provide the time to first citation distribution and investigate its behaviour via the hazard rate.

Another important aspect in survival analysis is how additional information on observations, referred to as covariates or explanatory variables influence the time to the

event of interest. The Cox model (Cox, 1972) is probably the most popular method to model the influence of covariates on the time to the event of interest. In this study, we aim to infer on the effect of different characteristics of publications on the time to first citation. In other words, is the document type, number of authors, collaboration type or the field of a publication influencing the time it takes for that publication to receive the first citation? To our best knowledge, the influence of the explanatory variables document type, collaboration or field have not been accounted so far in the time to first citation analysis.

These methods in survival analysis have been previously used to model the time to first citation distribution by van Dalen and Henkens (2005) and Bornmann and Daniel (2010). Both studies restrict themselves to publications in a specific area of research, i.e. demography and chemistry. van Dalen and Henkens (2005) propose to model the hazard rate of the time to first citation distribution under the parametric assumption of a Gompertz distribution, which, in turn, lead to hazard rate which are decreasing over time. This restriction is unintuitive and in particular, it does not fit the data of the present study. Bornmann and Daniel (2010) are very brief in explaining the methods and, more importantly, the results of the analysis are not consistent in presenting their results, as they first refer to the differences in the survival curves and later on to the differences in the hazard rate. It is not very clear, for example, if the publication characteristics have an effect on the hazard rate.

Time to first citation distribution

We consider all the publications in Web of Science (WoS) that appeared in 2000 and their first citations up until 2013. That accounts for 1,202,371 publications, from which 62.62% received their first citation until the end of 2013. The first citation of publication A is defined as the publication date (month) of a publication B that cites firstly publication A, that is the minimum publication date of all publications that cite publication A. Needless to say that since the study is restricted to WoS, we refer to the first citation covered by WoS. Moreover, we exclude self-citations, hence we condition on publication B having no common authors with publication A.

The time to first citation of publication A is the time period (in months) between the publication date of publication A and the publication date of a publication B that cites firstly publication A. The time to first citation can sometimes be negative, but this is mostly an artefact due to the slow reviewing or publication process in different journals, etc. We exclude such observation from our study.

We chose the publication date to be registered in months given the availability of the data, but also for a better insight in the first citation process. Moreover, this avoids the issue of highly discrete data. Nonetheless, it is noteworthy that the publication date in months is not available for all data. For these cases, the first month of the year (January) or the middle one (July) is usually reported.

The histogram of the time to first citation for the publications in WoS that appeared in 2000 and received their first citation within the period 2000-2013 is presented below.

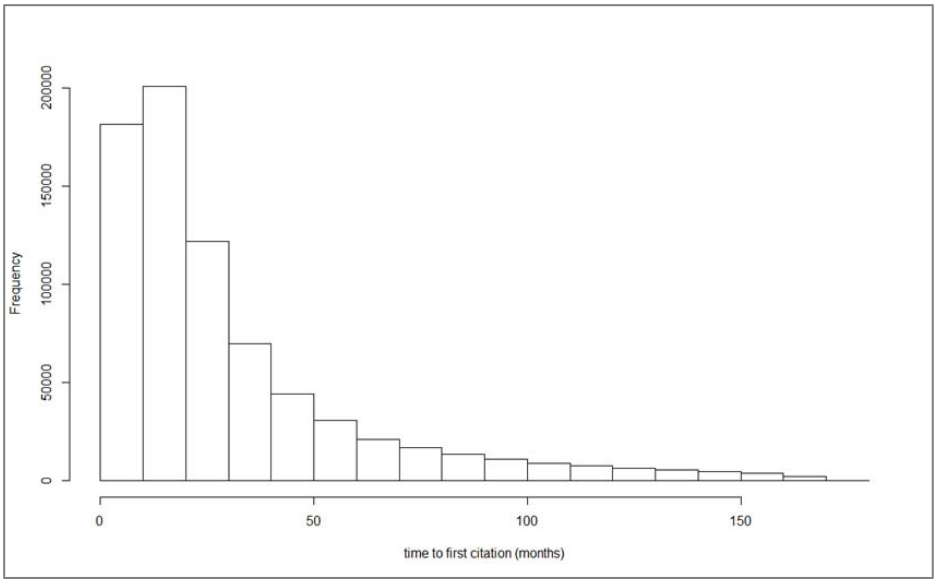

Figure 1. Histogram of the time to first citation for publications in 2010.

Most of the publications received their first citation shortly after publication. As expected, the proportion of publications that receive citations decreases over time. There are however publications that receive their first citation 13 years after their publication.

The histogram provides information on the time to first citation distribution of publications that received at least a citation until 2013. As mentioned beforehand, there is however no information on the publications that have not received any citation, apart from the percentage of the uncited publications.

Censored observations

It would be desirable though that the uncited publications also contribute to the distribution of the time to first citation, as they influence the probability of being firstly cited. Within this framework, the uncited publications did not experience the event of interest (first citation) by the duration of the study. What it is known is that their first citation occurs after the analysis ended.

In survival analysis, these observations are referred to as right censored observation. The publications that received their first citation within the period of analysis are called uncensored observations. Modelling time to event data requires that observations, both censored and uncensored have an observed time of interest, denoted as the follow-up time. For the uncensored observations, the follow-up time is the time to their first citations. For the censored observations, the follow-up time is the time period (in months) between their publication date and the end of analysis, that is December 2013, and it is referred to as the censored time.

For example, the censored time of a publication that appeared in January 2000 is 168 moths, whereas the censored time of a publication from June 2000 is 163 months. It needs to be distinguished between a publication with its time to first citation 163 months, for example it appeared in January 2000 and was firstly cited in December 2013, and a publication with its censored time 163 months. For this, we use an indicator Δ that is 1 if the publication has been cited and 0 if the publication remains uncited for the period of analysis.

The hazard rate

We are now interested in modelling the first citation rate on small units of time and its evolution in time. For this we will make use of the hazard rate, a functional of the time to first citation distribution. The hazard rate is referred to as the force of mortality in sociology, or the failure rate, in reliability. All these terms adhere to the pessimistic tone consistently used in survival analysis.

The hazard rate quantifies the rate at which first citations occur per unit of time relative to the proportion of publications that have not been yet cited. For a continuous random variable X, the hazard function is defined as

$$\lambda(t) = \lim_{\Delta t \searrow 0} \frac{P(t \leq X < t+\Delta t | X \geq t)}{\Delta t}.$$

In our case X denotes the time to first citation. We assume that the underlying time to first citation is continuous, while the observed data is discretized by measurement.

In order to compute the hazard rate at a given time point t, one needs to calculate the conditional probability in the numerator. In the present study, this is the probability of being firstly cited in the time interval [t,t+Δt), given that the publication has not been cited before time t. The conditioning ensures that at each time point t, only the publications that have not been cited up until time t are considered, therefore also the publications that are not cited throughout the entire period of analysis, i.e. the censored observations. Dividing this conditional probability by Δt, that is the width of the interval [t,t+Δt), we obtain the rate of the first citation occurrence per unit of time. By taking the limit Δt↘0 gives the instantaneous rate of occurrence of first citation. Note that, by definition, the hazard rate is not a (conditional) probability, or a density.

The hazard rate is a functional of the time to first citation distribution and can be derived for any parametric distribution and also estimated for a nonparametric distribution. The most straightforward example is the exponential distribution, for which the hazard rate is a constant function.

The hazard rate for the publications in the study is depicted in Figure 2 below.

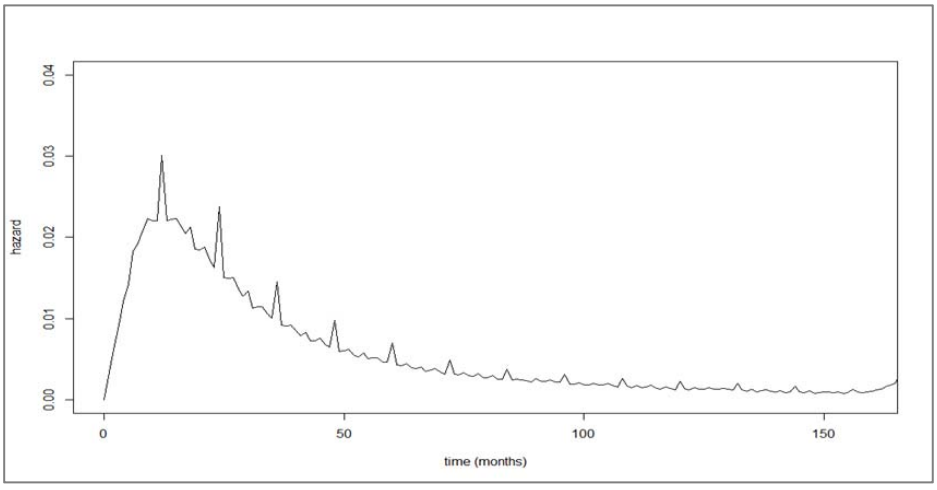

Figure 2. Hazard rate of publications in 2010.

First of all, we notice some spikes in the hazard function, which occur at the beginning and in the middle of each year in the citation window. This is due to the fact that certain journals publish once or twice a year. Moreover, when the publication date of certain

journal issues is unknown, the publication date is typically assigned to the beginning or middle of the year.

It seems that, per unit of time, publications receive their first citation at an increasing instantaneous rate up until a given time, that we refer to as the first citation peak, and despite the spikes, at decreasing instantaneous rates after the first citation peak. This shape suggests an unimodal hazard rate.

The first citation peak is for this dataset 24 months. In terms of conditional probabilities, the results can be interpreted as follows. Given that publications have not been cited before, on small unit intervals, they get cited for the first time with higher probability in the first 2 years after publications and with lower probability afterwards. The conditional probability decreases with time, but flattens after a while. That is, the decrease of the hazard is rather steep until 50 months and flattens afterwards. It can be inferred that first citation instantaneous rate is low and does not change significantly for documents that have not been cited for 4-5 years after publication.

Additional information – covariates

We are now interested in what can possibly influence the time to first citation and its hazard rate. This additional information is recorded as explanatory variables that are typically referred to as covariates in survival analysis, or as control variables in econometrics.

We consider the following covariates: document type, number of authors, collaboration type and field. By field we refer to the 250 subject categories to which journals are assigned in WoS. Surely, other covariates might be included, such as number of institutions or countries, number of pages, journal impact, etc.

Assume that covariates do not change over time, that they have a fixed value at the publication date. There can be however, covariates that change over time (time dependent covariates), such as journal impact, authors' visibility or performance.

The Cox model

The most famous model that incorporates the information on certain covariates in survival analysis is the Cox model (Cox, 1972). Regardless the fact that the model is more than 40 years old, it has been widely used and numerous versions, for particular issues with the data, have been proposed and investigated ever since.

The Cox model specifies the hazard rate at time t of a publication with a given covariate vector z as

$$\lambda(t|z) = \lambda_0(t)\exp(\beta' z),$$

where λ_0 is the underlying baseline hazard and β' is the transpose of the vector of underlying regression coefficients. Notice that if we take all covariates to be zero, we obtain the baseline hazard.

Within the Cox model, the hazard has two components. The first one, the baseline hazard, is the nonparametric part and it indicates how the hazard varies in time. The second term specifies parametrically, via an exponential function, the dependence on the covariates. It is then obvious why the Cox model is considered a semi-parametric model. Moreover, it is worth mentioning that the baseline hazard can be left unspecified when one want to estimate the regression coefficients and this flexibility has been particularly attractive for researchers.

Ever since the model was proposed, there was a great interest in estimating the regression coefficients β, that reflect how changes in the covariates produce a change in the hazard rate. The estimates were obtained via a partial likelihood method that avoided the bothersome issue of estimating the baseline hazard λ_0.
We have fitted the Cox model with the following covariates

- Document type
- Collaboration type
- Number of authors.

We will focus on estimating the (baseline) hazard and not on the regression coefficient estimation. We need to stress that conditioning on the covariates to be at a baseline value, i.e. z=0, is not the same thing as not accounting for covariates. This can be determined from the equation specifying the Cox model, but also from the figure below.

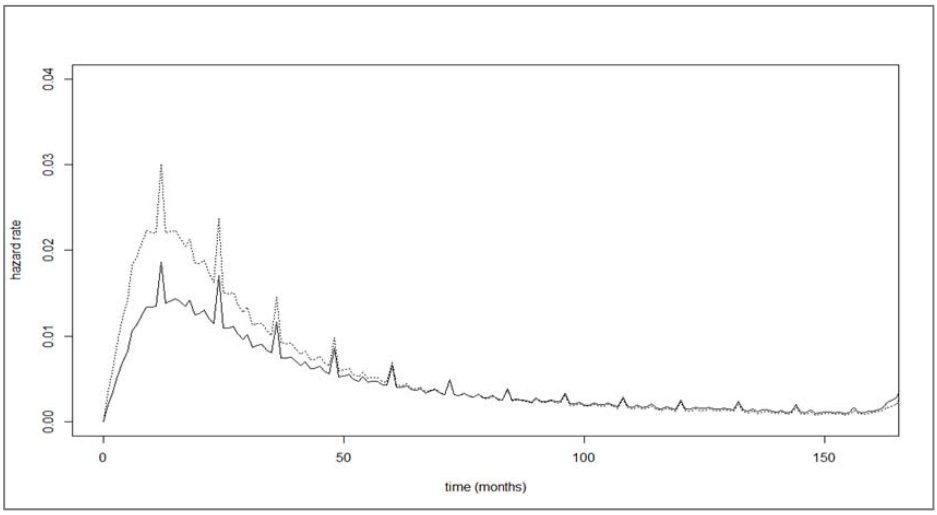

Figure 3. Hazard rate in the presence of no covariates (dotted) and baseline hazard (solid line).

Apparently, accounting for covariates shifts the hazard down in the first 60 months after the publication date and has no effect afterwards. The baseline hazard follows the same trend as the hazard rate in the presence of no covariates that is increasing until 24 months after the publication date and decreasing afterwards. Therefore, we can conclude that the covariates have a scale effect rather than a shape effect on the hazard. Furthermore, it seems that there is a proportional effect of the covariates on the baseline hazard, at least in the first 50 months. This represent a visualization of the goodness of fit of the Cox model and additionally, several tests suggest that the model fits the data well.
We want to investigate now whether certain characteristics of the publication, such as the collaborative status or the field have an impact on the instantaneous first citation rates.

Collaboration

It is commonly thought that publications that have resulted from an international collaboration are more visible to the academic community and hence receive more citations than national collaborative publications or publications that do not result from any inter institutional collaboration. It would be interesting to see if the collaboration type also influences how fast a publication receives its first citation.

As mentioned beforehand, we have fitted a Cox model with document type, collaboration type and number of authors as covariates. All the covariates have a (statistical) significant influence on the time to first citation.

To show the difference in the hazard rates among the different types of collaboration, we compute the hazard rate for publications with international, national and no collaborations. All the other covariates are set to their baseline level. Figure 4 depicts these differences.

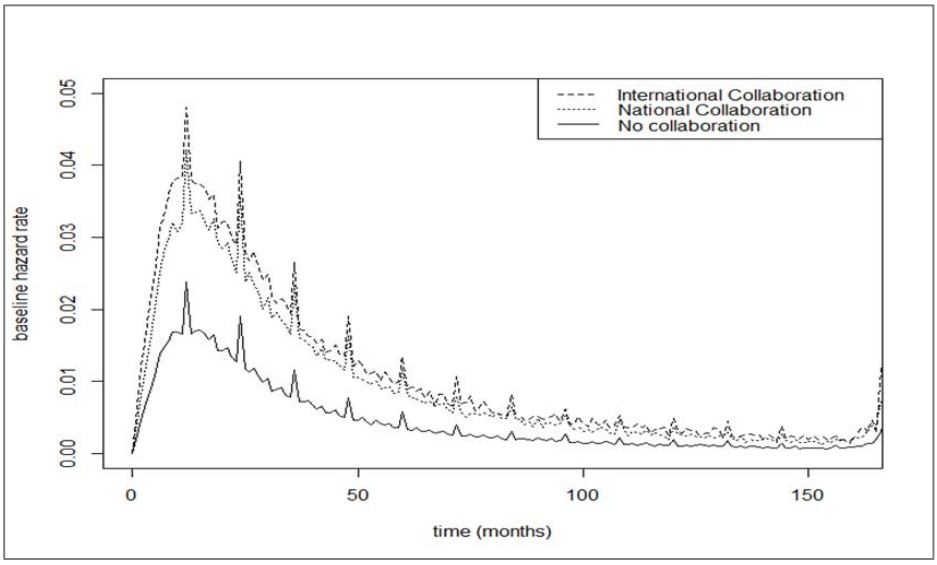

Figure 4. Baseline hazard rates in terms of collaboration type: international collaboration (dashed), national collaboration (dotted) and no collaboration (solid line).

It seems that there is a significant scale difference in the instantaneous first citation rate among publications that represent international and international collaborations and those that do not result from such collaborations. There are however small differences between baseline hazard of the international and national collaborative publications. Nonetheless, the publications that resulted from an international collaboration register higher instantaneous first citation rates than publications that represent national collaborations and these publications have, in turn, higher instantaneous first citation rates than publications whose authors are affiliated to a single institution. Similar to the overall (baseline) hazard rates, there are less and less differences in the hazard rates of different collaboration types 100 months after publication.

Contrary to the popular belief however, it seems that, apart from a scaling factor, publications receive their first citation at similar rates irrespective their collaboration type. The maximum hazard function is attained by publications of all collaboration types at the same time point, which is 24 months after the publication date. This is not different from the overall baseline hazard.

To condition further on specific values of the other covariates, we have considered the document type ‘Article’ and assume the publications has 3 authors, which is close to the overall average of the entire dataset, that is 3.31.

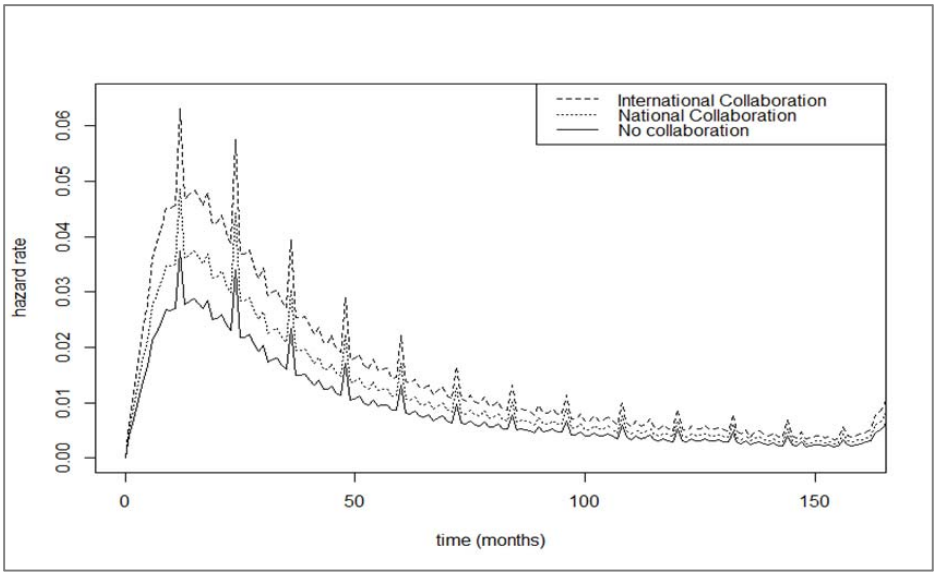

Figure 5. Hazard rates for articles with mean number of authors. International collaboration (dashed), national collaboration (dotted) and no collaboration (solid line).

Figure 5 depicts the hazard rates of articles that result from different collaborations and are written by three researches. We notice that the differences in the hazard rates have decreased. Despite similar behaviour over time, international collaborations still achieve the highest hazard rates over time, followed by national collaborations and articles produced by the same institution (no collaboration).

Field

We are also interested to see whether the field assigned to a certain publication affects the rate of being firstly cited. Nonetheless, more than half of the journals in WoS are assigned to at least two fields and some journals are assigned to six fields. This means that the field covariate cannot be uniquely defined for each publication. This difficulty cannot be overcome by using the WoS subject category assignment and hence the field cannot be included as a covariate in the Cox model. A solution is to adopt the publication-level classification system proposed by Waltman and van Eck (2012). Within this approach each publication is assigned to an unique cluster. Employing the publication-level classification system is deferred to future research.

In order to still assess the influence of the field on the time to first citation distribution, we have limited the data of all publication from 2000 to three fields: Biochemistry & Molecular Biology, Economics and Mathematics. We have now a number of 80,745 publications that have been published in 2000 and are assigned to the three fields.

We have fitted the Cox model with the following covariates

- Document type
- Collaboration type
- Number of authors
- Field

All four covariates have a (statistical) significant effect on the hazard rate. We are interested in the baseline hazard rates for the data grouped by the field. The differences

between the three baseline hazards can be observed in Figure 6. Once again, the other covariates have been set to zero.

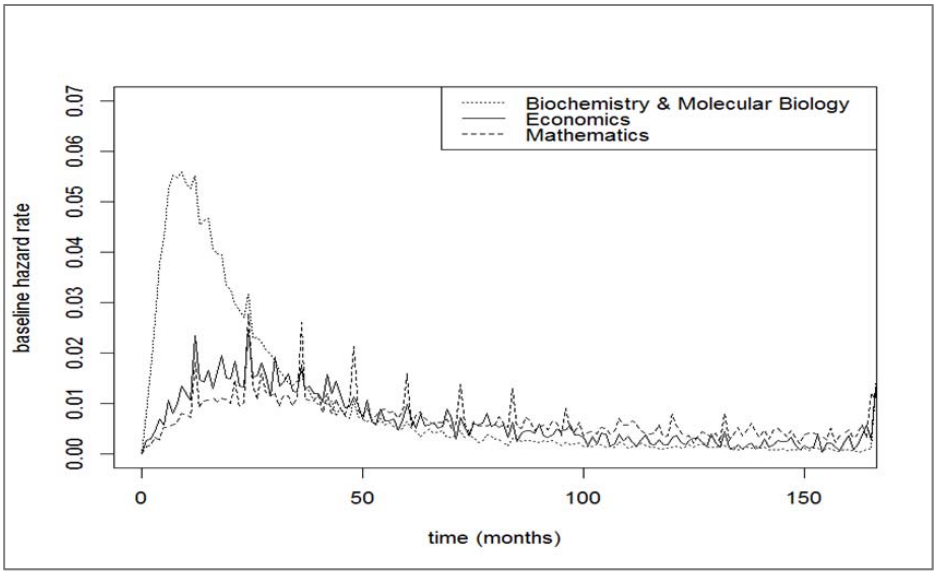

Figure 6. Baseline hazard rates in terms of field: Biochemistry and Molecular Biology (dotted), Mathematics (dashed) and Economics (solid line).

The three baseline hazard rates differ in both shape and scale. Firstly, it seems that the publications that appeared in 2000 in Biochemistry and Molecular Biology achieve their maximum first citation rate earlier than publications in Economics or Mathematics. The peak in Biochemistry and Molecular Biology is registered at 12 months, whereas the publications in Economics and Mathematics have a baseline hazard rate peak around 24 months.

We observe that there are large changes over time in the baseline hazard rate of publication in Biochemistry and Molecular Biology. Moreover, during the first part of the citation window, publications in Biochemistry and Molecular Biology have an instantaneous first citation rate three times as higher than the instantaneous first citation rates in Economics and Mathematics. The publications in Economics and Mathematics exhibit similar hazard rate behaviour.

It is noteworthy and interesting that after 60 months, the order of the three baseline hazard rates completely reverse, that is publications in Mathematics have higher baseline hazard rates than publications in Economics, that have higher baseline hazard rates than the publications in Biochemistry & Molecular Biology.

Discussion and conclusions

The first citation is probably the most important citation a publication receives. It can determine entirely the number or speed of further citations. Besides a simple citation count, it also changes the status of a publication, from being uncited to being cited. In some fields, being cited is even sufficient to become frequently cited.

The time to first citation also contributes to the number or speed of further citations. Apart from the famous sleeping beauties (van Raan, 2004), it is obvious that the more it takes for a publication to receive its first citation, the lower the probability of receiving further citations.

Time to first citation is the first step in modelling how publications accumulate citations in general over time. It is still unknown whether the time to first citation differs significantly from the time to second citation, etc.

We aimed to model the time to first citation and used a set of publications that appeared in 2000 and are included in the WoS database. Probably the most important aspect of our approach is that we employed nonparametric or semi-parametric methods of estimation. In other words, we let the data speak for itself. This ensures a greater flexibility and avoids the bothersome issue that a given model fits a particular data well, say publications that appear in a certain year and within a specific field, but fails to fit another particular data appropriately. While this is not a problem specific only to the first citation analysis, for an example on this matter in the first citation analysis, see Rousseau (1994). Another important drawback of the parametric approach is that certain employed parametric models cannot incorporate specific shapes of the first citation data. Van Dalen and Hekens (2005) for example make use of a Gompertz hazard model that cannot incorporate an unimodal hazard, as we obtained in the present study.

Apart from the nonparametric choice of estimation, we have also incorporated the uncited publications in the distribution of the time to first citation by using methods developed in survival analysis. We stress the fact that the information on uncited publications should be accounted for in modelling the time to first citation distribution, otherwise the results of the estimation can be seriously biased, especially given the high percentage of uncited publications.

We have investigated the time to first citation distribution through its hazard rate, the instantaneous rate of being firstly cited. We observe that the hazard rate increase over the first 24 months and decreases afterwards. This is somehow expected, that publications receive their first citations at higher rates until a maximum and afterwards at lower and lower rates. What is surprising is the relative short period of time over which the hazard rate is increasing. It means that the probability of a publications being cited for the first time is increasing over the first 24 months, and decrease afterwards.

Furthermore, it is of high interest to investigate whether certain characteristics of publications influence their time to first citation. We included the document type, number of authors, collaboration type and the field. We have found that all these explanatory variables (covariates) influence the time to first citation and investigated the differences between the hazard rates of publications grouped by collaboration type. The hazard rates of the three collaboration types differ in scale and not in shape and attain the maximum at the same time point. Hence, it seems that publications receive their first citations at an increasing rate up to the same time point, namely 24 months regardless their collaboration type.

A different dataset has been chosen to investigate the influence of the field on the time to first citation. It seems that, for the three selected fields, the hazard rate of the publications differ not only in scale but also in shape. The publications in Biochemistry and Molecular Biology register higher rates than publications from Economics and Mathematics, but also they have increasing first citation rates over a shorter period of time than the publications from the other two fields. The order of the three hazard rates reverse after 60 months.

As mentioned in the previous section, the problem of the overlapping fields in WoS needs to be addressed in future research and this can be overcome by considering the

publication-level classification system proposed by Waltman and Van Eck (2012). Numerous investigations are further required and desired. For example it would be very interesting to investigate whether the time to first citation distribution, and in particular the hazard rate including self citations differs from the time to first citation excluding self citations. Other covariates can be included in the analysis, such as the impact of the journal, the performance or visibility of authors, etc. Of course, it is very interesting to see whether the shape of the hazard rate changes over the time of publication, not only through the citation window. The author expects that the hazard would have the same unimodal shape, but the maximum point would be attained at different time points that is the first citation peak would be time dependent.

In terms of estimation, it is highly desirable to account for the monotonicity of the (baseline) hazard that is to provide estimates of the baseline hazard rate under the assumption of monotonicity. This is in line with the research of Lopuhaä and Nane (2013), but needs some refinement to incorporate the estimation of a unimodal baseline hazard.

Abstract
This study scrutinizes potential author relationships according to the findings based on the tripartite citation analysis. It focuses on Author co-citation analysis (ACA), author bibliographic-coupling analysis (ABCA) and author direct citation analysis (ADCA). By algorithm design and empirical analysis, the deduction from results of ACA, ABCA and ADCA to potential author relationships mining could be probable, and the empirical process would be practicable.

Conference Topic
Citation and co-citation analysis

Introduction
Citation analysis is a mature quantitative research method in Bibliometrics and Scientometrics. It is widely used in scientific evaluation, scholarly communications, academic behavior analysis, and information retrieval. Author citation analysis mainly includes three types: author co-citation, author coupling, and author direct citation.

Author co-citation analysis (ACA) is the most widely used method for the empirical analysis of disciplinary paradigm, and is frequently studied and improved upon. Many ACA studies have been conducted since Small (1973) introduced document co-citation analysis and White and Griffith (1981) introduced ACA. Bibliographic coupling was proposed as early as 1963 (M. M. Kessler, 1963). However, author bibliographic-coupling analysis (ABCA), i.e. author-coupling relationships, did not get much attention until it is formally put forward and empirically studied by Zhao (Zhao & Strotmann, 2008).

Direct citation is sometimes also called inter-citation or cross citation (Zhang et al., 2009). Compared with co-citation and bibliographic coupling, direct citation is a direct citing relationship without a third party paper. Although researchers are aware of direct citation analysis and employed from time to time (Shibata et al., 2008), it was ignored because of the unavailability of data, difficulty of implementation, and long time windows to obtain a sufficient linking signal for clustering. However, scholars are gradually paying attention to this topic (Boyack & Klavans, 2010). A number of studies have focused on journal direct citation or comparative analysis of methods. The author direct citation analysis was more clearly explored by Wang et al. (2012). Wang used this method to reveal the knowledge communication and disciplinary structure in Scientometrics. This process is named "author direct citation analysis" (ADCA) (Yang & Wang, 2015).

All of these three kinds of citation analysis methods can reveal separately the author relationship in a field. Then, how about the similarities or diversity among the tripartite citation relationships at author level? And, how could the tripartite relationships be synthetically presented to the readers or the result users? We have tried to answer these two questions in previous studies (Wang, 2014), even though the effort is still limited. Persson (2010) and Gómez-Núñez et al. (2011, 2014, 2015) tried to combine these citation measures

in a normalized way to weight existing direct citation relationships between articles or journals.

The following question is worthy of investigation as well: Could we discover potential author relationships according to the findings based on the tripartite citation analysis? To give an example: in a field, author A's paper and author B's paper both are cited by the same paper C, then A and B have co-citation relationship, which can be marked as (A, co-citation, B). Author C and author D, when citing the same paper in their respective articles, have bibliographic-coupling relationship, marked as (C, bibliographic-coupling, D). In addition, if C and A cite each other, then C and A have direct-citation or cross-citation relationship, marked as (C, directly citing, A) or (A, directly citing, C) or (A, cross citation, C). According to these primary relationships, could we deduce an integrated relationship between A and D, or B and C, even B and D? And, what will be the association strength in these potential relationships? These are the key problems that we answer in this study.

Data and methodology

Basic Data

Since the journal *Scientometrics* is one of the most representative communication channels in the field of Scientometrics, it reflects the characteristic trends and patterns of the past decades in scientometric research (Schubert A 2002). This study is based on bibliographic data based on all types of documents published in *Scientometrics* from 1978 to 2011, retrieved from the Web of Science. Author names including the cited authors were normalized because some authors may report their names differently in different papers. We identified each author by his or her surname and first initial only; the same applies to cited authors.

Methodologies

In this study, bibliometrics method is applied to identify the core authors (94 first authors who have published 5 or more papers and simultaneously have a cited frequency over 10) in Scientometrics filed. Author co-citation analysis (ACA), author bibliographic-coupling analysis (ABCA) and author direct citation analysis (ADCA) are respectively used to discover author relationships with co-citation, bibliographic-coupling and direct-citation. Co-occurrence analysis and deductive reasoning methods are used to mine potential author relationships on the findings of the tripartite citation analysis. VBA program processes all kinds of citation analysis data. The final results of author relationship are visualized with Pajek.

Results and discussion

According to the tripartite citation analysis, we obtain three original relation matrixes and their corresponding normalized matrixes (Fig. 1). The normalization method is based on Salton's Cosine similarity measures, which returns similarity values ranging between 0 and 1. In order to describe the directivity of citing behaviour and achieve vectorial deducing, the direct citation matrix is unsymmetrical.

Figure 1. Normalized matrixes of tripartite citation analysis.

The following five steps could help us realize author relationship mining based on tripartite citation analysis, such as "A→C, B→D, B→C". These steps can also be seen as an algorithm in relation mining.

First step: Obtaining the fundamental citation relationship with strength(>0) among core authors from original matrixes

Tripartite adjacency matrixes are transformed into corresponding adjacency lists. ACA list $\{L_{1i},Q_{1i}\}$ versus matrix $\{O_{1i}, P_{1j}\}$, and relational degree X_i (i stands for the ID of author pair) in list can replace X_{ij} (i/j stand for different authors in the matrix) . ABCA list $\{L_{2i},Q_{2i}\}$ versus matrix $\{O_{2i}, P_{2j}\}$, and relational degree Y_i versus Y_{ij}. ADCA list $\{L_{3i},Q_{3i}\}$ and $\{L_{3j},Q_{3j}\}$ versus matrix $\{O_{3i}, P_{3j}\}$, and relational degree Z_i and Z_j versus Z_{ij} (the order between i and j denotes the citing direction). We used the Adjacency list in calculation process.

Second step: Filtering no-explicit-relationship author pairs

The no-relationship author pairs (X_i=0, Y_i=0, Z_i=0, and no cooperation), are filtered as $\{O_{4i},P_{4j}\}$ in the Adjacency matrix, and $\{L_{4i},Q_{4i}\}$ in the Adjacency list, which forms the basic object in subsequent analysis.

Third step: Mining the relationship of A →C from$\{L_{1i},Q_{1i}\}\{L_{3i},Q_{3i}\}\{L_{4i},Q_{4i}\}$

Remark the $\{L_{4i},Q_{4i}\}$ as $\{A_k,C_k\}$ (k stands for the number of author pairs), the goal is finding the Dk with the relations $\{A_k→D_k, C_k\text{-}D_k\}$. We looked for the synchronous relations with strengh between A_k and D_k, C_k and D_k, from $\{L_{1i},Q_{1i}\}\{L_{3i},Q_{3i}\}$, and matched the author pairs in $\{A_k,C_k\}$. The pseudo code is as follows:

If one author in the pair of $\{A_k,C_k\}$= one author in a pair of $\{L_{1i},Q_{1i}\}$, and another one in the pair of $\{A_k,C_k\}$= one author in a pair of $\{L_{3i},Q_{3i}\}$, and another one in the pair of $\{L_{1i},Q_{1i}\}$= another one in the pair of $\{L_{3i},Q_{3i}\}$

Then mark the "one author in the pair of $\{A_k,C_k\}$" (so as the "one author in a pair of $\{L_{1i},Q_{1i}\}$") as Cα, the "one author in a pair of $\{L_{3i},Q_{3i}\}$" (so as the "another one in the pair of $\{A_k,C_k\}$") as Aα, the "another one in the pair of $\{L_{1i},Q_{1i}\}$" (so as the "another one in the pair of $\{L_{3i},Q_{3i}\}$") as Dα

End with the relation between A_α and C_α according to D_α, and their relation strength equaling to the product of X_α and Y_α. If the order of author pair in $\{L_{4\alpha},Q_{4\alpha}\}$(i.e., $\{A_k,C_k\}$) is in reverse of the order of author pair in $\{L_{3\alpha},Q_{3\alpha}\}$(i.e., $\{A_k,D_k\}$), then the relation strength between Aα and Cα will be the negative value.

Finally, choose the top value (Take the absolute value of the negative value) as the final relation strength of A_α and C_α.

Fourth step: Mining the relationship of B →D from$\{L_{2i},Q_{2i}\}\{L_{3i},Q_{3i}\}\{L_{4i},Q_{4i}\}$

Remark the $\{L_{4i},Q_{4i}\}$ as $\{B_k,D_k\}$ (k stands for the number of author pairs), the goal is to find the A_k with the relations $\{A_k→D_k, A_k\text{-}B_k\}$. We looked for the synchronous relations with strengh between A_k and D_k, A_k and B_k, from $\{L_{2i},Q_{2i}\}\{L_{3i},Q_{3i}\}$, and matched the author pairs in $\{A_k,C_k\}$.This process is similar with the process of A→C, so the pseudo code is omitted.

Fifth step: Mining the relationship of B →C from$\{L_{1i},Q_{1i}\}\{L_{2i},Q_{2i}\}\{L_{3i},Q_{3i}\}\{L_{4i},Q_{4i}\}$

Remark the rest (no relationship like A→C and B→D) of $\{L_{4i},Q_{4i}\}$ as $\{B_k, C_k\}$ (k stands for the number of author pairs), the goal is to find the A_k and D_k with the relations $\{A_k→ D_k, A_k\text{-}B_k, C_k\text{-}D_k\}$. We looked for the synchronous relations with strengh between A_k and D_k, A_k and B_k, Ck and D_k, from $\{L_{1i},Q_{1i}\}\{L_{2i},Q_{2i}\}\{L_{3i},Q_{3i}\}$, and matched the author pairs in $\{B_k,C_k\}$. The pseudo code as follows:

If one author in the pair of $\{B_k,C_k\}$= one author in a pair of $\{L_{2i},Q_{2i}\}$, and another one in the pair of $\{B_k,C_k\}$= one author in a pair of $\{L_{1i},Q_{1i}\}$, and another one in the pair of $\{L_{2i},Q_{2i}\}$=one author in the pair of $\{L_{3i},Q_{3i}\}$, and another one in the pair of $\{L_{1i},Q_{1i}\}$= another one in the pair of $\{L_{3i},Q_{3i}\}$

Then mark the "one author in the pair of $\{B_k,C_k\}$" (so as the "one author in a pair of $\{L_{2i},Q_{2i}\}$") as B_χ, "another one in the pair of $\{B_k,C_k\}$" (so as "the one author in a pair of $\{L_{1i},Q_{1i}\}$") as C_χ, one author in the pair of $\{L_{3i},Q_{3i}\}$(so as the "another one in the pair of $\{L_{2i},Q_{2i}\}$") as A_χ, another one in the pair of $\{L_{1i},Q_{1i}\}$(so as the "another one in the pair of $\{L_{3i},Q_{3i}\}$) as D_χ

End with the relation between B_χ and C_χ according to A_χ and D_χ, and their relation strength equaling to the product of X_χ and Y_χ and Z_χ. If the order of author pair in $\{L_{4\chi},Q_{4\chi}\}$(i.e., $\{B_k,C_k\}$) is in reverse of the order of author pair in $\{L_{3\chi},Q_{3\chi}\}$(i.e., $\{A_k,D_k\}$), then the relation strength between B_χ and C_χ will be the negative value.

Finally, choose the top value (take the absolute value of the negative value) as the final relation strength of B_χ and C_χ.

So far, all relationship among author pairs in $\{L_{4i},Q_{4i}\}$ have been built.

According to the above algorithm, potential relationships among not-directly-related core author set could be discovered by VBA programme and Access databases. The final results among A→C, B→D and B→C are visulized by Pajek as Figure 2 and 3.

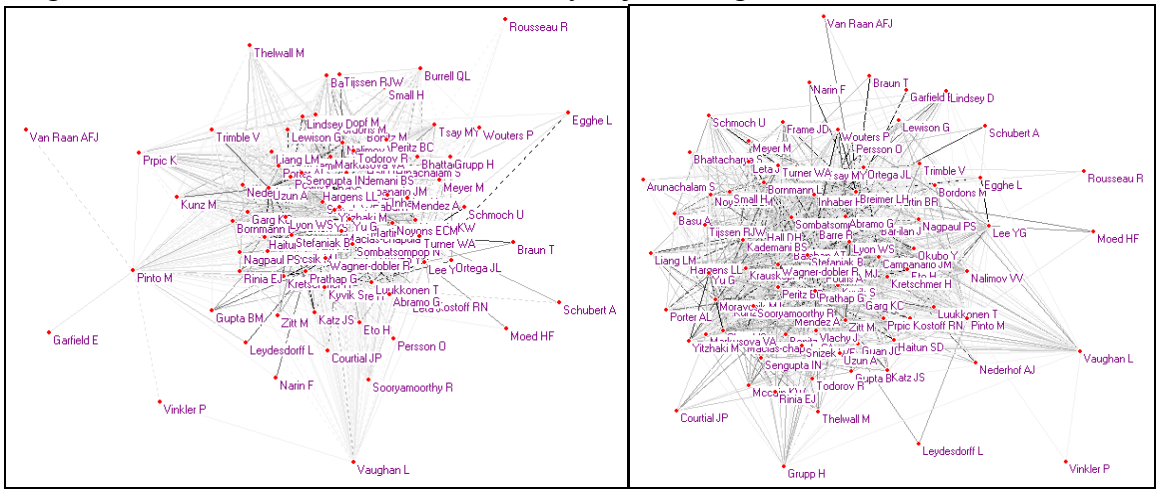

Figure 2. (a) Author relationship network of A→C. (b)Author relationship network of B→D.

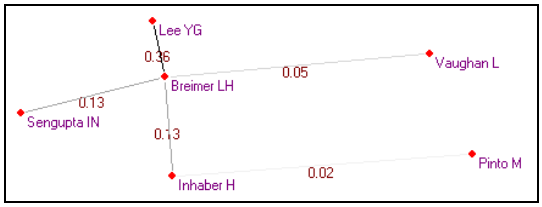

Figure 3. Author relationship network of B→C.

In Figure 3, the labels in the lines denote the value of the relationship similarity for authors in pairs. According to the results, there are different levels of potential relationship between Breimer LH and other authors, such as Inhaber H、Lee YG、Sengupta IN、Vaughan L.

Conclusions

Based on the algorithm design and empirical analysis, the deduction from results of ACA, ABCA and ADCA to potential author relationships mining could be probable, and the

empirical process would be practicable. The findings in Scientometrics field can help scholars discover more research fellows, which can promote scientific research cooperation and broader knowledge communication.

Abstract
Charles Dotter is described as the father of interventional radiology, a medical specialty born at the cross-border of radiology and cardiology. Dotter's landmark paper published in 1964 was poorly cited until 1979 and can be considered from a scientometric point of view as a sleeping beauty. Sleeping-beauties are article that suffer of a delayed recognition. This paper, will explore the bibliometric characteristics of this case study and the accuracy of Van Raan's criteria to define "sleeping beauty" in science will be discussed. "The prince" is identified through citation network analysis, and the sleeping period has been documented as a restless sleep period with science and social controversy that could be documented in publications databases by differentiating bibliographic references. Therefore, a category of "sleeping beauty" –like paper should be introduced. By the end, these observations should open new avenues in identifying "sleeping beauties".

Conference Topic
Citation and co-citation analysis

Introduction

Charles Dotter, father of interventional radiology

Charles Theodore Dotter (1920–1985) was a pioneering US vascular radiologist, credited with developing interventional radiology (IR): he invented the angioplasty and the catheter-delivered stent. On January 16, 1964, he percutaneously dilated a tight, localized stenosis of the superficial femoral artery in an 82-year-old woman with painful leg ischemia and gangrene who refused leg amputation. Percutenous transluminal angioplasty (PTA) was born, and Dotter with his trainee Dr. Melvin P. Judkins, described their technique in a landmark paper published in the medical journal "Circulation" (Dotter, 1964).

Today, Charles Dotter is described as the father of interventional radiology (IR), a sub-specialty of radiology using minimally invasive image-guided procedure to diagnose, as well as to treat diseases in every organ. The Oregon Health Sciences University (OHSU), where he spent his entire medical career, boasts the Dotter Interventional Institute. Furthermore, the Society of Interventional Radiology named a Dr. C.T. Dotter lecture to honor annually extraordinary contributions to the IR field (Rösch, 2003).

However, at first, the relationship between surgeons and radiologists was adversarial because the Dotter technique was a paradigmatic revolution, inviting radiologists to transgress medical specialty boundaries. It can be summed up by Dotter's formula at that time: "The angiographic catheter can be more than a tool for passive means for diagnostic observations; used with imagination, it can become an important surgical instrument". (Payne, 2001).

Therefore, as we found out, Dotter's landmark paper was poorly cited until 1979 and can be considered from a scientometric point of view as a sleeping beauty paper.

Sleeping beauty in scientific literature

In Scientometrics, the phenomenon of delayed recognition has been well described since the pioneering observations of Garfield, and referred to as premature discoveries, resisted discoveries, delayed recognition or sleeping beauties (Burrell, 2005; Braun, 2010). Van Raan (2004) defined "sleeping beauties" as articles that go unnoticed ("sleeps") for a long period of time and then, suddenly, receives a lot of citations by a "prince" (another article). Three variables were defined for such papers: depth of sleep, length of the sleep and awaking intensity. Some publication had heaping before sleeping, and are described as "all-element-sleeping beauties" (Li, 2012).

Objectives

In the present work, we explore the bibliometric characteristics of this case study, question the sleeping-beauty definition, explore the diffusion of Dotter concept during the sleeping period, and document the awaking phase and identify "the prince" through citation network analysis.

Method

A literature search on Dotter C.T. scientific production was conducted both in PubMed and Scopus databases. Citations of Dotter work were extracted from the Web of Science database until 12/31/2013. Then, a descriptive statistics analysis was led on the corpus (219 publications; 7866 citations). Scientific collaborations of C.T. Dotter was explored with Intellixir® to draw co-publications graph. Citations network pattern during time of the landmark paper was drawn using CitNetExplorer software tool (Van Eck, 2014). Complementary queries were run using Dotter or PTA as a keyword in different search fields for different types of documents.

Result

The scientific production of Charles Dotter

Dotter published his first paper in 1948 in a top medical journal, the New England Journal of Medicine (Jan 13; 239(2):51-4). During his 33 years at OHSU, he issued 219 publications; a quarter of his scientific production was disclose in high quality journals, and split between 2 main medical disciplines: radiology and cardiology (Table 1).

Table 1. Journal distribution of C.T. Dotter scientific production.

Source title	*Publications number*	*Impact factor*
Radiology	46	5,561
Am. J. Roentgenol. Radium Ther. Nucl. Med.	27	na
Circulation	19	12,755
New England J Medicine	8	52,589
Am. J. Roetgenol.	6	2,47

Dotter had many relations in the academic community: all along his career he co-published with 140 different authors, mainly with J. Rosch, F. Keller & J. Melvin (340, 215 & 68 co-publications respectively; Fig.1 and Table 2).

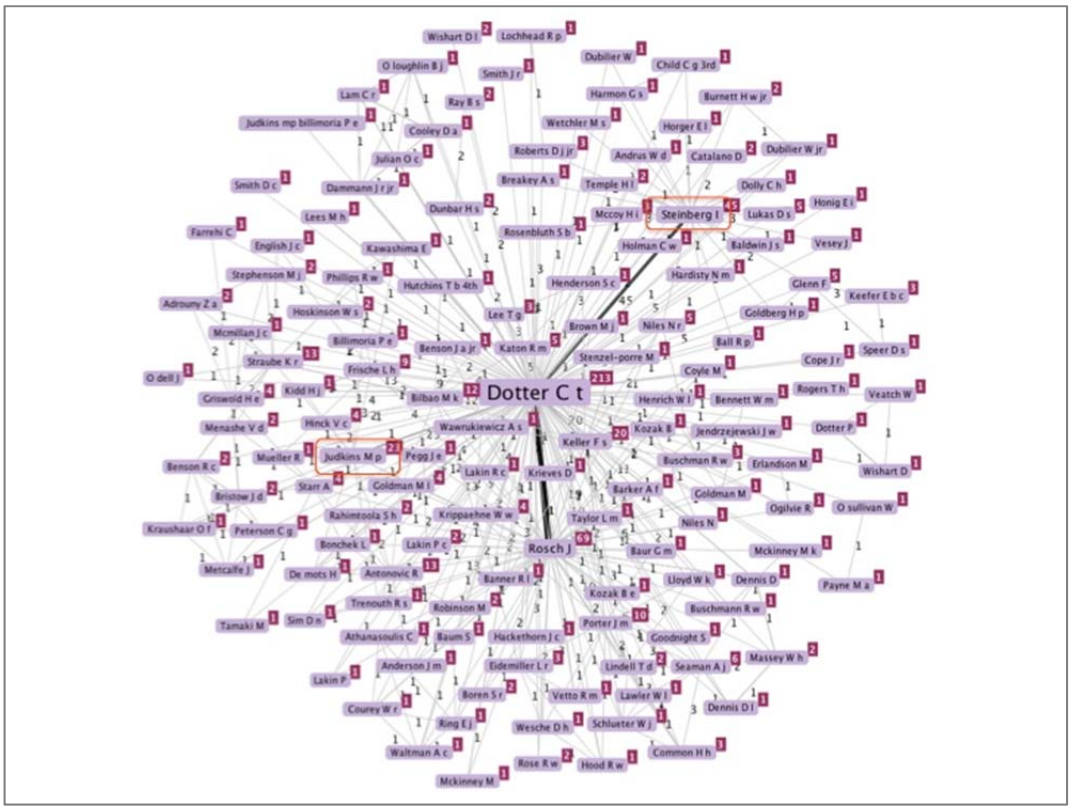

Figure 1. Network of C.T. Dotter co-publications.

Table 2. C.T. Dotter main scientific collaborators.

Author	Lab. / Dpt.	Institution	Publi.
Rösch, Johannes	Center of Cardiac Surgery	Friedrich Alexander University (DE)	340
Keller, Frederick S.	Dotter Interventional Inst.	Orgeon Health & Sciences Medical Center (USA)	215
Steinberg, Israel	Dpt. of Surgery, Medicine & Radiology	New Loma Linda Univ. (USA)	174
Judkins, Melvin P.	Coordinating Center for Collaborative studies in Coronary Artery Surgery	New York Hospital – Cornell Univ. (USA)	68
Bilbao, Marcia K.	Dpt. of Radiology	University of Oregon Mecial School (USA)	22

He published his last paper in 1981, four years before his death. By the end of his career, his scientific work totalized more than 4500 citations and reached 7866 citations at the end of 2013 (Fig. 2).

Dotter successfully diffused his results and obtained recognition from his academic community with an average of 52-251 citations every year.

It is interesting to point out that before his landmark paper was published in 1964, he was already an active researcher with 100 publications, well recognized by his academic community with 1068 citations at that time.

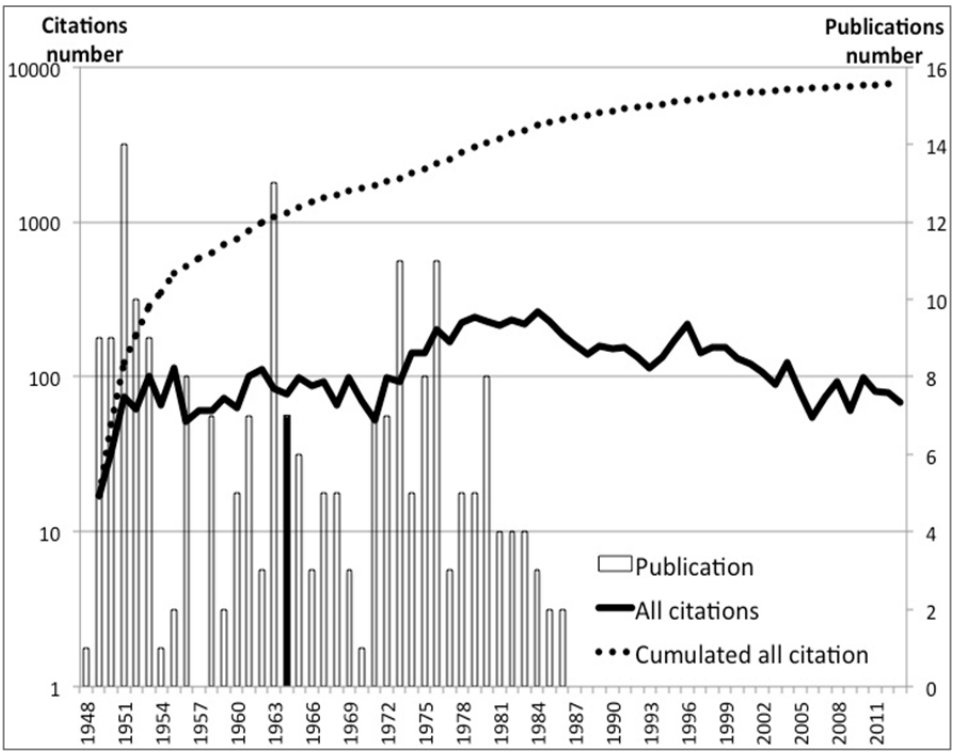

Figure 2. Dotter's publications and citations.

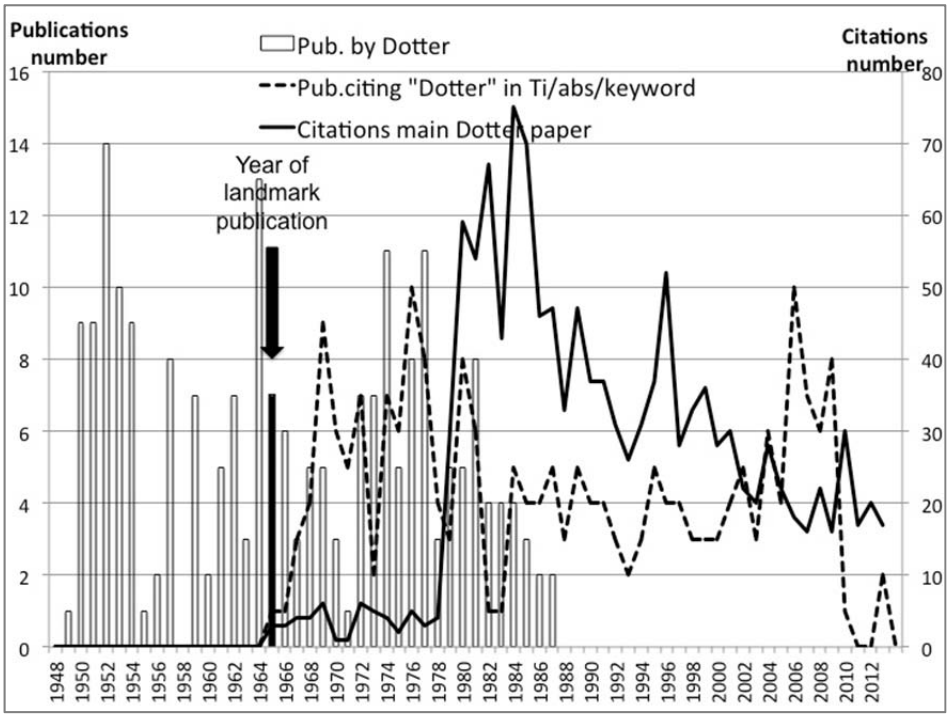

Figure 3. Dotter's main paper citations and Dotter's name apparition in the literature.

Dotter's landmark paper: a sleeping-beauty?

Dotter's landmark paper published in 1964 (Figure 2; black box) was cited with an average of 19.31 citations per year, totalizing 1275 citations today. However, during the first 14 years, his paper was cited only 51 times (Figure 3; full line) before suddenly gaining 29 citations in 1979 and more than 50 citations per year in the latter period.

Therefore, Dotter's main paper has the characteristics of a "sleeping beauty" despite the fact that it does not exactly fit Van Raan's definition (depth of sleep: 3.64 citations/year length of sleep period: 14 years; awake intensity: 52.25 citations/year).

During the delayed recognition period, Dotter was frequently named (n=76) within medical literature (Figure 3: dotted line), as well as his technique, percutaneous transluminal angioplasty (data not show) attesting that the "sleeping period" was traversed by a medical controversy.

The corresponding "Prince" was identified by visualizing the pattern of citations (Fig.4). A German cardiologist, A. Gruntzig, inventor of the coronary balloon angioplasty, was the first to referred to Dotter's previous work. He first did so in a paper published in German in the journal Deutsche Medizinische Wochenschrift in 1974, which had however only very little echo at that time until it was published in English in a well established journal in radiology (American J. of Roentgenology, 132:547-552, April 1979).

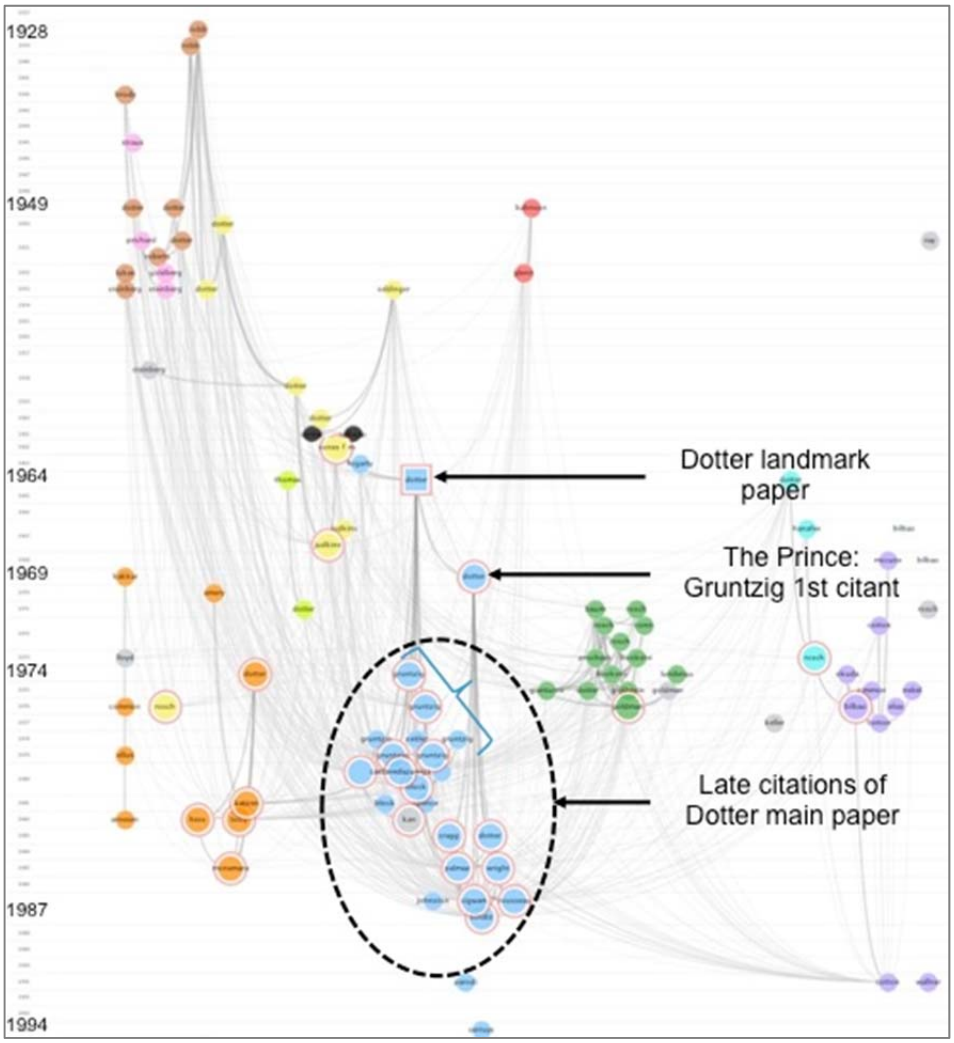

Figure 4. Citation network of CT Dotter paper and its direct and indirect successors.

Later on, Gruntzig's paper, citing Dotter pioneering work, was quickly cited in the medical literature (n=23, year +1) and its peak of citations coincided with the awaking of Dotter landmark paper citations (Figure 5).

Discussions

Dotter landmark paper has the characteristics of a sleeping-beauty but does not fit Van Raan's criteria. Therefore, this case study will discuss the accuracy of Van Raan's criteria to define

"sleeping beauty" in science, and introduce the category of "sleeping beauty" – like as a paper. Beside it is necessary to pinpoint that the sleeping period might indeed be a restless sleep period traversed by scientific controversy that could be traced back in publications databases by differentiating bibliographic references from citations in the text, or by analyzing the nature of the documents, especially article versus editorial, letter or review. These observations should open new avenues in identifying "sleeping beauties" in the literature, and nurture science resistance or controversy study in sociology of science.

Citation Distribution of Individual Scientist: Approximations of Stretch Exponential Distribution with Power Law Tails

O.S. Garanina and M.Yu. Romanovsky[1]

[1]*slon@kapella.gpi.ru*

Abstract
A multi-parametric family of stretch exponential distributions with various power law tails is introduced and is shown to describe adequately the empirical distributions of scientific citation of individual authors. The four-parametric families are characterized by a normalization coefficient in the exponential part, the power exponent in the power-law asymptotic part, and the coefficient for the transition between the above two parts. The distribution of papers of individual scientist over citations of these papers is studied. Scientists are selected via total number of citations in three ranges: 10^2-10^3, 10^3-10^4, and 10^4-10^5 of total citations. We study these intervals for physicists in ISI Web of Knowledge. The scientists who started their scientific publications after 1980 were taken into consideration only. It is detected that the power coefficient in the stretch exponent starts from one for low-cited authors and has to trend to smaller values for scientists with large number of citation. At the same time, the power coefficient in tail drops for large-cited authors.
One possible explanation for the origin of the stretch-exponential distribution for citation of individual author is done.

Conference topic
Citation and co-citation analysis

Introduction
The discussion of how citations of individual authors are distributed has a long history going back even to E. Garfield (1955). In general, there are two points of view on this: the distribution of papers of each scientist is a so-called stretch exponent $W \sim \exp(-x^{\alpha}/T)$, where x is the number of citations, T is some normalization, α is the power exponent coefficient (Redner, 1998; Laherrere & Sornette, 1998). Usually α is considered as 0,3-0,5 (Redner, 1998, Iglesias & Pecharroman, 2006). A slightly more complicated distribution was introduced by (Tsallis & de Albuquerque, 2000).
The second point is that the above distribution has power-law (Pareto, Zipf) character, i.e. $W \sim x^{-\beta}$ where β is the power (Silagadze, 1999; Vazquez 2001; Lehmann et al., 2003). Often, this dependence is treated as the asymptote (tail) of distribution for comparably large x. In this case, the main body is considered as log-normal (Redner, 2005; Stanley, 2010). It should be noted that there are more complicated models of citation distribution.
The idea of our work is to consider the citation distribution of individual scientists taking into account that the distributions for "various-ranking" scientists can be different. Also, it is interesting to join the above stretch-exponential distributions and power-law distributions: observation of tails of citation distributions of individual scientists often demonstrates a presence of small number of extremely-high cited articles, while other articles of considered scientists can be cited much more moderately. From this point of view, the consideration of citation data of a large set of authors (like in (Redner, 1998) etc.) provides rough enough results. Thus, we concentrate on analysis of citation distributions of individual scientists, taking into account some differences in the total number of citations of each. The cumulative distribution of the number of articles with some or larger number of citations will be analyzed.
Of course, the proposed approach is rough enough, since it does not take into account the co-authoring of cited articles. The authors think that it should be considered in further studies in case of wide scientific interest.

The descriptive model is based on our previous works for tailed distributions: Gauss for stock return distributions (Romanovsky & Vidov, 2011), and exponential Boltzmann distribution for new car sells, incomes and weights (Romanovsky & Garanina, 2015). The authors do not know consistently introduced mathematical formulae for distributions with exponential main part and power law asymptote.

Multi-parametric family of curves with stretch exponential main part and power law tail

To define the general form of the desired distribution, one may proceed from the results presented in (Romanovsky & Vidov, 2011) as a starting point. According to (Romanovsky & Vidov, 2011), the sum of a large quantity N of random values similarly distributed with the probability density function (PDF) of the Student's (generally, non-integer) type $\sim z_0^{2\beta}/(z_0^2+f^2)^{2\beta}$ has the distribution of the Gaussian form for comparably small values of fluctuations f:

$$W_G(f) \approx \frac{1}{\sqrt{\pi}} \exp(-f^2)$$

and $\sim 1/f^{2\beta}$ for large f (z_0 being a normalization constant, the sum is treated as random walks in (Romanovsky & Vidov, 2011)). The obvious mathematical generalization to get the exponential part with power-law tail is to perform the transformation $f^2 \to R/T$ (here T can be interpreted as an effective "temperature"). Upon switching from parameters N, z_0, β to parameters θ, T, $\sigma\beta$, the transformation yields the curve with the stretch exponential main part and a transition to power law at the tail in an explicit form of a PDF (Romanovsky & Garanina, 2015):

$$W_{T(\sigma\beta)\theta}(R) = \frac{1}{\sqrt{\pi T}} \int_0^\infty \cos(xR^\sigma) \left\{ \frac{2}{\Gamma(\beta - 1/2)} \left[(\beta - 3/2) \frac{xT}{4\theta} \right]^{\beta/2 - 1/4} K_{\beta - 1/2} \left[\sqrt{(\beta - 3/2) \frac{xT}{4\theta}} \right] \right\}^\theta dx \quad (1)$$

Here R is variable, Γ is the gamma-function, $K_{\beta-1/2}$ is the modified Bessel function of the 2nd kind (also known as ''McDonald function'').

The approximation of Eq. (1) for comparably small R (up to several units of $T^{1/2\sigma}$) is easily reduced to only a dependence on parameter T

$$W_T(R) \cong \frac{1}{T} \exp\left(-\frac{R^{2\sigma}}{T}\right) \quad (2)$$

The general drop off law for $W_{T\beta\theta}$ in the case of large R is $R^{-\beta\sigma}$. The parameter θ describes transition among (stretch) exponential and power-law part of (1). This transition goes under larger R (and smaller values of $W_{T(\sigma\beta)\theta}$) under larger values of θ.

To obtain a general form of W, note that

$$I_\beta(x) = \frac{2}{\Gamma(\beta - 1/2)} \left[(\beta - 3/2) \frac{xT}{4\theta} \right]^{\beta/2 - 1/4} K_{\beta - 1/2} \left[x \sqrt{(\beta - 3/2) \frac{T}{\theta}} \right], \quad (3)$$

It is easy to see that it is a monotonic function of β. Indeed, if $\nu = \mu + 1$, one finds, considering the rule for modified Bessel functions of the 2nd kind, that the ratio $I_\mu(x)/I_\nu(x)$ becomes

$$\frac{I_\mu(y)}{I_\nu(y)} = \frac{K_{\mu+1/2}(y) - K_{\mu-3/2}(y)}{K_{\mu+1/2}(y)} = 1 - \frac{K_{\mu-3/2}(y)}{K_{\mu+1/2}(y)} < 1$$

Furthermore, $\forall \eta : \nu > \eta > \mu$, and one finds that $I_\nu > I_\eta > I_\mu$. Thus, it is not necessary to investigate (1,3) with an arbitrary β. It is enough to consider the integer $\beta = 2, 3, \ldots$, while integrals with intermediate β will be ''locked'' among integrals with neighboring integers β that are expressed by means of elementary functions. Then $n = \beta - 1$,

$$K_{\beta - 1/2} \left[x \sqrt{(\beta - 3/2) \frac{T}{\theta}} \right] = K_{n+1/2} = \sqrt{\frac{\pi}{2x \sqrt{(\beta - 3/2) \frac{T}{\theta}}}} \sum_{k=0}^{n} \frac{(n+k)!}{k!(n-k)! \left[2x \sqrt{(\beta - 3/2) \frac{T}{\theta}} \right]^k} \quad (4)$$

The three functions $W_{T(\sigma\beta)\theta}$ for $\sigma\beta = 2, 1, 0.8$ are:

$$W_{T(\sigma\beta)\theta}(R) = \frac{1}{\sqrt{\pi T}} \int_0^\infty \cos(xR^{\sigma\beta}) \exp\left(-x\sqrt{\frac{\theta T}{2}}\right)\left(1 + x\sqrt{\frac{T}{2\theta}}\right)^{\theta} dx \qquad (5)$$

We used here the simplest form of the function (1) for β=2 for the following approximations of empirical data. The functions $W_{T(\sigma\beta)\theta}$ for σ= 0.5, 0.25, 0.2 are shown in Fig.1. It is seen as a well-coincidence of general functions with corresponding approximation exponents for comparably small values of variable R.

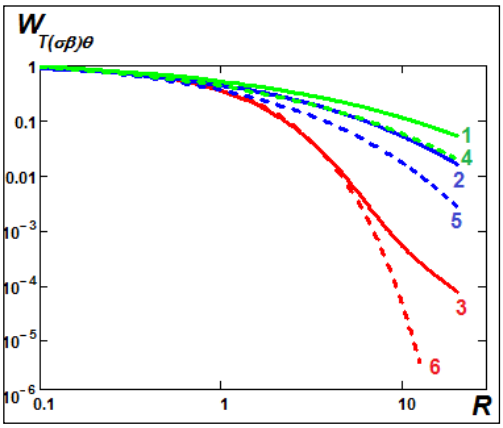

Figure 1. Functions $W_{T(\sigma\beta)\theta}$ for β=2 and σ=0.5 (curve 3), σ=0.25 (curve 2), σ=0.2 (curve 1) for comparably small R. The straight lines (4-6) are exponents $exp(-R^{2\sigma}/T)$ for σ=1,0.5,0.4, respectively. Here T=1, θ=300.

For large R, these functions drop off as R^{-2}, R^{-1}, $R^{-0.8}$, respectively (see Fig.2):

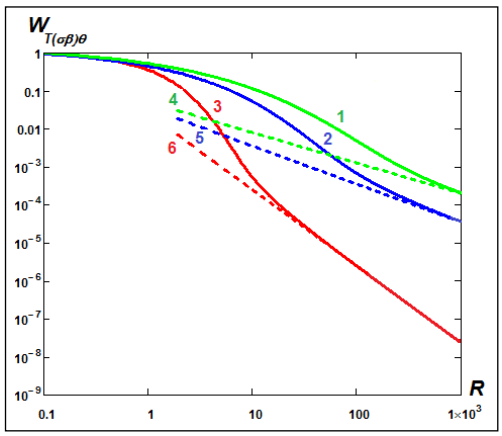

Figure 2. Functions $W_{T(\sigma\beta)\theta}$ for the same β and σ (curves 3-1) as on Fig.1. Hyperboles $R^{-\beta\sigma}$ (straight lines 6-4 on double-logarithmic plot) have σ=0.5, 0.25, and 0.2 (curve 4), respectively. Parameters T, θ are the same as on Figure 1.

Thus the introduced function (1) well-describes the stretch exponent for small (and moderate) values of argument, and provides power-law asymptotes for large R. We used these functions in the next section.

Distribution of citation of individual authors

It was found that the distributions of citations of individual authors are different. It can be expected due to, for example "Matthew effect" (see Bonitz et al., 1997; Bonitz & Scharnhorst, 2001; Stanley, 2010). One may expect that scientists with total number of citation in range 10^2-10^3, 10^3-10^4, and 10^4-10^5 have different distributions of citations. Let us call the scientists with total number of citations in these ranges as the "first-type scientist", etc. We study these intervals for physicists in the ISI Web of Knowledge. The scientists who started their scientific publications

after 1980 were taken into consideration only. We took 20 scientists for the first two ranges, and several scientists for the third. Typical examples of citation distributions are presented below on Figs. 3-5.

On Fig. 3, the cumulative citation distribution (i.e. the number of articles with citations larger than the value R) for experienced scientists with total number of citations in the first range 10^2-10^3 is presented:

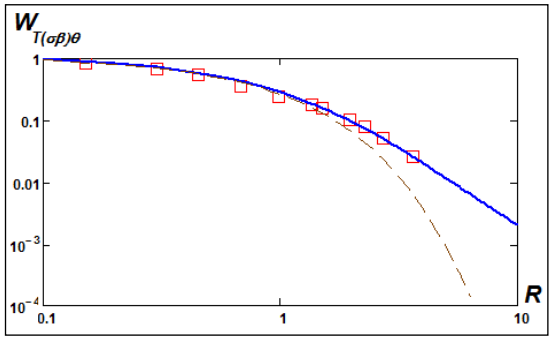

Figure 3. The distribution of articles over citations for the first-type scientist. Open squares are empirical points, the solid curve is $W_{T(\sigma\beta)\theta}$ (5) for β=2, σ=0.5, T=6.5, θ=10, dashed line is an exponent (2) with σ=0.5, T=6.5.

The function $W_{T(\sigma\beta)\theta}$ on Fig.3 is normalized on total number of articles of the first-type scientists in ISI Web of Knowledge. The variable R is the number of citations normalized on T that is the mean citation of this author. It is seen that the function $W_{T(\sigma\beta)\theta}$ (5) well describes the empirical data, the clear difference from the exponent (2) is on-site. At the same time, the total exit on the asymptotic curve $\sim R^{-2}$ does not realize. The last was observed for other-types scientists.

The citation distribution of the second-type scientist (this is a range of world well-known person) is demonstrated on Fig. 4:

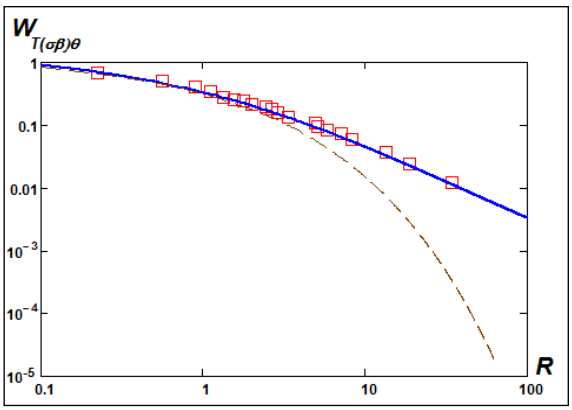

Figure 4. The distribution of articles over citations for the second-type scientist. Open squares are empirical points, the solid curve is $W_{T(\sigma\beta)\theta}$ (5) for β=2, σ=0.25, T=47.4, θ=5, dashed line is an exponent (2) with σ=0.25, T=46.

The normalization of $W_{T(\sigma\beta)\theta}$ on Fig.4 was on total number of articles also. Indeed, the variable R is normalized now on $T^{2\sigma} = (47.4)^{2\sigma} = 6.9$. The "difference" between empirical data as well as function (5) with pure stretch exponent $exp(-R^{1/2}/T)$ is larger than on Fig.3 for the first-type scientist. The total exit on the asymptotic curve $\sim R^{-1}$ is also not realized.

The citation distribution of the third-type scientist (this is a range of Nobel Prize winners) is demonstrated on Fig. 5:

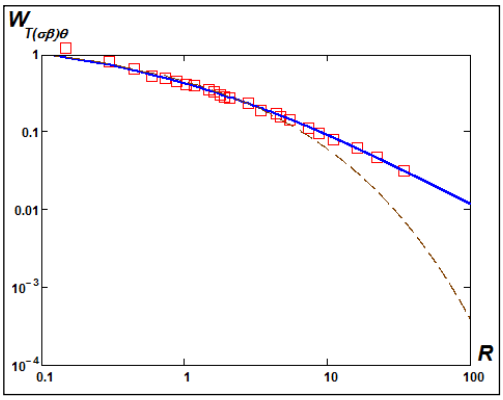

Figure 5. The distribution of articles over citations for the third-type scientist. Open squares are empirical points, the solid curve is $W_{T(\sigma\beta)\theta}$ (5) for β=2, σ=0.2, T=340, θ=5, dashed line is an exponent (2) with σ=0.2, T=340.

The normalization of $W_{T(\sigma\beta)\theta}$ on Fig.5 is the same, the variable R is normalized now on $T^{2\sigma} = 340^{2\sigma} = 10.3$. It is interesting that all values $T^{2\sigma}$ for all three-types scientists are close to each other and may characterize the citation distribution of individual scientists.

Explanation attempt

Let us try to explain the appearance of stretch exponents in cumulative distribution of such random values like citations. We start from the standard exponential distribution

$$W_1 = \exp(-x) \tag{6}$$

where we used normalization T=1 to simplify the following expressions.

How can these calculations be "translated" into the language of citations? The first cause of a citation of some article is the scientific results of this article. Since the author who can potentially cite the above article may find or not find this article, the process of citation due to the scientific significance looks like the two-body exchange (of information in this case) and is provided by distribution (6). Thus it may be that the basic cumulative distribution of citations arises due to the scientific significance of the article and looks like (6).

There are clear additional independent causes for citations. One of them is the name of author (or one of authors in case of co-authoring) of a potentially cited article. It may be the name of scientist in the group that works in the same area of science studied with the author of the cited paper, there arises another causes to cite some scientist. Since this scientist may also be chosen randomly in the process of information exchange, the probability distribution to cite this scientist looks like (6) as well. If now the citation is realized due to two causes: by scientific significance and cited article author, the random value of such citation is the factor of two random values characterized by distribution (6).

Since the causes for citation are independent, they can be considered as some coordinates. For two cases, they are above "scientific significance" and "author's name". The variation of these coordinates here are from small to large scientific significance and from large to small reputation of cited scientist. At the same time, we observe citation as being a principally one-dimensional value: the citation either exists or does not exist. Therefore, all distributions (6) reduce to one dimension. The transformation of coordinates in (7) $x^2 \rightarrow y$ provides than for cumulative distribution function

$$W_2(y) = \exp\left(-\sqrt{y}\right) \tag{7}$$

i.e. the main part of stretch exponent (2) with σ=0.25. These stretch-exponents distributions were observed by us and described in the chapter of this paper "Distribution of citation of individual authors".

The same procedure in case of three clearly existed "coordinates" provides cumulative distribution

$$W_3(y) = \exp\left(-\sqrt[3]{y}\right) \quad (8)$$

The same conduction for power-law tailed stretch exponential distributions should take into consideration the power exponents in tails for original distributions of "scientific significance" etc., and needs the volumetric calculations.

Conclusion

The 4-parametric family of functions representing the stretch exponential distribution for small and medium values of the argument combined with a power-law asymptotic tail, along with various transitions between these two parts, is introduced. These functions are demonstrated as good fits of the available empirical data for the cumulative distribution of citations to individual scientists.

Abstracting from the co-authoring of a cited paper, one may conclude that these cumulative distributions of papers of individual authors versus their citations have character of stretch exponent for small and moderate values of citations, and power-law form for asymptotic part. It looks that the "power of stretch", i.e. the introduced coefficient σ depends on the total number of citations, moreover, this coefficient starts from ½ (i.e. distributions start from normal exponent) and becomes smaller with an increase of the total number of citations. The power-law force becomes smaller in return.

The first attempt to explain the "main body" of distributions (stretch exponents) is provided.

Research Support Office and Bibliometrics Analysis, Nanyang Technological University, #B4-01, Block N2.1, 76, Nanyang Drive, Singapore 637331 (Singapore)

Introduction

It is widely presumed that international collaboration benefits the researchers and the organisations involved, and enhances the quality of research (Persson, 2010). However, research also suggests that the effects of international collaboration may vary across disciplines and the authors' countries (Moed, 2005).

In this study, we investigated the effect of international collaboration on the impact of publications of selected young universities, and compared to that of renowned old universities. The 5-year citations per paper (CPP) data, the international collaboration rate, the CPP differential between publications with and without international collaborations, and the difference between the percentages of international collaborated publications falling in the global top 10% highly cited publications and the percentage of overall publications falling in the global top 10% highly cited publications (Δ%Top10%) are used as the impact indications. These data are extracted from the Thomson Reuters Web of Science (WoS) database and Essential Science Indicator (ESI) based on papers published from 2004 to 2013. Young institutions ranked by the 2014 Times Higher Education (THE)'s 100 under 50 Universities are selected in this study, and some renowned universities (> 100 years old) are selected as references for "old universities".

To eliminate the discipline difference effect, the increment of 5-year (2010-2014) field weighted citation impact (FWCI) of internationally collaborated papers over the 5-year overall FWCI of the institutions in SciVal® of Elsevier is used as another indicator. The collaboration among 8 old institutions and 8 young institutions are investigated.

Results and Discussion

Correlation between International Collaboration rate and CPP in 5-year interval

Figure 1 shows the 5-year ESI CPP trends as a function of 5-year international collaborations rate trends for selected young and old universities. While old universities have higher CPP in general, there are strong correlation between international collaboration rate trends and 5-year CPP trends. For example, for old universities, the CPP increased 4.12 for every 10% increase in international collaboration rate for MIT, 3.42 for Univ Oxford, and 3.01 for Stanford Univ. Among young universities, for Nanyang Technol Univ (NTU), it is 2.24 CPP per 10% Intl Collab increment, and that for Plymouth Univ is 3.02, and 0.73 for King Fahd Univ of Petr and Min.

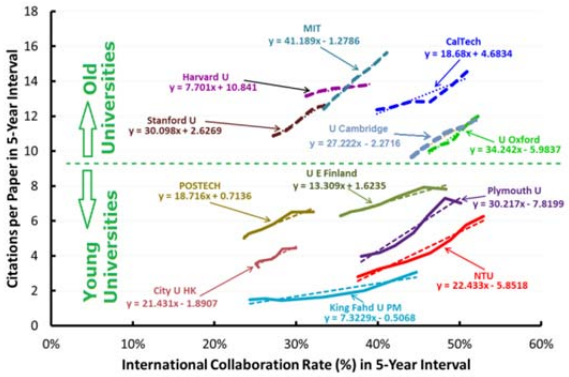

Figure 1. 5-Year CPP Trends vs. 5-Year International Collaborations Rate Trends for Selected Young and Old Universities.

The ΔCPP trends for publications with and without international collaborations for selected institutions are examined, and listed in Table 1.

Table 1. 5-Year Citations per Paper Differential between Publications with and without International Collaborations.

5-Year Period	Citations per Paper Difference between Publications with and without International Collaboration											
	Caltech	U E Finland	Univ Florence	Univ Tsukuba	Univ Melbourne	Univ Waikato	Kyushu Univ	MIT	NUS	HKUST	NTU	USM
2004-2008	5.5	3.04	3.59	5.19	4.5	2.68	2.26	3.24	0.78	1.03	0.2	1.08
2005-2009	5	3.38	3.68	5.65	4.06	1.68	2.62	3.25	0.66	1.44	0.51	0.97
2006-2010	4.2	3.42	3.79	4.87	4.3	2	2.55	3.38	0.63	0.55	0.43	0.65
2007-2011	4.2	4.1	3.91	4.85	4.42	2.1	1.85	2.68	0.82	1.33	0.47	0.11
2008-2012	4.8	4.44	4.38	4.65	4.77	2.86	1.75	2.29	1.28	1.44	0.05	-0.3
2009-2013	6.1	5.28	5.3	5.2	4.87	3.61	2.4	2.16	1.67	0.87	0.02	-0.7
ESI 2009-2013 CPP	15	8.53	7.68	6.48	8.66	5.43	5.28	15.7	7.83	6.7	6.92	3.47

From Table 1, we can find that in the case of Caltech, U Melbourne and U Tsukuba, the CPP difference between their international collaborated

publications and their publications without international collaboration is roughly 4 to 5. This explains the typical 5-year ESI CPP vs. international collaboration rate trends of these institutions: with the increase of international collaboration rate in their publications, the overall CPP of their papers has more weight from their international collaborated publications, and the overall CPP of their publications increased. Yet, for Hong Kong Univ of Sci & Techn (HKUST), Natl Univ Singapore (NUS) and NTU, the CPP gaps between publications with and without international collaboration are relatively small (around 0 to 1 CPP). This is because the fact that these institutions have attracted a lot of researchers with international background to work in these institutions, which makes the difference between their national research and international collaborated research relatively small.

Trends of difference between percentage of international collaborated publications falling in global top 10% highly cited publications and that for all publications (Δ%Top10%)

The study on difference between the percentage of international collaborated publications for an institution falling in the ESI global top 10% highly cited publications and the percentage of all publications of the same institution falling in the ESI global to top10% highly cited publications (Δ%Top10%) shows that, for all the selected young and old institutions, this difference is generally positive, means that internationally collaborated publications generally have a higher rate of high citation publications among all publications. Yet, this difference varies from one institution to another institution. For some renowned top universities like Caltech, Stanford University and University of Cambridge, although their overall CPP for their publications is already very high, the Δ%Top10% is still higher than the percentage of their overall publications falling in the global top 10%. Further investigation is needed to have an adequate explanation for this phenomenon.

Increment of field weighted citation impact (FWCI) of internationally collaborated papers over the FWCI of the involved institutions

Figure 2 shows the increment of FWCI for internationally collaborated papers over the overall FWCI of the two collaborating institutions among the selected 8 old institutions and 8 young institutions. 57 bilateral collaboration couples with 50 and more collaborating publications are identified among these 16 institutions, and the FWCI increment data for these collaboration couples are include in the plot. It can be seen that, international collaboration benefits both the young and the old institution, with the old institution to old institution collaboration provides the highest FWCI increment, followed by the old institution to young institution collaboration. Among the 57 bilateral collaborations, only 3 involved young institution to young institution collaboration, indicating that there are untapped potential for enhancement on bilateral collaboration among young institutions.

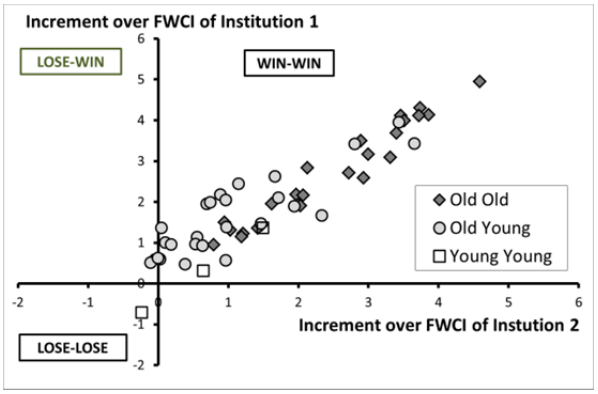

Figure 2. Increment of 5-year FWCI of internationally collaborated papers over the overall FWCI of the involved Institutions.

Conclusions

The investigation on the effect of international collaboration on the impact of publication of selected young universities and well established renowned universities show that, both young and old institutions received benefit from international collaboration using citation impact of their publications as indicator. For example, for old universities, the CPP increased 4.12 for every 10% increase in international collaboration rate for MIT and 3.42 for U Oxford. Among young universities, for NTU, it is 2.24 CPP per 10% Intl Collab increment, and that for Plymouth U is 3.02 CPP per 10% Intl Collab increment.

The percentage of publications fall in the ESI global top 10% highly cited publications for international collaborated publications is generally higher than that for all journal publications of the same institution. Yet, this difference varies from one institution to another institution.

The international collaboration also increases the FWCI of the institution, yet there are untapped potential to enhance the collaboration among young institutions.

Citation analysis as an auxiliary decision-making tool in library collection development

Iva Vrkić

ivavrkic@gfz.hr
University of Zagreb, Faculty of Science, Department of Geophysics, Geophysical Library, Horvatovac 95, 10000 Zagreb (Croatia)

Introduction

Academic libraries in Croatia are facing constant budget cuts, making it difficult to obtain access to current scientific and professional journals (Krajna & Markulin, 2011). At the end of 2008 the Croatian economy had plummeted into recession and the *Ministry of Science, Education and Sports* ceased the funding of scientific literature acquisition (Krznar, 2011).

Parallel to budget cuts, the prices of scientific journals increased. The period from 2009 to 2014 showed a threefold increase in prices of the journals acquired by the Geophysical library in Zagreb (Figure 1), making it necessary to review the need for the purchase of each journal.

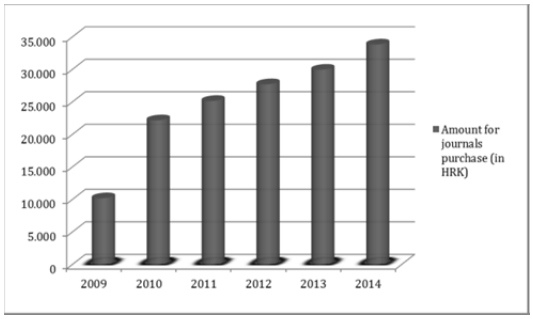

Figure 1. Threefold increase in prices of the journals acquired by the Geophysical library in Zagreb.

Quantitative and qualitative methods can be used to make optimal decisions regarding the purchase of journals (Gomez, 2002). The qualitative method is based upon interviewing lecturers and other competent scientific staff and taking their suggestions on which journals are essential. Their assessment of the journals' relevance is the most important guideline in creating an acquisitions policy. The quantitative method, on the other hand, provides the much-needed objectivity in the acquisitions process, but can only be used as an additional guideline to the qualitative method. This method can come in the form of usage statistics or the assessment of the journal's importance through citation analysis. Such an assessment is described in this paper. Although the quantitative method is objective, its results (list of most used/most relevant journals) cannot replace subject-matter experts' opinion, only inform them.

Methodology

The goal of this study is to determine the importance of certain journals for the geophysical community at the Faculty of Science in Zagreb. This will be done by compiling a list of journals most cited by the scientific staff at the Geophysical department from 2000 to 2014. References from all scientific papers published by the staff at the Department of Geophysics in the last 14 years were collected, and 6120 references were selected from journals cited by our geophysicists. The citation frequency was analysed, and references were listed for each journal.

Results and discussion

Assuming the citation frequency of articles from a certain journal confirms its importance for the scientists, the journals were listed by relevance after the data had been processed. The result is a list of 512 journals ranked by the number of citations. A "Top 15" list has also been created – 15 most cited journals by the members of the Department of Geophysics from 2000 to 2014 (Table 1).

Table 1. *Top 15* – most cited journals by the members of the Department of Geophysics form 2000 to 2014.

	Journal title	∑ citation
1	Journal of Geophysical Research	448
2	Journal of the Atmospheric Sciences	349
3	Quarterly Journal of the Royal Meteorological Society	335
4	Monthly Weather Review	222
5	Boundary-layer meteorology	213
6	Journal of Climate	202
7	Atmospheric Environment	195
8	Journal of Applied Meteorology and Climatology	185
9	Geofizika	162
10	Geophysical Research Letters	115
11	Tellus	114
12	International Journal of Climatology	108
13	The Astrophysical Journal	97
14	Bulletin of the Seismological Society of America	95
15	Annales Geophysicae	93

Data on the age of journal citations (cited by the members of the Department of Geophysics in a 14-

year period) was processed. Citation age is determined as the discrepancy between the publishing years of both the cited and the citing paper.

The citation age median for the whole set is 9 years. The histogram (Figure 2) shows that half of the citations are 0 to 9 years old, and rest of them are 10 to 133 years old. Citation frequency in 1st quartile shows statistically significant greater representation of citations in relation to the 2nd quartile ($\chi^2 = 9{,}86$; $P<0{,}0017$).

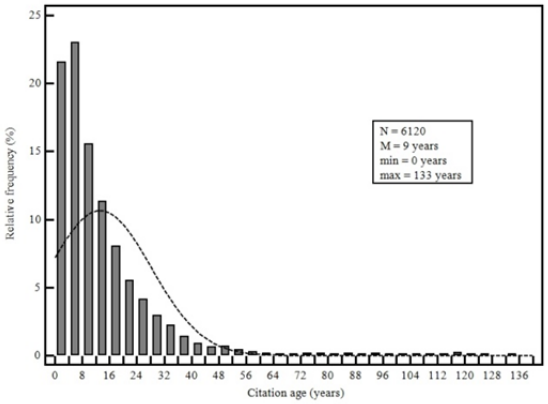

Figure 2. Citation frequency relative to citation age.

Therefore, recent scientific papers are the most cited.

Instead of a conclusion

Why is optimizing the library's acquisitions policy so important? The answer is, of course, because optimization is crucial in creating a list of the most relevant journals to be acquired, which can also be illustrated using the *Pareto principle*.

The Pareto principle is, amongst other thing, used to evaluate periodicals collections. It was named after Vilfredo Pareto, an Italian sociologist, who first used it to explain the distribution of land in Italy, where 80% of the land was owned by 20% of the population.

As previously mentioned, the principle applies to many different areas, so if applied to a periodicals collection, it will show that 20% of the periodicals in the collection will cover 80% of information needs. Also, 80% of the citations will be found in 20% of the periodicals (Dewland & Minihan, 2011).

This analysis further establishes the Pareto principle: 85,87% of the citations were found in the upper 20% of the periodical list. As a relatively low number of periodicals (20%) generates the most citations (85%), it's possible to conclude that, if an academic library strives to acquire the right periodicals and makes an optimal selection, it can provide good coverage of relevant information for its patrons, even if the quantity of said periodicals is low. In other words, a small but optimal selection of periodicals can cover the most of an institution's information needs.

Do First-Articles in a Journal Issue Get More Cited?

Tian Ruiqiang, Yao Changqing, Pan Yuntao, Wu Yishan, Su Cheng and Yuan Junpeng

trq2011@sina.com

Institute of Scientific and Technical Information of China, 15 Fuxing Road, 100038, Beijing (China)

Introduction

As the advice of peers on the quality of a submitted paper prior to publication, peer review can be regarded as the pre-publication evaluation. Bibliographic citations of scientific papers used as indicators of the visibility, impact, and quality of scientific publications, could be regarded as the post-publication evaluation.

Intentionally or not, journal editors often put the accepted manuscript with nice comments by peer reviewers at the top of all papers in an issue. The First-Articles of journal issues are generally regarded with higher importance, intense creativity or superior quality through peer review process. Judge A, Cable M, Colbert E (2007) deemed that journal editors placed the best paper in the "pole position", and they confirmed this anecdotal evidence further in their study. Specifically, 75% of 16 journals indicated that quality played some primary role in selection of the first articles. Wang (2015) also admitted that journals would choose the very best paper of an issue on the cover, "a paper that in 20 year's time might win a Nobel Prize", according to the opinion of Stang, the EIC of *Journal of the American Chemical society* (Ritter 2006).

Since there are evidences that peer reviewers can successfully discriminate between manuscripts that have a greater chance to be cited in future. Further, in this sense, we made a hypothesis that the best articles selected by peer reviews—usually the First-Articles, will be superior in receiving higher citations after publication. In this paper we will illustrate how peer review and the performance of journal papers measured by bibliometric indicators could concordance with each other. In particular, we examined whether there were obvious citation differences between First-Articles and non-First-Articles published in the same issue of a journal.

Data and Methodology

Twins data, a sampling method used in labour economics, reaches "other things being equal" to a certain extent. Twin studies are often employed to evaluate the inheritance of a trait by dissecting the genetic and environmental contributions to the trait.

In this study, we regard the First-Articles and non-First-Articles in the same issue as twins. They were published in the same time and have similar disciplinary backgrounds.

We select First-Articles from Scopus and Web of Science (WoS). First, we choose journals which publish research articles on their first pages rather than other types of documents, such as editorial, letters et al. And we find that most mathematic journals satisfy this criterion well. Thus we select top100 mathematical journals by their Impact Factors from JCR 2013. Then, we acquire twins data by retrieving articles published in those 100 journals between1995-1999 in Scopus and WoS. As a result, we obtained 19,411 articles in 62 journals in WoS on December 25, 2014 and 18,524 articles in 67 journals in Scopus on January 13, 2015 respectively. The difference of journal numbers is resulted that some journals were not indexed as early as 1995-1999 while included in 2013 JCR. And we identified 2050 out of WoS and 2229 out of Scopus First-Articles, excluding those articles published on supplementary issues, special issues. Table 1 provides an overview of the samples.

Table 1. Descriptive statistics of the samples

	Scopus		WoS	
	Fr	**Non -Fr**	**Fr**	**Non-Fr**
Articles	2229	16295	2050	17361
		67 journals		62 journals

Results

First-Articles receive higher CPP&CTC

The indicator CPP (the average number of citations received per article) and CTC (the contributions to total journal citations) were taken as the criterion to assess the citation position of First-Articles and non-First-Articles in their own disciplinary citation environment. It revealed obvious differences in citations between the First-Articles and non-First-Articles. As shown in Table 2, in WoS, the First-Articles received higher average citation (AC) (16.56) since publishing, while the non-First-Articles got 13.69. In Scopus, the First-Articles accumulated 17.00 of AC, those non-First-Articles of 14.00. In WoS, the First-Articles contribute 12.5% to total citations (TC) of the journal when their proportions in total documents remain only 10.6%. Though the non-First-Articles got 89.4% share of total documents, their contributions of TC remain 87.5%. And the case is almost the same in Scopus: the First-Articles contribute 14.2% to TC when the proportions of articles remain only 12%. Though

the non-First-Articles got 88% of articles, their contributions of TC remain 85.8%.

Based on ANOVA test, we found significant difference between TC of 2050 First-Articles and 17361 non-First-Articles in WoS at the 0.05 significance level. Similarly, in Scopus there is also significantly different between 2229 First-Articles and 16295 non-First-Articles. Specifically, TC of First-Articles is significantly higher than non-First-Articles. From WoS, the non-First-Articles received mean TC of 13.69. While under same circumstance, First-Articles received clearly higher mean TC of 16.56. In terms of Scopus, the non-First-Articles reached at 14.00 of mean TC. And this time, the similar backgrounds, First-Articles performed more excellent, reaching notably higher mean TC of 17.00. Therefore, First-Articles are higher impact than non-First-Articles both in WoS and Scopus.

Table 2. TC difference in ANOVA test

	WoS			Scopus		
	Num	**Mean**	**SD**	**Num**	**Mean**	**SD**
Fr	2050	16.56	30.13	2229	17.00	27.08
N-Fr	17361	13.69	24.03	16295	14.00	24.51
P			0.000			0.000

Nearly 24% First-Articles are most highly cited, while non-cited articles account for only 10%

It shows 22.6% First-Articles in average are also the papers with highest TC among papers published in the same journal issues in WoS. And the proportion keeps stable in the observe window. In Scopus, the percentage of the most highly cited papers in First-Articles goes to almost 25%. In 1997, it even reached a peak of 27%.

Table3. Citation difference of First-Articles and non-First-Articles in WoS& Scopus

	WoS	**Scopus**
CPP-Fr	16.56	17.00
CPP-Non-Fr	13.69	14.00
CTC-Fr	0.125	0.142
CTC-NFr	0.875	0.858
Num highC	463	552
Num zeroC	228	179
highC %	0.226	0.248
ZeroC%	0.111	0.080
ZeroC Total %	0.124	0.107

As shown in Table 3, the percentage of non-cited papers in 62 mathematics journals in WoS is 12.4%. While it is much lower for First-Articles, the uncitedness rate drops to 11.1% in a whole through a period of nearly two decades. As for Scopus database, the share of papers never cited in 67 journals in mathematics decline to10.7%. In addition, the proportion of uncitedness for First-Articles stays to 8.0% on average.

Conclusion

To verify the hypothesis that the best articles selected by peer reviewers, usually the First-Articles, will be superior in receiving higher citations after publication compared with non-First-Articles published in the same journal issue, we first obtained twins data of First-Articles and non-First-Articles by retrieving articles published in top 100 (in terms of JCR 2013 JIF) mathematic journals in Scopus and WoS. Then we employed indicators CPP, CTC and TC, based on which we applied ANOVA to contrast citation bias of First-Articles and non-First-Articles in both Scopus and WoS. Results showed that there existed significant difference between First-Articles and non-First-Articles in receiving citations after publication. On the basis of these empirical grounds, we suggested that the First-Articles are biased in citations compared with non-First-Articles. We also found that it revealed a higher proportion of First-Articles to be most highly cited and comparatively lower proportion to be uncited. Furthermore, it presented a good consistency in conclusion in Scopus and WoS.

The results suggest that the peer reviewer's best recommendation go accordance with highest bibliometric indicator performance. Deliberately or not, papers received best recommendations in pre-publication evaluation process often are arranged as the First-Articles in a journal issue. The First-Articles are generally regarded as ones of high importance intense creativity or superior quality judged by peer reviewers; therefore they are expected to have a greater chance to get highly cited in the future. In fact, such understanding is supported by our analysis in this paper. After publication, those First-Articles are more likely to receive higher citations. Accordingly, peer reviewers' best recommendations and the excellent performance of journal papers measured by bibliometric indicators concordance with each other in the case of First-Articles.

Introduction

Productivity measurement has become a major issue for university leaders. Federal and state governments support teaching and research with significant investments. When university leaders are seeking new funding, it is not uncommon that they need to justify their request with productivity measurement metrics and equally important research output consumption metrics. However, it is often very difficult for university leaders to generate these metrics as they lack access to relevant data and tools to analyse and visualize large amounts of data.

Interested to address the diverse needs of university leaders, ProQuest and Indiana University analysed the ProQuest Dissertation & Theses Global (PQDT Global) database, an extensive and trusted collection of 3.8 million graduate study dissertations with 1.7 million full text records and editorially assigned metadata created by subject area experts. The database offers comprehensive North American and significant international coverage. Worldwide access to the database is logged at the dissertation level by ProQuest. Usage data mining is important for understanding user behaviour (Srivastava et al., 2000). The ProQuest Dissertations Dashboard released in 2014 provides easy access to dissertations, metadata, and usage data. It is available for free to leaders of any university that shares dissertation data with ProQuest.

ProQuest Data Analysis and Visualization

Analyses were conducted and results visualized to answer questions that seemed of particular interest to university leaders and those seeking to assess the performance of a school as a whole.

Study 1: How much attention are my school's dissertations getting?

A school's ability to generate interest in their students' dissertations may not only reflect the reputation of the school, but have long-term effects on those students' marketability and also in attracting future generations of students to join the school.

Figure 1 plots the production and access data for computer science dissertations for a selected institution given in red and labelled 'Subject University' and two groups of peer institutions rendered in green and blue. Other institutions that have published computer science dissertations are given in grey. The three institutions in the top-right corner of the plot—publishing many theses that attract many views—include both well-regarded private research institutions as well as for-profit colleges with practically open admissions. This implies that while thesis production and usage are important, they should not be used as a sole indicator for the quality of a program.

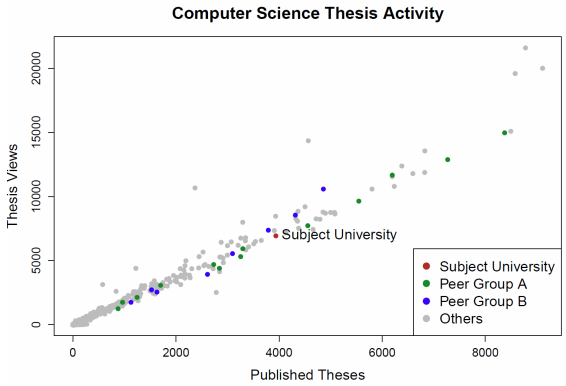

Figure 1. Comparing Subject-Area Specific Thesis Access Activity with Peer Groups.

Study 2: How can I quickly compare the number of dissertations and associated download activity for a large number of universities?

Given all dissertations or dissertations in a certain subject area, university leaders might like to understand the "market share" of an institution within a comparison or peer group.

In Figure 2, two peer groups of institutions are compared. Each institution is represented by a rectangle. Each rectangle is sized based on the total corpus of computer science dissertations available in the ProQuest dataset for that institution.

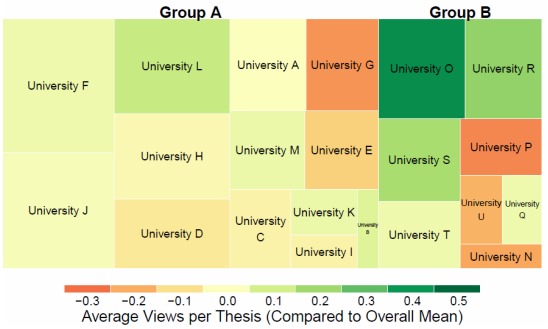

Figure 2. Treemap Comparing Thesis Production and Usage in Computer Science.

Colours tell how frequently the average dissertation at that institution is accessed in comparison to the group average. Computer science dissertations written at Universities L, O, and R are accessed more frequently than the group average, while those published at Universities G or P are accessed less.

Study 3: How is dissertation information flowing in and out of my university?

Universities are both producers and consumers of information (Mazloumian et al., 2013). Administrators are interested to understand which dissertations from which universities are used at their own institution but they also want to know who is accessing their own institution's dissertations. Plus, they might need to compare this in-flow and out-flow of information with the flows calculated for other universities.

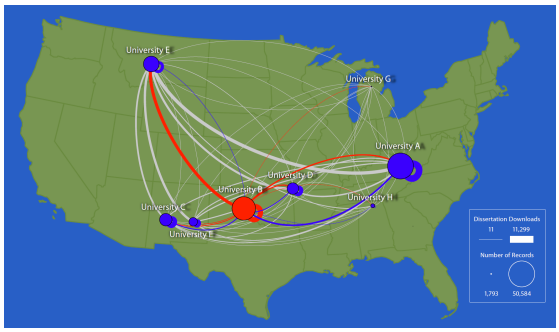

Figure 3. Information Flows within Peer Group

The example in Figure 3 looks at information flow between a group of peer schools. One institution, labelled University B, is highlighted. Red edges depict information flowing out of that institution, while blue flows show information flowing into that institution. The thicker the line, the greater is the number of dissertations. (Information always flows clockwise on the curved lines).

Future Directions

Currently, ProQuest dissertation data is not linked to publication, funding or other data. However, there is much interest in being able to study career trajectories in a more comprehensive manner (Ni & Sugimoto, 2012; Ostriker, Kuh, & Voytuk, 2011) and to examine the reputation and funding of dissertation advisors and the success (in terms of funding and publication records) of their advisees in more detail. Citation counts for dissertations, user ratings and altmetrics data, e.g., social media data, are valuable indicators of impact that we would like to explore. We also think that productivity and usage datasets can be leveraged to study the emergence of new disciplines and cross-disciplinary subject areas (Sugimoto, Li, Russell, Finlay, & Ding, 2011).

INDICATORS

An Alternative to Field-normalization in the Aggregation of Heterogeneous Scientific Fields

Antonio Perianes-Rodriguez[1] and Javier Ruiz-Castillo[2]

[1] *antonio.perianes@uc3m.es*
Universidad Carlos III, Department of Library and Information Science, SCImago Research Group, C/ Madrid, 128, 28903 Getafe, Madrid (Spain)

Universidad Carlos III, Departamento de Economía, C/ Madrid, 126, 28903 Getafe, Madrid (Spain)

Abstract
A possible solution to the problem of aggregating heterogeneous fields in the all-sciences case relies on the normalization of the raw citations received by all publications. In this paper, we study an alternative solution that does not require any citation normalization. Provided one uses size- and scale-independent indicators, the citation impact of any research unit can be calculated as the average (weighted by the publication output) of the citation impact that the unit achieves in all fields. The two alternatives are confronted when the research output of the 500 universities in the 2013 edition of the CWTS Leiden Ranking is evaluated using two citation impact indicators with very different properties. We use a large Web of Science dataset consisting of 3.6 million articles published in the 2005-2008 period, and a classification system distinguishing between 5,119 clusters. The main two findings are as follows. Firstly, differences in production and citation practices between the 3,332 clusters with more than 250 publications account for 22.5% of the overall citation inequality. After the standard field-normalization procedure where cluster mean citations are used as normalization factors, this figure is reduced to 4.3%. Secondly, the differences between the university rankings according to the two solutions for the all-sciences aggregation problem are of a small order of magnitude for both citation impact indicators.

Conference Topic
Indicators; Citation and co-citation analysis

Introduction
As is well known, the comparison of the citation impact of research units is plagued with obstacles of all sorts. For our purposes in this paper, it is useful to distinguish between the following three basic difficulties. (i) How can we compare the citation distributions of research units of different sizes even if they work in the same homogeneous scientific field? For example, how can we compare the output of the large Economics department at Harvard University with the output of the relatively small Economics department at Johns Hopkins? The next two difficulties have to do with the heterogeneity of scientific fields: the well-known differences in production and citation practices makes it impossible to directly compare the raw citations received by articles belonging to different fields. Given a classification system, that is, a rule for assigning any set of articles to a number of scientific fields, field heterogeneity presents the following classic hindrances in the evaluation of research units' performance. (ii) How can we compare the citation impact of two research units working in different fields? For example, how can we compare the citation impact of MIT in Organic Chemistry with the citation impact of Oxford University in Statistics and Probability? Finally, (iii) how can we compare the citation impact of two research units taking into account their

output in all fields? For example, how can we compare the citation impact of MIT and Oxford University in what we call the *all-sciences* case?

As is well known, the solution to the first two problems requires size- and scale-independent citation impact indicators. We will refer to indicators with these two properties as *admissible* indicators. Given an admissible indicator, in this paper we are concerned with the two types of solutions that the third problem admits. Firstly, the problem can be solved in two steps. One first uses some sort of normalization procedure to make the citations of articles in all fields at least approximately comparable. Then, one applies the citation indicator to each unit's normalized citation distribution. Secondly, consider the Top 10% indicator used in the construction of the influential Leiden and *SCImago* rankings. In the Leiden Ranking this indicator is defined as "*The proportion of publications of a university that, compared with other similar publications, belong to the top 10% most frequently cited…Publications are considered similar if they were published in the same field and the same publication and if they have the same document type*" (Waltman et al., 2012a). A similar definition is applied in the SCImago ranking (Bornmann et al., 2012) Note that this way of computing this particular indicator in the all-sciences case does not require any kind of prior citation normalization. For our purposes, it is useful to view this procedure as the average (weighted by the publication output) of the unit's Top 10% performance in each field. We note that this important precedent can be extended to *any* admissible indicator. Thus, given a classification system and an admissible citation indicator, we can compute the citation impact of a research unit in the all-sciences case as the appropriate weighted average of the unit's citation impact in each field. Independently of the conceptual interest of this proposal, we must compare the consequences of adopting it versus the possibility of following a normalization procedure.

Intuitively, the better the performance of the normalization procedure in eliminating the comparability difficulties across fields, the smaller will be the differences between the two approaches. Consider, for example, what we call the standard field-normalization procedure in which the normalized citations of articles in any field are equal to the articles' original raw citations divided by the field mean citation. Under the universality condition, that is, if field citation distributions were identical except for a scale factor, then the standard field-normalization procedure would completely eliminate all comparability difficulties. However, the universality condition, once claimed to be the case (Radicchi et al., 2008), is not usually satisfied in practice: even appropriately normalized, field citation distributions are seen to be significantly different from a statistical point of view (Albarrán et al., 2011a; and Waltman et al., 2012a). Therefore, at best, normalization procedures provide an approximate solution to the original comparability problem.

Using a measuring framework introduced in Crespo et al. (2013), recent research has established that different normalization procedures perform quite well in eliminating most of the effect in overall citation inequality that can be attributed to differences in production and citation practices between fields. This is the case for large Web of Science (WoS hereafter) datasets, classification systems at different aggregation levels, and different citation windows (Crespo et al., 2013, 2014; Li et al., 2013; Waltman & Van Eck, 2013; Ruiz-Castillo, 2014). The reason for the good performance of target (or cited-side) normalization procedures is that field citation distributions, although not universal, are extremely similar (Glänzel, 2007; Radicchi et al., 2008; Albarrán & Ruiz-Castillo, 2011; Albarrán et al., 2012; Waltman et al., 2012a; Radicci & Castellano, 2012; Li et al., 2013). It should be noted that this research on target normalization procedures uses WoS classification systems distinguishing at most between 235 sub-fields.

In principle, given the good performance of normalization procedures, we expect that the differences between the two approaches would be of a small order of magnitude.

Nevertheless, this is an empirical question that has never been investigated before. To confront this question, in this paper we conduct the following exercise.

- Ruiz-Castillo & Waltman (2015) apply the publication-level algorithmic methodology introduced by Waltman and Van Eck (2012) to a WoS hereafter dataset consisting of 9.4 million publications from the 2003-2012 period. This is done along a sequence of twelve independent classification systems in each of which the same set of publications is assigned to an increasing number of clusters. In this paper, we use the classification system recommended in Ruiz-Castillo and Waltman (2015), consisting of 5,119 clusters, of which 4,161 are referred to as significant clusters because they have more than 100 publications over this period. For the evaluation of research units' citation impact, we focus on the 3.6 million publications in the 2005-2008 period, and the citations they receive during a five-year citation window for each year in that period. It should be noted that, using the size- and scale-independent technique known as Characteristic Scores and Scales, Ruiz-Castillo and Waltman (2015) show that, as in previous research, significant clusters are highly skewed and similarly distributed.
- Our research units are the 500 universities in the 2013 edition of the CWTS Leiden Ranking (Waltman et al., 2012b). We analyze the approximately 2.4 million articles – about 67% of the total– for which at least one author belongs to one of these universities. We use a fractional counting approach to solve the problem –present in all classification systems– of the assignment of responsibility for publications with several co-authors working in different institutions. The total number of articles corresponding to the 500 universities is approximately 1.9 million articles –about 50% of the total.
- We evaluate the citation impact of each university using two size- and scale-independent indicators. Firstly, we use the Top 10% indicator, already mentioned. Secondly, one characteristic of this indicator is that it is not monotonic in the sense that it is invariant to any additional citation that a high-impact article might receive. Consequently, we believe that it is interesting to use a second indicator possessing this property. In particular, we select a member of the Foster, Greer, and Thorbecke (FGT hereafter) family, introduced in Albarrán et al. (2011b). We apply this indicator to the set of high-impact articles mentioned before. As will be seen below, the fact that both of our indicators are additively decomposable facilitates the comparability of the two solutions to the all-sciences aggregation problem.
- Using Crespo et al.'s (2013) measurement framework, Li et al. (2013) indicate that the best alternative among a wide set of target normalization procedures is the two-parameter system developed in Radicci and Castellano (2012). However, recent results indicate that the standard, one-parameter field-normalization procedure exhibits a good performance in reducing the effects on overall citation inequality attributed to differences in production and citation practices between fields (Radicchi et al., 2008; Crespo et al., 2013, 2014; Li et al., 2013; and Ruiz-Castillo, 2014). Consequently, in this paper we adopt this procedure in the usual solution to the all-sciences aggregation problem.
- We present two types of results. Firstly, we assess the performance of the standard normalization procedure in facilitating the comparability of the citations received by articles belonging to different clusters. Secondly, we assess the consequences of adopting the two solutions to the all-sciences aggregation problem by comparing the corresponding university rankings according to the two citation impact indicators.

The rest of the paper is organized into three sections. Section II presents the citation impact indicators, as well as the two solutions to the all-sciences aggregation problem. Section III describes the data, and includes the empirical results, while Section IV concludes.

The aggregation of heterogeneous scientific fields in the all-sciences case

Notation and citation indicators

It is convenient to introduce some notation. Given a set of articles S, and J scientific fields indexed by $j = 1,\ldots, J$, a *classification system* is an assignment of articles in S to the J fields. Let I be the number of research units, indexed by $i = 1,\ldots, I$. In this Section, the assignment of articles in S to the I research units is taken as given. Let $\boldsymbol{c_{ij}} = \{c_{ijk}\}$ be the *citation distribution of unit i in field j*, where c_{ijk} is the number of citations received by the k-th article, and let $\boldsymbol{c_j}$ be the *citation distribution of field j*, that is, the union of all research units' citation distributions in that field: $\boldsymbol{c_j} = \cup_i \{\boldsymbol{c_{ij}}\}$. Finally, let $\boldsymbol{C} = \cup_i \cup_j \{\boldsymbol{c_{ij}}\}$ be the *overall citation distribution*, or the citation distribution in the all-sciences case. For later reference, let N_{ij} be the number of articles in distribution $\boldsymbol{c_{ij}}$, let $N_i = S_j N_{ij}$ be the total number of articles published by unit i, let $N_j = S_i N_{ij}$ be the total number of articles in field j, and let $N = S_i S_j N_{ij}$ be the total number of articles in the all-sciences case.

A *citation impact indicator* is a function F defined in the set of all citation distributions, where $F(\boldsymbol{c})$ is the citation impact of distribution $\boldsymbol{c}$. Let $\boldsymbol{c^r}$ be the r-th replica of distribution $\boldsymbol{c}$. An indicator F is said to be *size-independent* if, for any citation distribution $\boldsymbol{c}$, $F(\boldsymbol{c^r}) = F(\boldsymbol{c})$ for all r. An indicator F is said to be *scale-independent* if for any $\lambda > 0$, and any citation distribution $\boldsymbol{c}$, $F(\lambda\boldsymbol{c}) = F(\boldsymbol{c})$. An indicator F is said to be *additively decomposable* if for any partition of a citation distribution $\boldsymbol{c}$ into G sub-groups, indexed by $g = 1,..., G$, the citation impact of distribution $\boldsymbol{c}$ can be expressed as follows:

$$F(\boldsymbol{c}) = S_g\, (M_g/M) F(\boldsymbol{c_g}),$$

where M_g is the number of publications in sub-group g, and $M = \Sigma_g\, M$ is the number of publications in distribution $\boldsymbol{c}$.

Consider the following two difficulties for comparing the citation impact of any pair of research units: the two units may be of different sizes, and if they work in different fields, then their raw citations are not directly comparable. As it is well known, these two difficulties can be overcome using a size- and scale-independent indicator. The following two indicators are good examples of size- and scale-independent indicators that, in addition, are additively decomposable.

1. Let $\boldsymbol{X_j}$ be the set of the 10% most cited articles in citation distribution $\boldsymbol{c_j}$, and let $\boldsymbol{x_{ij}}$ be the sub-set of articles in $\boldsymbol{X_j}$ corresponding to unit i, so that $\boldsymbol{X_j} = \cup_i\{\boldsymbol{x_{ij}}\}$ with $\boldsymbol{x_{ij}}$ non-empty for some i. If n_{ij} is the number of articles in $\boldsymbol{x_{ij}}$, then the *Top 10% indicator for unit i in field j*, T_{ij}, is defined as

$$T_{ij} = n_{ij}/N_{ij}. \qquad (1)$$

Of course, for field j as a whole, if $n_j = \Sigma_i\, n_{ij}$ is the number of articles in $\boldsymbol{X_j}$, then $T_j = n_j/N_j = 0.10$.

2. Let z_j be the *Critical Citation Line* –CCL hereafter– for citation distribution $\boldsymbol{c_j}$, and denote the articles in $\boldsymbol{c_j}$ with citations equal to or greater than z_j as *high-impact articles*. For any high impact article with citations c_{il}, define the *CCL normalized high-impact gap* as $(c_{il} - z_j)/z_j$.

Consider the family of FGT indicators introduced in Albarrán et al. (2011b) as functions of normalized high-impact gaps. The second member of this family, A_{ij}, is defined as

$$A_{ij} = (1/N_{ij})[S_l(c_{il} - z_j)/z_j], \quad (2)$$

where the sum is over the high-impact articles in citation distribution $\boldsymbol{c_j}$ that belong to unit i. We refer to this indicator as the *Average of high-impact gaps for unit i in field j*. For the entire field j as a whole, the average of high-impact gaps is defined as

$$A_j = (1/N_j)[S_k (c_k - z_j)/z_j],$$

where the sum is over the high-impact articles in citation distribution $\boldsymbol{c_j}$.

To facilitate the comparison with T_{ij}, in the sequel we will always fix z_j as the number of citations of the article in the 90th percentile of citation distribution $\boldsymbol{c_j}$. In that case, the set of high-impact articles coincides with the set of the 10% most cited articles in citation distribution $\boldsymbol{c_j}$. The two main differences between the two indicators are the following. Firstly, one or more citations received by a high-impact article increases A_{ij} but does not change T_{ij}. In other words, A_{ij} is monotonic but T_{ij} is not. Secondly, T_{ij} is more robust to extreme observations than A_{ij}.

The solution to the all-sciences aggregation problem using the standard field-normalization procedure

For any i, let $\boldsymbol{c_i} = (\boldsymbol{c_{i1}},\ldots, \boldsymbol{c_{ij}},\ldots, \boldsymbol{c_{iJ}})$ be the *raw citation distribution of unit i in the all-sciences case*. Differences in production and citation practices across fields make impossible the direct comparison of the raw citations received by articles in different fields. In order to achieve some comparability, one possibility is to use some normalization procedure. For any article k in citation distribution $\boldsymbol{c_{ij}}$, the normalized number of citations c^*_{ijk} according to the *standard field-normalization procedure* is defined as

$$c^*_{ijk} = c_{ijk}/\mu_j.$$

For any i, let $\boldsymbol{c^*_i} = \cup_j \cup_k \{c^*_{ijk}\} = (\boldsymbol{c^*_{i1}},\ldots, \boldsymbol{c^*_{ij}},\ldots, \boldsymbol{c^*_{iJ}})$ be the *normalized citation distribution of unit i in the all-sciences case*. Since normalized citations are now comparable, it makes sense to apply any indicator to citation distribution $\boldsymbol{c^*_i}$. For any i, let $\boldsymbol{F^*_i} = F(\boldsymbol{c^*_i})$ be the citation impact of distribution $\boldsymbol{c^*_i}$ according to the indicator F. For any pair of research units u and v in the all-sciences case, the citation impact values $\boldsymbol{F^*_u}$ and $\boldsymbol{F^*_v}$ are now comparable, and can be used to rank the two units in question.

Note that, since $\boldsymbol{c^*_i}$ for $i = 1,\ldots, I$ forms a partition of $\boldsymbol{C^*}$ and F is assumed to be additively decomposable, we can write

$$F^* = F(\boldsymbol{C^*}) = S_i (N_i/N)\boldsymbol{F^*_i}.$$

Thus, if we rank universities by the ratio $\boldsymbol{F^*_i}/F^*$, $i = 1,\ldots, I$, then the value one can serve as a benchmark for evaluating the research units in the usual way. For later reference, since $\boldsymbol{c^*_{ij}}$ for $j = 1,\ldots, J$ forms a partition of $\boldsymbol{c^*_i}$, for each i we can write

$$\boldsymbol{F^*_i} = F(\boldsymbol{c^*_i}) = S_j (N_{ij}/N_i)\boldsymbol{F^*_{ij}}, \quad (3)$$

where $F^*_{ij} = F(\boldsymbol{c}^*_{ij})$ for all j, that is, F^*_{ij} is simply the citation impact of citation distribution $\boldsymbol{c}^*_{ij}$ according to F.

A solution to the all-sciences aggregation problem without field-normalization

For any i and any j, denote by $F_{ij} = F(\boldsymbol{c}_{ij})$ the citation impact of distribution $\boldsymbol{c}_{ij}$ according to F. A convenient measure of citation impact for unit i in the all-sciences case, F_i, can be defined as the weighted average of the values F_{ij} achieved in all fields, with weights equal to the relative importance of each field in the total production of unit i:

$$F_i = S_j\,(N_{ij}/N_i)F_{ij} \qquad (4)$$

The comparison of expressions (4) and (5) illustrate the differences between the two solutions to the all-sciences aggregation problem when the evaluation of the units' citation impact is made with additively decomposable indicators. Finally, it is convenient to compute the weighted average of these quantities as follows:

$$F = S_i\,(N_i/N)F_i.$$

Thus, as before, if we rank universities by the ratio F_i/F, $i = 1,\ldots, I$, then the value one can serve as a benchmark for evaluating the research units in the usual way. In practice, we have information concerning some but not all research units. Therefore, we compute F as the following weighted average: $F = \mathrm{S}_j\,(N_j/N)F_j$, where $F_j = \mathrm{F}(\boldsymbol{c}_j)$.

The aim of the paper

The main aim of this paper is the comparison between the rankings of research units obtained with and without the standard field-normalization procedure, $(F^*_1, \ldots, F^*_I)$ and $(F_1, \ldots, F_I)$, respectively.

To understand the way the results will be presented, we need to review the connection between the performance of the normalization procedure and the relationship between the solutions to the all-sciences aggregation problem. For that purpose, we need to introduce some more notation. For any j, let $\boldsymbol{x}_j$ be the set of high-impact articles in distribution $\boldsymbol{c}_j$, that is, the set of articles in $\boldsymbol{c}_j$ with citations equal to or greater than z_j, or the set of the 10% most cited articles in $\boldsymbol{c}_j$. Let us denote by $\boldsymbol{X} = (\boldsymbol{x}_1,\ldots, \boldsymbol{x}_j,\ldots, \boldsymbol{x}_J)$ the set of high-impact articles in the all-sciences case. On the other hand, let $\boldsymbol{Y}$ be the set of the 10% most cited articles in the overall normalized citation distribution $\boldsymbol{C}^* = \cup_j \{\boldsymbol{c}^*_j\}$. Let $\boldsymbol{y}_j$ be the sub-set of articles in $\boldsymbol{Y}$ belonging to field j, so that $\boldsymbol{Y} = (\boldsymbol{y}_1,\ldots, \boldsymbol{y}_j,\ldots, \boldsymbol{y}_J)$. Note that, in practice, the sets $\boldsymbol{y}_j$ might be empty for some j.

Under the universality condition, that is, if all fields are equally distributed except for a scale factor then, at every percentile of field citation distributions, normalized citations will be the same for all fields. In other words, the normalization procedure will work perfectly. In particular, in this situation we would have $z_j/\mu_j = z^*$ for all j. Consequently, we would have $\boldsymbol{y}_j = \boldsymbol{x}_j$ for all j, and $\boldsymbol{Y} = \boldsymbol{X}$. Since citation distributions $\boldsymbol{c}^*_{ij}$ and $\boldsymbol{c}_{ij}$ have the same number of articles and our indicators are a function solely of high-impact articles, we would have $F^*_{ij} = F(\boldsymbol{c}^*_{ij}) = F_{ij} = F(\boldsymbol{c}_{ij})$ for all i and j. In view of equations (4) and (5), we would have $F^*_i = F_i$ for all i. In other words, the rankings $(F^*_1, \ldots, F^*_I)$ and $(F_1, \ldots, F_I)$ will be identical.

As we know, in practice the universality condition is not satisfied. However, the better the performance of the normalization procedure, that is, the closer is the set $\boldsymbol{Y}$ to set $\boldsymbol{X}$, the more similar the rankings $(F^*_1, \ldots, F^*_I)$ and $(F_1, \ldots, F_I)$ are expected to be for any F. Note that this

conjecture has to be verified in practice. In any case, the empirical section begins by assessing the performance of the normalization procedure.

On the other hand, independently of the normalization procedure's performance, we should measure the consequences of adopting the two solutions to the all-sciences aggregation problem using indicators with different properties. The reason, of course is that whenever $\boldsymbol{Y}$ and $\boldsymbol{X}$ differ, that is, when the set of high-impact articles under the two solutions differ, the consequences for the university rankings might be of a different order of magnitude depending on the citation impact indicator we use. This is the reason why we will study the situation using the Top 10% and the Average of high-impact gaps.

Empirical results

The data and descriptive statistics

As indicated in the Introduction, our dataset results from the application of a publication-level methodology to 9,446,622 distinct articles published in 2003-2012 (see Ruiz-Castillo & Waltman, 2015). Publications in local journals, as well as popular magazines and trade journals have been excluded (see Ruiz-Castillo & Waltman, 2015 for details). We work with journals in the sciences, the social sciences, and the arts and humanities, although many arts and humanities journals are excluded because they are of a local nature. The classification system consists of 5,119 clusters, and citation distributions refer to the citations received by these articles during a five-year citation window for each year in that period. In this paper, we focus on the set of 3,614,447 distinct articles published in 2005-2008. In terms of the notation introduced in Section II.1, we have $\boldsymbol{C} = \cup_j \{\boldsymbol{c_j}\} = (c_1,\ldots, c_N)$ with J = 5,119, and N = 3,614,447.

The research units are universities. Publications are assigned to universities using the fractional counting method that takes into account the address lines appearing in each publication. An article is fully assigned to a university only if all addresses mentioned in the publication belong to the university in question. If a publication is co-authored by two or more universities, then it is assigned fractionally to all of them in proportion to the number of address lines. For example, if the address list of an article contains five addresses and two of them belong to a particular university, then 0.4 of the article is assigned to this university, and only 0.2 of the article is assigned to each of the other three universities.

We know the total number of address lines of every publication, but we have information about the number of address lines of specific institutions only for the 500 LR universities. This number is well below I, the total number of research units in the notation introduced in Section II.1. There are 2,420,054 distinct articles, or 67% of the total, with at least one address line belonging to a LR university. The total number of articles in the LR universities according to the fractional counting method is 1,886,106.1, or 52.2% of the total. The distribution of this total among the 500 universities is available in Perianes-Rodriguez & Ruiz-Castillo, 2014a.

The performance of the normalization procedure

We assess the performance of the normalization procedure using the measurement framework introduced in Crespo et al. (2013), we first estimate the effect on overall citation inequality attributable to differences in production and citation practices between clusters, and then the reduction in this effect after applying the standard field-normalization procedure. Given the many clusters with very few publications (see Ruiz-Castillo & Waltman, 2015), we apply this method to the 3,332 clusters with more than 250 publications. These clusters include 3,441,666 million publications, or 95.2% of the total.

We begin with the partition of, say, each cluster citation distribution into P quantiles, indexed by $p = 1,.., P$. In practice, in this paper we use the partition into percentiles, that is, we choose $P = 100$. Assume for a moment that, in any cluster i, we disregard the citation inequality within every percentile by assigning to every article in that percentile the mean citation of the percentile itself, μ_i^p. The interpretation of the fact that, for example, $\mu_i^p = 2\ \mu_j^p$ is that, on average, the citation impact of cluster i is twice as large as the citation impact of cluster j in spite of the fact that both quantities represent a common underlying phenomenon, namely, the same *degree of citation impact* in both clusters. In other words, for any π, the distance between μ^p and μ_j^p is entirely attributable to the difference in the production and citation practices that prevail in the two clusters for publications with the same degree of excellence in each of them. Thus, the citation inequality between clusters at each percentile, denoted by $I(p)$, is entirely attributable to the differences in citation practices between the 3,332 clusters holding constant the degree of excellence in all clusters at quantile π. Hence, any weighted average of these quantities, denoted by *IDCC* (*I*nequality due to *D*ifferences in *C*itation impact between *C*lusters), provides a good measure of the total impact on overall citation inequality that can be attributed to such differences. Let $\boldsymbol{C'}$ be the union of the clusters citation distributions, $\boldsymbol{C'} = \cup \{\boldsymbol{c_j}\}$ for $j = 1,\ldots, 3{,}332$. We use the ratio

$$IDCC/I(\boldsymbol{C'}) \qquad (6)$$

to assess the relative effect on overall citation inequality, $I(\boldsymbol{C'})$, attributed to the differences in citation practices between clusters (for details, see Crespo et al., 2013).

Finally, we are interested in estimating how important scale differences between cluster citation distributions are in accounting for the effect measured by expression (6). For that purpose, we use the relative change in the *IDPC* term, that is, the ratio

$$[IDCC - IDCC^*]/IDCC, \qquad (7)$$

where *IDCC** is the term that measures the effect on overall citation inequality attributed to the differences in cluster distributions after applying the standard field-normalization procedure (for details, see again Crespo et al., 2013). The estimates of expressions (6) and (7) are as follows:

Table 1. The effect on overall citation inequality, I('C), of the differences in citation impact between clusters before and after standard field-normalization, and the impact of normalization on this effect.

		Normalization impact =100 [*IDCC – IDCC*/IDCC*]
Before MNCS normalization, 100 [*IDCC/I(C')*]	22.5 %	-
After MNCS normalization, 100 [*IDCC*/I(C')*]	4.3 %	84.3 %

It can be observed that the effect of the differences in citation practices between such a large number of clusters represents 22.5% of overall citation inequality, a figure much larger than what has been found in the previous literature for at most 235 sub-fields. Nevertheless, the standard field-normalization procedure reduces this effect down to 4.3%, quite an achievement.

Differences in university rankings under the two solutions to all-sciences aggregation problem

The university rankings without and with normalization according to the Top 10% indicator, T_i and T^*_i, and according to the Average of high-impact gaps, A_i and A^*_i can be found in Perianes-Rodriguez & Ruiz-Castillo (2014a). We begin with the comparison of university rankings according to T_i and T^*_i. The Pearson correlation coefficient between university values is 0.995, while the Spearman correlation coefficient between ranks is 0.992. However, high correlations between university values and ranks do not preclude important differences for individual universities. In analyzing the consequences of going from T_i to T^*_i, we must take two aspects into account. Firstly, we should analyze the re-rankings that take place in such a move. Secondly, we should compare the differences between the university values themselves. Fortunately, we have a relevant instance with which to compare our results: the differences found in Ruiz-Castillo and Waltman (2015) in going from the university rankings according to T_i using the Web of Science classification system with 236 journal subject categories, or sub-fields, and the classification system we are using in this paper with 5,119 clusters.

As much as 38.4% of universities experience very small re-rankings of less than or equal to five positions, while 67 universities, or 13.4% of the total, experience re-rankings greater than 25 positions. These figures are 20.2% and 39.0% when going from the WoS classification system to our dataset. Among the first 100 universities, 61 experience small re-rankings in going from T_i to T^*_i, while only 44 are in this situation in the change between classification systems. As far as the cardinal changes is concerned, 78.4% of universities have changes in top 10% indicator values smaller than or equal to 0.05 when going from T_i to T^*_i. This percentage is 71% among the first 100 universities. These figures are 50.1% and 60.0% in the change between classification systems. For most universities, the differences are more or less negligible. Although for some universities more significant differences can be observed, the conclusion is clear. The differences observed in university rankings according to the top 10% indicator when we adopt the two solutions for solving the all-sciences aggregation problem are considerably less than according to the same indicator when we move from the WoS classification system to our dataset (Perianes-Rodriguez & Ruiz-Castillo, 2014a).

The Pearson correlation coefficient between the university rankings according to the average of high-impact gaps, A_i and A^*_i, is 0.596, while the Spearman correlation coefficient between ranks is 0.984. However, the low Pearson correlation coefficient is due to the presence of the well-known extreme observation of the University of Göttingen (Waltman et al., 2012b; Ruiz-Castillo & Waltman, 2015). Without this university, this correlation coefficient becomes 0.986. In any case, as before, high correlations between university values and ranks do not preclude important differences for individual universities. The ordinal differences in university rankings according to this indicator with and without field-normalization are of a similar order of magnitude as those obtained with the top 10% indicator. For example, 33.0% of universities experience very small re-rankings of less than or equal to five positions, while 80 universities, or 16.0% of the total, experience re-rankings greater than 25 positions. Among the first 100 universities, only 44 experience small re-rankings in going from A_i to A^*_i (in comparison with 61 when going from T_i to T^*_i). As far as the cardinal changes is concerned, 64.2% of universities have changes in indicator values smaller than or equal to 0.05 when going from A_i to A^*_i –a comparable figure with 78.4% when going from T_i to T^*_I (Perianes-Rodriguez & Ruiz-Castillo, 2014a).

The conclusion is inescapable. In spite of the fact of the limitations of the standard normalization procedure in the presence of so many clusters, the differences observed in university rankings when we adopt the two solutions for solving the all-sciences aggregation problem are of a relatively small order of magnitude regardless of which of then two rather different citation impact indicators is used in obtaining the university rankings.

Conclusions

The heterogeneity of the fields distinguished in any classification system poses a severe aggregation problem when one is interested in evaluating the citation impact of a set of research units in the all-sciences case. In this paper, we have analyzed two possible solutions to this problem. The first solution relies on prior normalization of the raw citations received by all publications. In particular, we focus on the standard field-normalization procedure in which field mean citations are used as normalization factors. The second solution extends the approach adopted in the Leiden and SCImago rankings for computing the Top 10% indicator in the all-sciences case to any admissible indicator. This solution does not require any prior field-normalization: the citation impact of any research unit in the all-sciences case is calculated as the appropriately weighted sum of the citation impact that the unit achieves in each field.

Using a large WoS dataset consisting of 3.6 million publications in the 2005-2008 period and an algorithmically constructed publication-level classification system that distinguishes between 5,119 clusters, this simple alternative has been confronted with the usual one when the citation impact of the 500 LR universities are evaluated using two indicators with very different properties: the top 10% indicator, and the average of high-impact gaps.

The shape of the citation distributions of 4,161 significant clusters with more than 100 publications in our dataset has been previously shown to be highly skewed and reasonable similar (Ruiz-Castillo & Waltman, 2015). Previous results with WoS classification systems that distinguishes at most between 235 sub-fields indicate that, when this is the case, the standard field-normalization procedure performs well in reducing the overall citation inequality attributed to the differences in production and citation practices between fields. In this paper we have shown that this is not exactly the case, even when we restrict the attention to 3,332 clusters with more than 250 publications. Therefore, a priori it was not obvious what to expect when confronting the solutions to the all-sciences aggregation problem with and without prior field-normalization.

Interestingly enough, the differences between the university rankings obtained with both solutions is of a relatively small order of magnitude independently of the citation impact indicator used in the construction of the university rankings. In particular, these differences are considerably smaller than the ones obtained in Ruiz-Castillo and Waltman (2015) for the move from the WoS classification system with 236 sub-fields to the one used in this paper with 5,119 clusters.

In principle, it seems preferable to evaluate the citation impact of research units in the all-sciences case avoiding any kind of prior normalization operation. However, the empirical evidence presented in this paper indicates that that the use of the traditional methodology does not lead to very different results. This is a convenient conclusion, since there are instances when normalization is strongly advisable. For example, when one is interested in studying the research units citation distributions in the all-sciences case –as we do in the companion paper Perianes-Rodriguez and Ruiz-Castillo (2014b).

It should be noted that, before being accepted, it would be convenient to replicate the results of this paper for other datasets, other classification systems, other types of research units, and other ways of assigning responsibility between research units in the case of co-authored publications.

Correlating Libcitations and Citations in the Humanities with WorldCat and Scopus Data

Alesia Zuccala[1] and Howard D. White[2]

Abstract
The term *libcitations* was introduced by White et al. (2009) as a name for counts of libraries that have acquired a given book. Somewhat like citations, these library holdings counts, which vary greatly, can be taken as indicators of the book's cultural impact. Torres-Salinas and Moed (2009) independently proposed the same measure under the name *catalog inclusions*. Both articles sought an altmetric for authors of books in, e.g., the humanities, since the major citation indexes, oriented toward scientific papers, have not served them well. Here, using very large samples, we explore the libcitation-citation relationship for the same books by correlating their holdings counts from OCLC's WorldCat with their citation counts from Elsevier's Scopus. For books cited in two broad fields of the humanities during 1996-2000 and 2007-2011, we obtain positive, weak, but highly significant correlations. These largely persist when books are divided by main Dewey class. The overall results are inconclusive, however, because the Scopus citation counts for the books tend to be very low. Further correlational research should probably use the much higher book citation counts from Google Scholar. Nevertheless, a qualitative analysis of widely held and widely cited books clarifies the libcitation measure and helps to justify it.

Conference Topic
Indicators

Introduction
Journal-oriented scientists have long had citation counts as an indicator of the impact of their articles, and journal-based citation indexes cater to them. But the same indexes cover citations to books less well, and book-oriented scholars in the humanities and softer social sciences feel themselves at a disadvantage, especially if citation measures are going to be used in performance evaluations and funding decisions (see Kousha, Thelwall, & Rezaie 2011 for a review). White et al. (2009) responded to this lack by proposing that one measure of a book's cultural impact could be the number of libraries that hold it. The idea behind this altmetric was that librarians who acquire a book are somewhat like scholars who cite it, in that both acts involve assessment and choice on behalf of communities of readers. To bring out the parallel, White et al. called the librarians' formal act of acquisition a *libcitation* (first syllable as in "library"). They wrote that the libcitation count (also known as a library holdings count) for a particular book "increases by 1 every time a different library reports acquiring that book in a national or an international union catalog. Readers are invited to think of union catalogs in a new way: as 'librarians' citation indexes'" (p. 1084). OCLC's WorldCat was mentioned as a prime example of a union catalog—that is, one that pools the cataloging records of OCLC member libraries and reports how many of them hold each cataloged item.

At the same time and wholly independently, Torres-Salinas and Moed (2009) made an identical proposal. Their name for libcitations (our term here) was *catalog inclusions*, and they, too, stressed the parallel between such inclusions and citations to journal articles (p. 11). They, too, named WorldCat as a potential source of library holdings data. Moreover, both

they and White et al. raised the possibility of empirically testing the relationship between libcitation counts and citation counts for the same set of books: are the two correlated?

The question is important because citation counts, when scrupulously used, have become a standard performance indicator in many disciplines, and, given the inadequacies of citation data for books, it would be very interesting if libcitations could serve a similar purpose. Torres-Salinas and Moed (2009, p. 24) saw correlation research of this sort in terms of validating the holdings-count idea:

> One way of doing this is to examine...the degree of correlation between the number of times book titles are cited in the serial literature on the one hand, and the number of library catalogs in which they are included on the other.

That is just what the present paper does for books (aka titles) in two broad fields in the humanities: *History* and *Literature & Literary Theory*. It draws on a special database of book citation data from Elsevier's Scopus and libcitation data for the same books from WorldCat, as described in Zuccala and Guns (2013), a research-in-progress paper. White et al. (2009, p. 1094) had anticipated what would be found:

> It is an open question whether libcitation counts for books and book chapters will correlate significantly with citation counts for the same works. Indeed, they may not. Our exploratory trials have shown some books to be high in both citation and libcitation counts. Occasionally, a book turns up that is well cited despite being held by relatively few libraries. More common are books that are meagerly cited, but relatively widely held. This overall mix produces low correlations.

These remarks were occasioned by spot-checking citation counts in the Web of Science. Using Scopus instead, Zuccala and Guns (2013) provided the first empirical answer to the open question: they found low but significant correlations.

The present paper continues this line of analysis (also described in Sieber and Gradmann, 2011). We do not hypothesize that libcitations *cause* citations (or the reverse)—merely that the two variables may positively co-vary.

Our database covers more than 100,000 books, and it now allows correlations to be obtained in the 10 main Dewey subject classes. As before, it has a total libcitation count for each book, but also disaggregates that total into counts for members of the Association of Research Libraries (ARL) and counts for non-members. The non-members include thousands of academic and public libraries whose collections are not primarily intended to support advanced research. In contrast, the 125 ARL institutions own very large subject collections that support graduate degree programs and specialized faculty research in many disciplines. (When multiple libraries in ARL institutions buy the same book, its count can go well beyond 125.) The books with the greatest cultural impact achieve libcitation counts in the thousands by appealing to ARL members and non-members alike. Plum Analytics, a commercial firm specializing in altmetrics, now includes a book's holding count in WorldCat as one of its indicators of "usage."

The results of our analyses, while interesting and suggestive, return us to a common criticism of both the Web of Science and Scopus: within the time frame of our study, they pick up too few citations to books to correlate those citations with libcitations on a firm basis. Both WoS and Scopus have recently expanded their efforts to capture citations to books, but it is too early to assess the full effect of these new data on bibliometrics. Kousha, Thelwall and Rezaie (2011) demonstrate that Google Books and Google Scholar give considerably higher citation counts for books than Scopus does. Our findings point to the same conclusion.

Overview of the database

Here we re-present several details about our database from Zuccala and Guns (2013) and add some new ones. The Scopus database from Elsevier supplied our citation data, which was

granted through the Elsevier Bibliometrics Research Program. Having requested separate datasets in *History* and *Literature & Literary Theory*, we further limited them to citations that appeared in journal articles during two periods, 1996-2000 and 2007-2011. We examined the Scopus data to determine the overall frequency with which various types of publications were cited: books, research articles, conference proceedings, review papers, notes, and other materials. Cited materials that were "non-sourced"—that is, that did not have a Scopus identification number linking them to a source journal—were classified as books, the unit of analysis in which we were interested.

Table 1 shows the number of journals in each field (as classified by Scopus) from which we drew citing articles. The lower part of Table 1 gives the numbers (N's) of books cited in the journal articles in each field and period. It will be seen that, in both fields, the N's of books cited in the earlier period are much smaller than those in the later, because Scopus covered fewer humanities articles in the 1990s.

Table 1. Journals and journal citation data in Scopus (April 2011).

Journal counts and classification codes	
History (N=494 source journals)	ASJC 1202 (Scopus Classification Code)
Literature & Literary Theory (N=419 source journals)	ASJC 1208 (Scopus Classification Code)
Both History and Literature (N=110 source journals)	Both ASJC 1202 and ASJC 1208
Counts of books cited during 1996-2000	*Counts of books cited during 2007-2011*
History (N=20,996)	History (N=50,466)
Literature & Literary Theory (N=7,541)	Literature & Literary Theory (N=35,929)

We searched the apparent books in WorldCat, using an API developer key granted to us by the Online Computer Library Center (OCLC). The key allowed us to match titles cited *at least once* in Scopus with titles held by *at least one ARL and one non-ARL library* covered by WorldCat. (These libraries, while mostly North American, include participants worldwide.) For every matched title (confirming that it was a book), we retrieved the OCLC accession number, ISBN number, publisher's name, publisher's location, and library count data. These were added to the book's citation data from Scopus to create a unique Scopus-WorldCat relational database.

Once a book has been published, it takes time for it to be acquired and cataloged by a library. A book published in a given year could have been acquired by a library no earlier than that year, but might have been acquired up to and including November 2012. Our holdings counts were current as of that cut-off date.

To improve publication-date accuracy, we analyzed only books published in the six years immediately preceding our two five-year citation windows. Thus, the books cited in 1996-2000 were limited (by filtering their Scopus records) to those published during 1990-1995. The books cited in 2007-2011 were likewise limited to those published during 2001-2006.

Converted to the four files at the bottom of Table 1, our book data come to 114,932 cases in all, 81 percent of which are unique titles. The remaining 19 percent are titles that appear more than once. Some were cited in both our earlier and later periods. Others were cited in both the History and the Literature journals, or in the journals that Scopus has assigned to both fields jointly, as shown in Table 1. We did not attempt to re-assign these latter titles to a single field, but allowed them to enter into the counts for both fields. There seems no easy way to avoid double counting, because that is the way in which Scopus has structured the data. Even so, a trial analysis with duplicates removed does not greatly affect the correlations.

Data analyses and results

Our data analyses were conducted with SPSS, the Statistical Package for the Social Sciences. Table 2 gives summary statistics for the titles in History and Literature. Means and standard deviations have been rounded to whole numbers. As noted in Zuccala and Guns (2013, p. 357), both citations and libcitations exhibit the highly skewed distributions typical of bibliometrics. However, the subsets of ARL libcitations for both History and Literature have bimodal distributions, with peaks at 1-4 and 100-104 holding libraries, and a low point at 45-54 libraries. In other words, the ARL libraries tend to acquire large numbers of rarely held titles, large numbers of widely held titles, and markedly fewer titles with holdings counts in between. This saddle-shaped distribution may reflect the opposing needs of specialized researchers: on their behalf, ARL libraries acquire many books held by few other members, but also many books that almost every member *must* have. The titles with the maximum counts in Table 2 (e.g., 92 citations; 4,725 libcitations) will be named in Tables 6 through 9.

Table 2. Summary statistics for two fields in combined time periods.

History combined periods N=71462					
	Minimum	Maximum	Mean	Std. Dev.	Median
Citations	1	92	2	3	1
ARL libcitations	1	212	59	40	63
Non-ARL libcitations	1	4603	278	351	178
Total libcitations	2	4725	338	372	250
Literature combined periods N=43470					
	Minimum	Maximum	Mean	Std. Dev.	Median
Citations	1	91	2	3	1
ARL libcitations	1	215	62	38	67
Non-ARL libcitations	1	4603	305	395	189
Total libcitations	2	4725	367	412	267

In Table 3, *citation* counts for every book are correlated with total *libcitation* counts for every book in major subsets of the database. Citation counts are also separately correlated with the libcitation counts for ARL members and non-members. (Only the libcitation variables are labeled, but the unlabeled citation variable is present in all the cells.) These are Spearman rho correlations, calculated with ranks of the count values rather than the counts themselves. Unlike Pearson r's, rho's do not require the assumption of normally distributed populations and so accommodate bibliometric skew (Zuccala & Guns, 2013: 357).

Table 3. Total, ARL, and non-ARL libcitations to books correlated with citations to the same books in two fields, two periods, and combined periods.

History 1996-2000			**History 2007-2011**			**History combined**		
Total	ARL	Non-ARL	Total	ARL	Non-ARL	Total	ARL	Non-ARL
0.26	0.29	0.25	0.25	0.28	0.24	0.24	0.26	0.23
N=20996			N=50466			N=71462		
Literature 1996-2000			**Literature 2007-2011**			**Literature combined**		
Total	ARL	Non-ARL	Total	ARL	Non-ARL	Total	ARL	Non-ARL
0.23	0.28	0.22	0.18	0.24	0.17	0.20	0.24	0.19
N=7541			N=35929			N=43470		

The rho's are all positive and weak, with values much like those in Zuccala and Guns (2013, p. 357). Because of the large numbers of books involved, all are significant at $p < .001$ by

one-tailed test. The hypothesis of no relationship can thus be safely rejected: citations and libcitations do capture a certain amount of scholarly impact in common. A sign of this in Table 3 is that citations, which are essentially a researchers' practice, always correlate a bit more highly with libcitations from research libraries—that is, ARL members. However, none of the rho's are strong enough to indicate that libcitations can substitute for citations as a measure. Libraries, especially ARL members, do buy many books that turn out to be well cited, but they buy even more books that are not highly cited in the journals covered by Scopus. This raises questions about the citation-libcitation relationship that we will return to later with specific examples.

Table 4 may clarify the situation in our two subject fields. The total libcitation counts for books have been divided at their medians. Citation counts for the same books have been collapsed into three groups, as shown in the column labels. In both History and Literature, the two variables are directly related: as citation counts rise, the percentage of books with above-median libcitation counts also rises sharply. For example, in History, only 43% of books cited once have libcitation counts in the top half, whereas for books cited two to four times the comparable figure is 59%, and for books with five or more citations, 79%. The percentages in the Literature table are almost identical.

Table 4. Libcitations and citations cross-tabulated in two fields for combined periods.

History combined periods				
	Citations			
Libcitations	1	2-4	5 or more	
GT Median	43%	59%	79%	50%
LE Median	57%	41%	21%	50%
	100%	100%	100%	100%
N =	46578	19165	5719	71462
Literature combined periods				
	Citations			
Libcitations	1	2-4	5 or more	
GT Median	44%	59%	78%	50%
LE Median	56%	41%	22%	50%
	100%	100%	100%	100%
N =	29876	10668	2926	43470

However, this effect must be viewed in light of the extreme skew of the citation counts seen in the column marginals. Roughly two-thirds of all books in our samples have only one citation each, and roughly another quarter have only two to four citations. The fraction of titles with five or more citations is relatively small. Thus, the Spearman rho's for these grouped variables, though highly significant ($p < .001$), are even lower than when the variables are ungrouped in Table 3—only 0.22 for History and 0.19 for Literature.

We turn to a finer breakdown of the data. As mentioned in Zuccala and Guns (2013, p. 358), historians who publish in History journals do not exclusively cite works of history, nor do literary scholars who publish in Literature journals exclusively cite works of literature or literary theory. Instead, both groups cite books across the full range of subjects covered by the Dewey Decimal Classification. We were able to get the Dewey class numbers for most of our book titles from WorldCat. (Some books do not receive Dewey classifications.) In Table 5 we subdivide the books cited in History and Literature journals in our two time periods by their main Dewey classes.

Class 000 in Dewey is formally "Computer science, information, general works." This class is traditionally used for general reference books and books in trans-disciplinary fields such as librarianship, journalism, publishing, and reading. Historians and literary scholars mainly cite

books in areas like these, rather than in computer science. Hence, we have shortened the long label here to "General works."

The Table 5 cells contain 120 replications of our correlational study in subsets of the data. We are again correlating each book's total citations with its total libcitations, as well as the libcitation counts from ARL members and ARL non-members. In making comparisons, be aware that non-ARL libcitations make up by far the larger share of total libcitations. The two categories thus tend to produce correlations that are similar or identical, and so the non-ARL results will not be separately discussed here.

Table 5. Libcitations correlated with citations to books by field, period, and main Dewey classes.

	History 1996-2000				**History 2007-2011**			
Main Dewey Classes	Libcites	ARL	Non-ARL	N =	Libcites	ARL	Non-ARL	N =
000 General works	0.20	0.21	0.20	350	0.23	0.28	0.22	794
100 Philosophy and psychology	0.20	0.21	0.19	1055	0.18	0.20	0.17	2041
200 Religion	0.27	0.27	0.26	1766	0.27	0.29	0.25	4186

500 Science	0.20	0.27	0.19	914	0.13	0.23	0.11	1543
600 Technology	0.25	0.35	0.23	824	0.12	0.24	0.09	1990
700 Arts and recreation	0.21	0.24	0.20	1056	0.19	0.26	0.18	3788
800 Literature	0.17	0.26	0.15	1620	0.20	0.26	0.19	4725
900 History and geography	0.28	0.31	0.27	4388	0.27	0.29	0.25	10439
	Literature 1996-2000				**Literature 2007-2011**			
Main Dewey Classes	Libcites	ARL	Non-ARL	N =	Libcites	ARL	Non-ARL	N =
000 General works	0.09	0.08	0.09	155	0.17	0.36	0.14	548
100 Philosophy and psychology	0.19	0.22	0.18	585	0.23	0.27	0.22	1919
200 Religion	0.13	0.19	0.12	398	0.25	0.29	0.23	2221
300 Social sciences	0.14	0.16	0.14	1344	0.19	0.22	0.18	6322
400 Language	0.22	0.24	0.21	505	0.22	0.24	0.20	1218
500 Science	0.04	0.09	0.04	115	0.06	0.12	0.06	516
600 Technology	0.13	0.28	0.11	130	0.09	0.24	0.07	703
700 Arts and recreation	0.18	0.21	0.17	591	0.22	0.26	0.20	3268
800 Literature	0.23	0.31	0.21	2616	0.26	0.31	0.25	11171
900 History and geography	0.14	0.25	0.12	742	0.21	0.26	0.20	3963

Even with Table 5's extensive partitioning, the N's underlying the correlations are large enough that most of the rho's remain highly significant ($p < .001$ by one-tail test). Of the correlations between citations and total libcitations, 21 out of 40 remain at or above 0.20. Large N's can cause correlations that are statistically but not substantively significant (Babbie 2015, p. 469). Nevertheless, certain patterns do lend substance to the overall analysis:

- Some 33 of the 40 ARL correlations remain in the 0.20s or higher.
- Some 37 of the 40 ARL correlations are higher than those for the non-ARL libraries in their row. This reinforces the supposed connection between citations and libcitations in research environments.
- As examples of subject accord, the ARL correlation for books classed in *900 History and geography* is second-highest (0.31) in History 1996-2000, and tied-highest (0.29) in History 2007-2011.
- As further examples of subject accord, the ARL correlation for books classed in *800*

Literature is highest (0.31) in Literature 1996-2000, and second-highest (0.31) in Literature 2007-2011.

- In both our History periods, the lowest correlations occur for books classed in *400 Language*. The N's for books in this class, which is historically Dewey's smallest, are likewise small. While historians make use of research from all fields, it is unsurprising that books on language are not their chief resource.
- In both our Literature periods, the lowest correlations occur for books classed in *500 Science,* and the N's for books in this class are small as well. One would not expect literary scholars to cite numerous science books. However, one might expect them to cite more books in *400 Language* than historians, and that is what the data show.
- Table 5 in fact shows wide variation in the number of books that Scopus authors have cited in each class. In both History periods, books classed in *300 Social Sciences* are most numerous. This makes sense because of the close interplay between historical and social scientific topics. Books classed in *900 History and geography* are the second-most numerous, and books in *800 Literature* are third. In both Literature periods, the same three classes dominate but in another order: *800 Literature* first, as seems fitting, then *300 Social Sciences* and *900 History and geography*. For our two broad fields in the humanities, these are reassuringly reasonable outcomes.

Since libcitations are a new altmetric, we think it informative to display the titles that have top-ranked libcitation counts in particular contexts (as do both Torres-Salinas and Moed, 2009 and White et al., 2009). This allows a qualitative as well as a quantitative analysis. White (2005) proposed the label *bibliograms* for bibliometric distributions in which not only the ranked counts but also the terms associated with them are analyzed as communications. "Bibliograms," he wrote (p. 443), "consist of (1) at least one seed term that sets a context, (2) terms that co-occur with the seed across some set of records, and (3) counts of how frequently terms co-occur with the seed by which they can be ordered high to low." Here, we use main Dewey class names as seed terms. We then rank the books that co-occur with them (as OCLC accession numbers) by their libcitation or citation counts. Lastly, the OCLC numbers are used to retrieve full bibliographic data from WorldCat so that we can comment on the authors, titles, and nature of the top-ranked books.

Table 6 comprises extracts from 40 bibliograms. We display, for our two fields and two time periods, the titles with the highest *total* libcitation counts in each of the 10 main Dewey classes. Many of these books have subtitles, but they have been omitted in favor of authors' surnames (or those of first authors in collaborations). We also display their ARL libcitation counts and their citation counts in Scopus.

The books in Table 6 do not resemble typical scientific articles. They are the sort of titles that present readers, like everyone else, may have purchased for reasons having nothing to do with bibliometrics. They exemplify the broad cultural impact of the humanities—for example, standard reference works on language, music, religion; biographies of famous men (Peter Gay's *Freud*, David McCullough's *Truman* and *John Adams*); novels (Toni Morrison's *Paradise*, Dan Brown's *The Da Vinci Code*); popularizations of science (Dava Sobel's *Longitude*, Malcolm Gladwell's *Blink*, Carl Sagan's *Cosmos*); best-selling social critiques (Susan Faludi's *Backlash*, Robert Hughes's *Culture of Complaint*); advice for business executives (James Collins's *Good to Great*, Thomas Peters and Robert Waterman's *In Search of Excellence*). While some exemplify high scholarship, others are not scholarly at all (Ernest Hemingway's *A Moveable Feast*); some are even children's books (David Wiesner's *Flotsam*, Peter Spier's *Noah's Ark*, both Caldecott Medal winners). They come to the fore here because they were bought by thousands of libraries, and they had citation counts of at least one in Scopus. Persons at research universities who specialize in manifestations of popular culture are legion.

Table 6. Books with highest libcitation counts by field, period, and main Dewey class.

Thus, even the most pop-cultural books in Table 6 are widely held by ARL members. It is a misconception that these libraries acquire only works of rarified scientific or scholarly status. In fact, they buy innumerable works that would also be found in public and school libraries. The best example is the single most widely held item in our database—*The Da Vinci Code*, owned by 122 (of 125) ARL members. Whatever one may think of this novel, it had a huge impact for several years, and scholars in the humanities will want copies on hand, if only to attack Dan Brown's transgressions. Nevertheless, the citation counts for these books in Table 6's leftmost column are very low. Brown's novel has the most, and these may include book reviews.

By contrast, Table 7 displays the titles that are *most* highly cited in our categories. As implied earlier, relatively high citation counts tend to signal a research orientation, and these 40 books, which have the top counts in their respective Dewey classes, are almost all distinctly more academic than those in Table 6. Their *total* libcitation counts tend to be lower than those in Table 6, suggesting more specialized readerships. (The exception is *The Guardian*, a Nicholas Sparks novel.) A fair number of them address themes prominent in the humanities (race, class, gender, imperialism), and their authors include names famous to postmodern scholars, if not to the general public (e.g., Edward Said, Gilles Deleuze, Judith Butler, Donna Haraway, Gayatri Spivak, and, with two books, Giorgio Agamben).

Three-fourths of these books are held by a hundred or more ARL libraries. Of those that are not, some may reflect genuinely narrower acquisition by ARL members. Others (if not errors) may reflect delayed or incomplete reporting of an acquired book that makes its libcitation count deceptively small. That may have happened, for instance, with Spivak's *Death of a Discipline*, whose ARL count in Table 7 is only 22, but whose count as an e-book in WorldCat is 1,246 at this writing.

In any event, ARL libcitation counts range unbrokenly over values from 1 to 215. Given this variation, why are the correlations of ARL counts with citations not higher? We have already noted that they tend to be higher than correlations of *total* libcitations with citations, but only slightly. In both cases the problem is the same: the great majority of books in our database have only one citation (or at most a few). Thus, a key variable in our study has little variability. As one illustration, Table 8 lists the five books with the highest ARL libcitation counts in our two fields (time periods combined, and omitting the *Oxford English Dictionary*, already shown). These books are best-sellers not only among ARL members but in libraries of all kinds. Yet their citation counts in Scopus are minuscule and much the same, just as they were for the books in Table 6. To anyone familiar with these titles, it is incredible that Table 8 reflects their full citation records. Rather, their true counts are not being captured.

Not too long ago, this assumption could only have been checked with data from the Web of Science, but now we can spot-check citations to books in Google Scholar. When that is done, the results are very different from what Scopus shows, whether the Scopus figures are as low as one or as high as 92. Table 9 suggests the nature of the problem. The counts there reflect our judgment calls, such as to include only those for the 2000 edition of *DSM-IV-TR* or the 2007 edition of *The Elements of Style*. Google Scholar itself does not break down by edition the many citations to the feminist classic *In a Different Voice*. Nor does it allow us to extract citations to books in our two periods of study. Nevertheless, the Google Scholar counts indicate where further correlational research should be directed (see also Prins et al., 2014).

Discussion

The correlations in this paper suggest that libcitations and citations are not entirely different measures of impact. However, we are left wanting citation counts for books that do not have so many low, tied values. It is possible that better data would again produce low or even negligible correlations. It is also possible that the correlations would be much higher than those seen here. The libcitation measure draws on a varied mix of assessments, and they are not necessarily the same as those that go into scholars' acts of citation. But, as our data make plain, they indicate major intellectual achievements no less forcefully than citations. In fact, one can argue that many of the humanities titles in Table 6 are *truly* major achievements, in that they have reached large publics beyond academe.

What, then, do libcitations measure? Briefly, they estimate the potential readerships, or users, of a given book. Citations, in contrast, measure actual uses to which the book has been put within research-oriented communities. It is therefore not surprising that citations and libcitations are associated, especially if the latter come from libraries that serve researchers,

such as those in ARL. But libcitations also measure broad cultural impacts that citations may miss, because libcitations rest on chains of judgments within the world of publishing, and this world, which subsumes the scholarly one, extends into every part of life. The chains include authors, agents, past editors who have built publishers' reputations, present-day editors of various kinds, referee-readers, marketers, and wholesalers. Librarians are only the last link.

This speaks to the common objection that librarians do not evaluate individual titles, but put their acquisitions on automatic pilot through approval plans and the like; how, then, can libcitations reflect genuine worth? On the contrary, librarians are highly attuned to potential demand in their communities, and it is they who approve the approval plans and buy into the pre-formed collections. It is quite true that such moves favor some publishers over others, but that is because librarians trust the chains of judgment those publishers represent. And so do their communities, who routinely expect librarians to have acquired certain books they learn about and are displeased if they have not.

Libcitations are sales figures—a market measure. They reflect virtual unanimity on the worth of some titles, but they vary enormously. In our database, although the counts run to the high values seen in our tables, many titles are held by only one ARL and one non-ARL library, just as many papers have only a citation or two. Research on libcitation-citation correlations should continue, but even if they remain low, that does not invalidate the libcitation measure. It is better thought of as a free-standing gauge of authors' cultural impact. Having published a book, what author would not prefer a thousand libraries to hold it rather than 10?

Acknowledgments

The authors are grateful to the Elsevier Bibliometrics Research Programme (http://ebrp.elsevier.com/) and OCLC WorldCat for granting access to the data used to build the unique database for this study. We also thank Dr. Roberto Cornacchia for helping to develop the database, as well as Maurits van Bellen and Robert Iepsma for their data cleaning and standardisation work. Dr. Stefanie Haustein of the École de bibliothéconomie et des sciences de l'information (EBSI), Université de Montréal, kindly provided information on the library holdings-count measure at Plum Analytics.

A Vector for Measuring Obsolescence of Scientific Articles

Abstract
Diachronous studies of obsolescence categorized articles into three general types: "flashes in the pan", "sleeping beauties" and "normal articles", by using quartiles to identify first 25% and last 75% articles reaching 50% of their total citations, or by using averages to define threshold values of sleeping and awakening periods. However, the average-based and quartile-based criteria, sometimes, less effectively distinguished "flashes in the pan" and "sleeping beauties" from normal articles. In this research, we proposed a vector for measuring obsolescence of scientific articles, as an alternative to these criteria. The obsolescence vector is designed as $O = (G_s, A^-, n)$, where n is the age of an article, G_s and A^- are parameters for revealing the shape of citation curves. Among Nobel laureates' 28,340 articles, each of which received over 20 citations, we identified 265 flashes in the pan (approximately 1%) and 40 sleeping beauties (approximately 0.1%) by the obsolescence vector. By a few case studies, it is verified that obsolescence vector yielded more reasonable classifications than did the average-based and quartile-based criteria.

Conference Topic:
Indicators

Introduction
In a previous study (Li et al., 2014), we introduced G_s index, an adjustment of Gini coefficient, for measuring the inequality of "heartbeat spectrum" of "sleeping beauties". "Sleeping beauty" in science was first proposed by van Raan (2004), in order to describe a phenomenon where papers did not achieve recognition in citations until many years after their original publication. As in the fairy tale, a princess (an article) sleeps (goes unnoticed) for a long time and then, almost suddenly, is awakened (receives a lot of citations) by a prince (another article). "Heartbeat spectrum" was defined as a vector of a sleeping beauty's annual citation(s) received in the sleeping period.

How to categorize recognition to a paper as "early", "delayed" or "normal"? Diachronous studies of obsolescence answered this question, by using quartiles to identify first 25% and last 75% articles reaching 50% of their total citations (Costas et al., 2010), or by using averages to define threshold values of sleeping and awakening periods (van Raan, 2004; van Dalen & Henkens, 2005). In this research, we propose an obsolescence vector based on the G_s index, as an alternative to both approaches.

Literature review
"Obsolescence" (or "ageing") studies, in the field of bibliometrics, attempt to answer the question how long does the information in a research paper remain current, by measuring the number of citations the paper received since publication (Cunningham & Bocock, 1995). There are two approaches to measure obsolescence: "synchronous" and "diachronous" distribution (Nakamoto, 1988). They are also referred to as "citations from" and "citations to" approaches (Redner, 2005), or "retrospective citation" and "prospective citation" approaches

(Burrell, 2002; Glänzel, 2004). The former considers the age distribution of references of a paper in a particular year, while the latter analyzes the distribution of citations over time.

A number of metrics has been proposed, from a synchronous perspective, to measure obsolescence of scientific literature. "Half-life" was described (Burton & Kebler, 1960) as "half the active life", which means the time during which one-half of the currently active literature was published. Price (1970) suggested the percentage of references (from all articles) up to five years old as an index to reveal obsolescence of scientific documents, which is also named "Price Index".

From a diachronous perspective, a citation curve (Garfield, 1989; Avramescu, 1979; Li et al., 2014) is the time distribution of citations a paper received. It is also referred to as "life-cycle" (Cunningham & Bocock, 1995), "citation patterns" (Li & Ye, 2014; Wang, Song, & Barabási, 2013; Guo & Suo, 2014; Redner, 2005), or "citation history" (Redner, 2005; ABT, 1981; Persson, 2005; Vlachý, 1985; Costas et al., 2010). A "typical citation curve" describes the history of an article which received a few citations in the first following years after publication, then rose to a citation peak, but afterwards was gradually less cited with time. It is identified that lognormal function best fits typical citation curves (Egghe & Rao, 1992). For most scientific papers, death (no longer being cited by other papers) comes within ten years after publication (Price, 1976). Nevertheless, the minority appears exponential increase in citations in a long time, whose citation curves fit exponential function (Li & Ye, 2014).

The peaking time of citations features the shape of citation curves, reflecting the immediacy of publications. Some articles were noticed immediately after publication but ignored very soon, and hence were named as "flashes in the pan" (van Dalen & Henkens 2005; Costas et al., 2010). Their citations peaked much earlier than typical citation curves. Some went unnoticed for a long time and then, almost suddenly, received a lot of citations, and hence were referred to as "sleeping beauties" (van Raan, 2004), "premature discoveries" (Stent, 1972; Wyatt, 1975), "resisted discoveries" (Barher, 1961) or "delayed recognition" (Cole, 1970). Their citations peaked much later than typical citation curves. Van Raan (2004) suggested three criteria for distinguishing sleeping beauties: (1) they deeply slept (receive at most 1 citation per year on average), or less deeply slept (between 1 and 2 citations per year on average) for a few years after publication; (2) they slept at least five years; and (3) they were awakened by over 20 citations during the four years following the sleeping period. However, the criteria are not always applicable to answer Garfield (1980)'s question how abrupt a citation boost must be to suggest delayed recognition. Moreover, the criteria ignored the citations received after the awakening period (Li, 2014; Li & Ye, 2012).

Different from van Raan's average-based criteria, Costas et al. (2010) used quartiles. They identified the year after publication in which the document received for the first time at least 50% of its citations ("Year 50%"), then calculated, for all documents of the same year of publication in the same field, the percentiles 25 and 75 of the distribution function of the value of "Year 50%", and recorded them as "P25" and "P75". As a result, the articles were categorized into "flashes in the pan" ("Year 50%" <"P25"), "delayed recognition" ("Year 50%" >"P75") and the rest as "normal publications" ("P25"≤"Year 50%"≤"P75"). These criteria considered the whole citation history of articles rather than only sleeping and awakening periods, and avoided the deficiency of van Raan's definitions. However, the excessive percentages of early and delayed recognition identified by these criteria caused the originally rare phenomena normal.

Methodology

Design of the obsolescence vector

Suppose there are seven ten-year old articles whose citation curves are drawn in Figure 1. P_1 is a sleeping beauty who deeply slept for six years (received no citations) but was suddenly awakened by 40 citations in the following four years. P_2 is a flash in the pan, which immediately received 32 citations within the first two years after publication, but was ignored afterwards and rarely received citations. P_3 is a typical citation curve, which reached citation-peak in the fourth year. It was successfully fitted by the lognormal function in the program OriginPro 8 ($R^2 = 0.972$). P_4 is an article whose citations increase exponentially. Exponential function successfully fits the curve with $R^2 = 0.983$. Both P_5 and P_6 are waveform curves, but they have different initial values, hence have distinct normalized curves in Figure 1. P_7 is a horizontal line, and coincides with the 45 degree diagonal in the right side of Figure 1, which is called "the line of equality" and indicates absolutely even distribution.

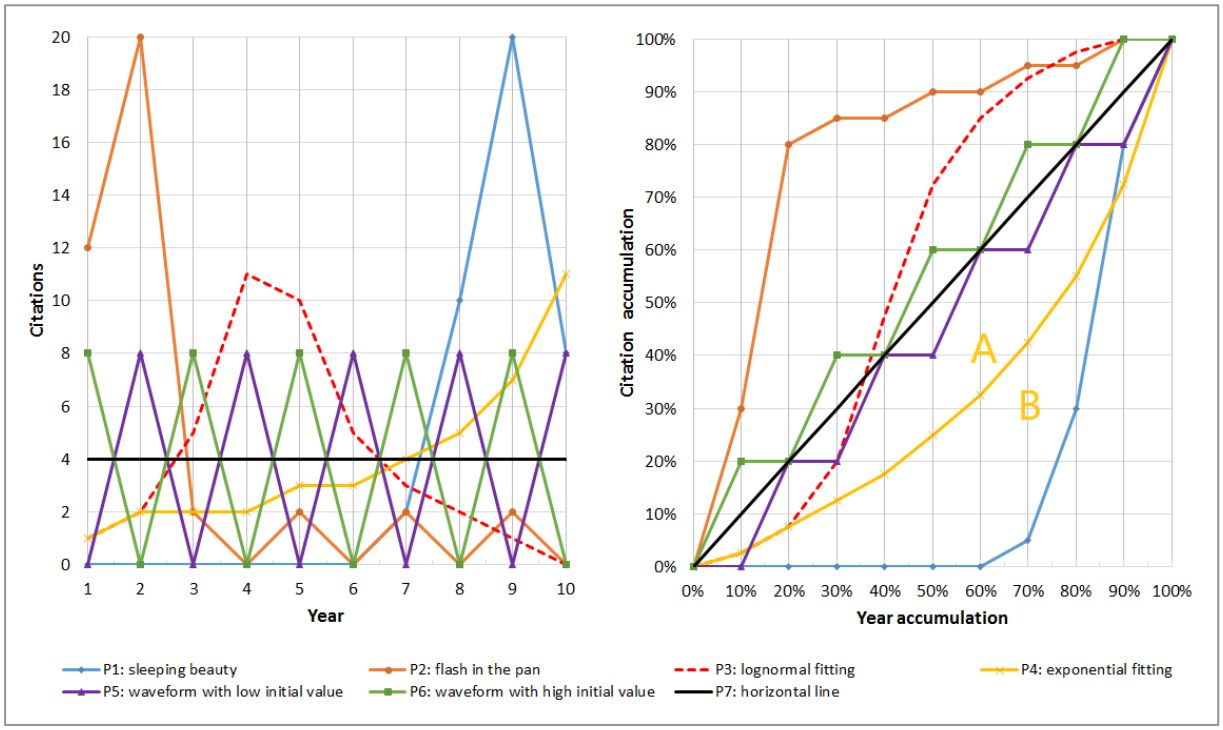

Figure 1. From citation curves to normalized cumulative citation curves of P1-P7 (left: citation curves; right: normalized cumulative citation curves).

The value of G_s, taking P4 as an example, equals to the ratio of the area that lies between the line of equality and the normalized cumulative citation curve (marked A in Figure 1) over the total area under the line of equality (sum of A and B), i.e.,

$$G_s = \frac{A}{A+B}. \quad (1)$$

The normalized cumulative citation curve (hereafter "normalized curve") of P4 is a "Lorenz curve", because the sequence of citations is in an ascending order. Since the areas A and B form an isosceles right triangle, we have

$$A + B = \frac{1}{2}. \quad (2)$$

Thus, putting Eq. (2) into Eq. (1), we have

$$G_s = 2A. \quad (3)$$

The calculation of G_s is determined by the calculation of the area B which can be divided into several trapeziums and a triangle. In this study, we remain the expression of the segment function of G_s in our previous study (Li et al., 2014),

$$G_s = \begin{cases} 1 - \frac{2\times[n\times c_1+(n-1)\times c_2+\cdots+c_n]-C}{C\times n}, & C > 0 \\ 1, & C = 0 \end{cases} \quad (4)$$

but redefine the parameters. In the new definition, n is the age of a paper, C is the total number of citations the paper received during the n years, and $c_i (i \in \{1,2,\cdots,n\})$ is the number of citations the paper received in the i^{th} year after publication. Here, $Gs \in (-1,1]$ and depends on the age (n) of articles. The value of G_s gradually approaches to -1, if the article no longer receives citations.

The value of G_s, to certain extent, characterizes the shape of citation curves:

(1) large G_s indicates delayed recognition, while small G_s denotes early recognition, as P_1 and P_2 shown in Table 1;

(2) $G_s < 0$ implies that there exists leaping early in citation curves, for example, both P_2 and P_6 received a large number of citations immediately after publication, while P_3 has a fast rising period although it does not have immediacy; and

(3) $G_s = 0$ suggests a horizontal citation curve (as P_7), or a citation curve including at least one high-citation period (to guarantee $A^- < 0$) which is offset by at least one low-citation period.

The value of A is not always positive. For P_2, $A<0$, since its normalized curve in Figure 1 is above the line of equality. Since

$$A = A^+ + A^- , \quad (5)$$

putting Eq. (5) into Eq. (3), we have

$$A^- = \frac{1}{2}G_s - A^+. \quad (6)$$

A^+ is the area between the line of equality and the normalized curve under the line of equality. Similar to the calculation of G_s, we calculate A^+, and accordingly have the value of A^-. In case of P_3, the intersection of the normalized curve and the line of equality in Figure 1 exists in between the accumulation year 30% and 40%. Therefore, there is a minor error (a difference) between the output and target of A^+ values of P_3. In cases of P_1, P_4 and P_5, there is no error in the calculation of A^+.

The fast rising period of a citation curve is hidden from the value of G_s if $A^- < 0 < A^+$. In case of $A^+ = 0$, we have

$$A^- = A = \frac{1}{2}G_s. \quad (7)$$

Hence, the value of A^- provides complementary explanation to the shape of citation curves:

(1) recognition to the article is normal or delayed rather than early if $A^-=0$;

(2) there exists leaping in the citation curve of the article if $A^-<0$; and

(3) citation leaping appears early if $A^- = \frac{1}{2}G_s$.

We propose a vector for measuring obsolescence of scientific articles: $O=(G_s, A^-, n)$, where G_s is an index revealing the history of citations, A^- is a parameter uncovering citation leaping and age n is an adjusting parameter. We calculated the obsolescence vectors for P_1-P_7 as shown in Table 1.

Table 1. Obsolescence vectors for P1-P7.

Article	*Citation curve*	*Citations*	*A*	A^+	*Obsolescence vector*		
					G_s	A^-	*n*
P1	Sleeping beauty	40	0.335	0.335	0.670	0.000	10
P2	Flash in the pan	40	-0.300	0.000	-0.600	-0.300	10
P3	Lognormal fitting	40	-0.075	0.028	-0.150	-0.103	10

P6	Waveform with high initial value	40	-0.050	0.000	-0.100	-0.050	10
P7	Horizontal line	40	0.000	0.000	0.000	0.000	10

Criteria for categorizing the patterns of obsolescence

In this research, we use the terms "flashes in the pan", "sleeping beauties" and "normal articles" as the patterns of obsolescence, but provide three different approaches for measurement, in order to characterize obsolescence vector. We remain van Raan's average-based criteria in the first approach. By following the criteria, we define variables for "flashes in the pan": "noticed" (van Dalen and Henkens, 2005) as receiving over 10 citations, "ignored" as receiving less than two citations per year on average and "immediately" as within two years since publication. We also define the duration of light disappearing for at least five years, since a flash is likely to reappear. Then, we suggest average-based criteria as follows:

flashes in the pan (F_1): articles which received more than 10 citations in the first two years since publication, and then in the next five years received no more than 2 citations per year on average;

sleeping beauties (S_1): articles which received no more than 2 citations per year on average in the first five years since publication, and then in the next four years received more than 20 citations; and

normal articles (N_1): which neither satisfy the criteria for F_1 nor for S_1.

The second approach uses quartiles. We adjust "relative ranking in a field" in Costas et al. (2010) to "relative age", since the former requires the population of articles in a filed which involves a huge dataset. Thus, for a single article, we record the percentiles 25 and 75 of its age as "A25" and "A75". Then, we define quartile-based criteria for the patterns of obsolescence as follows:

flashes in the pan (F_2): articles that reached "Year 50%" within 25% of its age, i.e., "Year 50%" <"A25";

sleeping beauties (S_2): articles that reached "Year 50%" with the time exceeding 75% of its age, i.e., "Year 50%" >"A75"; and

normal articles (N_2): which neither satisfy the criteria for F_1 nor for S_1, i.e., "A25"≤"Year 50%"≤ "A75".

Based on the obsolescence vectors of the seven cases in Table 1, we propose new criteria for categorizing the patterns of obsolescence as follows,

flashes in the pan (F_3): $G_s \leq$ -0.6 and $A^- = \frac{1}{2} G_s$;

sleeping beauties (S_3): $G_s \geq 0.6$ and $A^- = 0$; and

normal articles (N_3): which neither satisfy the criteria for F_3 nor for S_3.

Data

A dataset was prepared to make comparisons of the above three sets of criteria, and to verify the efficiency of the proposed obsolescence vector. From the Web of Science, we collected 58,963 articles of 629 Nobel Prize winners during the period of 1901-2012, in the fields of Chemistry, Physics, Physiology or Medicine, and Economic Sciences. The definition S_2 requires that a sleeping beauty should have more than 20 citations. For the purpose of comparisons, we eliminated articles, which received no more than 20 citations, and remained a collection of 28,340 articles published between 1900 and 2000. Then, we searched the number of annual citations to these articles up to 2011 in the Web of Science. Thus, every article in this collection aged at least eleven, which is sufficient for a sleeping beauty with the shortest sleeping period to be awakened.

Results

Obsolescence vector as an alternative to average-based and quartile-based criteria

The life-cycles of most articles in the dataset have already drawn to their close. As shown in Table 2, the peak of G_s distribution appears in the interval (-0.4,-0.2] and the values of G_s for 84.3% articles are negative. Moreover, 95.0% of the articles have $A^-<0$. Small G_s values (minus) indicate the end of cife-cycles, as shown by article P_2 in Figure 1. It is calculated that 68.4% of the articles with $G_s > 0$ have $A^- < 0$. Thus, there are only a small fraction of citation curves having the shape of P_1, P_4 and P_5 in Figure 1. What they have in common is that there is no citation rise and fall in the initial stage of citation curves. The rise and fall of citations must be a citation leaping or like a lognormal shape. Articles with the largest and smallest G_s values are categorized into sleeping beauties (S_3) and flashes in the pan (F_3), respectively. The obsolescence vector for the former (Rayleigh, 1914) is O = (0.892, 0, 98). Although published as early as in 1914, it received no citations until 1992. It does not satisfy S1, since it was not awakened by more than 20 citations within four years after sleeping period. However, it satisfies S_2, since recognition to it was delayed to the last four years of its age. This example reveals the deficiency of S_1. The latter (Ryle & Bailey, 1968) has an obsolescence vector O = (-0.960, -0.480, 44). The article received 26 citations immediately in the publication year, but the number rapidly fell to zero four years later and it was never cited till the end. It satisfies both F_1 and F_2.

Table 2. Comparisons of the three approaches to measuring obsolescence.

G_s	N	$N(A^-<0)$	F_1	S_1	F_2	S_2	F_3	S_3	$F_1\&F_3$	$F_2\&F_3$	$S_1\&S_3$	$S_2\&S_3$
(-1,-0.8]	494	494	41	0	489	0	265	0	34	262	0	0
(-0.8,-0.6]	3,897	3,897	62	6	3,856	0	1,734	0	57	1,704	0	0
(-0.6,-0.4]	6,808	6,808	30	16	5,250	0	0	0	0	0	0	0
(-0.4,-0.2]	7,213	7,213	21	22	985	0	0	0	0	0	0	0
(-0.2,0]	5,477	5,477	7	25	25	0	0	0	0	0	0	0
(0,0.2]	2,894	2,344	7	27	0	15	0	0	0	0	0	0
(0.2,0.4]	1,140	543	5	26	0	228	0	0	0	0	0	0
(0.4,0.6]	348	141	2	7	0	304	0	0	0	0	0	0
(0.6,0.8]	65	17	1	1	0	65	0	37	0	0	1	37
(0.8, 1)	4	0	0	0	0	4	0	3	0	0	0	3
Total	**28,340**	**26,934**	**176**	**130**	**10,605**	**616**	**1,999**	**40**	**91**	**1,966**	**1**	**40**

It seems that the condition $G_s \leq$ -0.6 and $A^- = \frac{1}{2} G_s$ for flashes in the pan is a loose condition, since it yields 1,999 flashes in the pan in the dataset. If it is intensified to be $G_s \leq$ -0.8 and $A^- = \frac{1}{2} G_s$, the number of flashes in the pan shrinks to 262, closer to the result of criterion F_1. Considering that 81.6% of the articles aged over 20, we suggest the criterion for flashes in the pan be $G_s \leq$ -0.8 and $A^- = \frac{1}{2} G_s$ on condition that n≥20.

The criterion S_3 for sleeping beauties is more stringent than S_1 and S_2, and selected only 40 qualified articles from the dataset. The 40 articles is a subset of the collection by S_2, but covers 39 articles out of the collection by S_1. In Table 2, there are six articles satisfying S_1 whose G_s values exist in the interval (-0.8, -0.6]. For example, the article in Figure 2 received only nine citations within the first five years after publication, but suddenly received 25 citation in the following four years. It also satisfies S_2, since it reached "Year 50%" within ten years (13.9% of its age) after publication. Nevertheless, this article is more like a "typical citation curve" which spent seven years to gradually reach citation-peak and slowly declined to death afterwards. The obsolescence vector of this article is O = (-0.648, -0.324, 72) which does not satisfy S_3. Moreover, we identified 3,897 articles of its kind, which have $G_s \in$ (-0.8, -0.6]. Therefore, it is more reasonable to categorize it as a "normal article" rather than a "sleeping beauty".

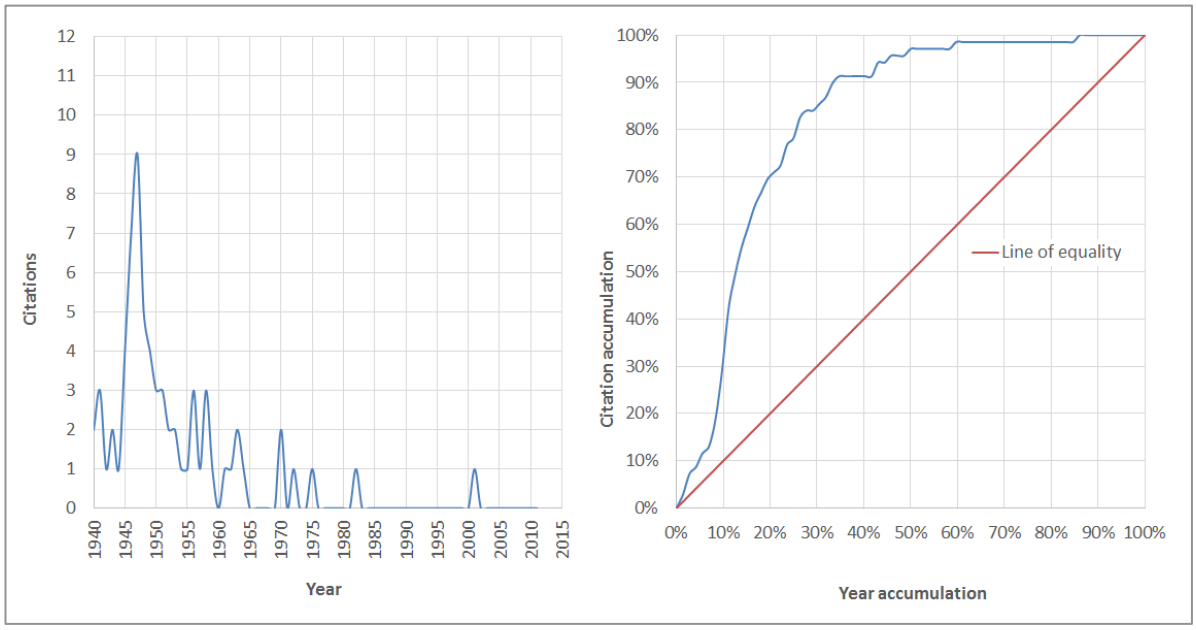

Figure 2. A sleeping beauty by average-based and quartile-based criteria, but a normal article by obsolescence vector (Landsteiner, 1940).

Citation-curve differences of obsolescence

The calculation of G_s values, sometimes, remains citation leaping under cover. As shown in Figures 3, Zewail's and Corey's articles were published in the same year of 2000, and have the same G_s values 0.083. However, they received different citations and have different citation curves. The obsolescence vector of the two articles are O=(0.083, 0, 12) and O=(0.083, -0.004, 12), respectively. Due to the citation leaping since 2007, the normalized curve of Corey's article in Figure 3 surpassed the line of equality in 2010 and yielded $A^- < 0$ which does not appear in the normalized curve of Zewail's article. Therefore, it is a sign of citation leaping to have A^-<0.

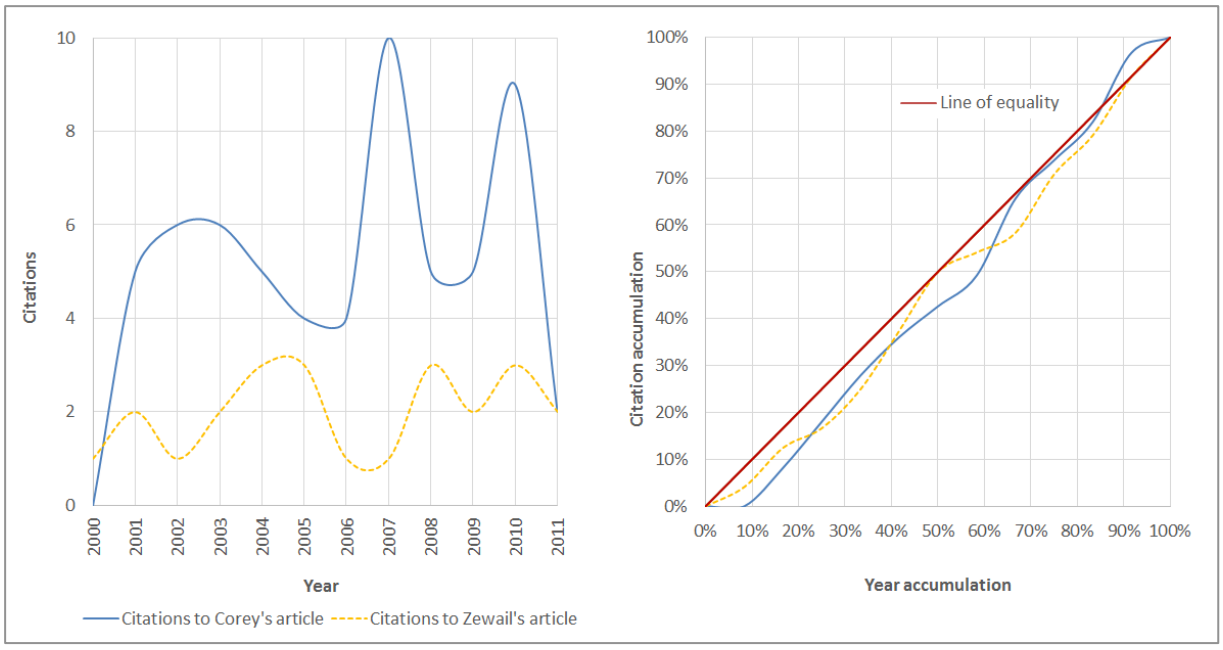

Figure 3. Zewail's article with O = (12, 0.083, 0) and Corey's article with O = (12, 0.083, -0.004).

Age differences of obsolescence

The years of 1950, 1990 and 2000 were selected for the publication years for sampling articles, in order to explore age differences of obsolescence. They were aged 62, 22 and 12, respectively. It appears that older articles have smaller G_s values while younger ones have larger G_s values. It is clear in Table 3 that the peak of G_s distribution among the intervals shifted from (-0.6, -0.4] in 1950, to (-0.4,-0.2] in 1990, even to (-0.2, 0] in 2000. Most of the old articles have been ignored and receive rare or no citations after recognition, similar to the example in Figure 2. Therefore, their G_s values gradually decline. It is hence identified that age exerts significant influence on the values of G_s.

Table 3. Age differences of obsolescence.

G_s	*Year* 1950		*Year* 1990		*Year* 2000

Disciplinary differences of obsolescence

The obsolescence of economic sciences is slower than that of fundamental sciences, including chemistry, physics and physiology & medicine. It is a sign of slow obsolescence to have more positive G_s values and less $A^- < 0$. In Table 4, the distribution of G_s values of economic sciences peaked in the interval (0, 0.2], while in other disciplines, it peaked in the interval (-0.4,-0.2] or (-0.6,-0.4]. The percentage of $A^- < 0$ in positive G_s values is only 50.4%, far less

than 69.8-75.8% in fundamental sciences. Moreover, older articles tend to have higher absolute G_s values, in each of the four disciplines.

Table 4. Disciplinary differences of obsolescence

Discussion

Further discussion on $A^- < 0$

Significant citation leaping is likely to result in recurring appearance of $A^-<0$ area. For example of Hsu et al.'s article (1997), citation leaping appeared twice in the citation curve. The first citation peak appeared in 1998, the second year after publication, which led the normalized curve to reach the line of equality. In 1999, the article received six citations. The normalized curve hence surpassed the line of equality. However, the citation leaping disappeared afterwards, and the normalized curve dropped under the line of equality. Nevertheless, the second citation peak, higher than the first one, appeared in 2005 and boosted the normalized curve above the line of equality again. Comparing this example with the supposed waveform citation curves, i.e., P_5 and P_6 in Figure 1, it is identified that the appearance of $A^-<0$ area is originated by citation leaping. Furthermore, double appearance of $A^-<0$ area indicates double citation leaping in which the first one happened immediately after publication and the second one is higher. However, the characteristics of double or multiple appearance of $A^-<0$ area are not in consideration of the new designed obsolescence vector, since the number of this kind is rare.

Limitations

The obsolescence vector cannot differentiate two citation curves if there is multiplier relationship between their annual citations. For example, both (0, 8, 0, 8, 0, 8, 0, 8, 0, 8) and (0, 4, 0, 4, 0, 4, 0, 4, 0, 4) have the same obsolescence vector O=(0.1, 0, 10). The obsolescence vector is applicable to categorize articles into "flashes in the pan", "sleeping beauties" or "normal articles", by distinguishing citation leaping in citation curves. It does not characterize citation history of "normal" articles, which account for a large percent. As normal articles, P_3-P_6 in Figure 1 have entirely different obsolescence patterns. However, they cannot be uncovered by obsolescence vector.

It is controversial whether someone who won a major prize has received increased citations on all his/her work (Hugget, 2013; Mazloumian et al., 2011). However, the results are generalized from articles of Nobel laureates rather than randomly sampled authors, and hence are potentially biased. In addition, "recognition" is referred to as a large number of citations,

e.g., 20. Thus, whether the obsolescence vector is applicable to articles receiving less than 20 citations requires further research.

Conclusions

We proposed a vector for measuring obsolescence of scientific articles, $O = (G_s, A^-, n)$, where n is the age of an article, G_s and A^- are parameters for the shape of the article's citation curves. By distinguishing inequality of citation distribution, obsolescence vector is applicable to categorize articles into three general types:

flashes in the pan: $G_s \leq$ -0.8 and $A^- = \frac{1}{2} G_s$ for n≥20 or $G_s \leq$ -0.6 and $A^- = \frac{1}{2} G_s$ for n<20;
sleeping beauties: $G_s \geq 0.6$ and $A^- = 0$; and
normal articles: which neither satisfy the criteria for F_3 nor for S_3.

The age, subject category and citation curve of articles exert significant influence on G_s values. Older articles tend to have higher absolute G_s values. The criterion for "flashes in the pan" is adjustable in terms of the age of articles. In case of articles younger than, e.g., ten years old, as shown in Figure 1, it is feasible to mildly adjust the criterion as $G_s \leq$ -0.6. Disciplinary differences exist in the proposed obsolescence vector. Articles in economic sciences appear higher G_s values than those in fundamental sciences, including chemistry, physics and physiology & medicine. In case of articles receiving no more citations, their G_s values tend to decline, till to -1.

As an alternative to average-based and quartile-based criteria, the obsolescence vector avoided overlooking the period after sleeping beauties being awakened, and tightened the loose conditions by using quartiles. By obsolescence vectors, we identified 265 flashes in the pan (approximately 1%) and 40 sleeping beauties (approximately 0.1%), among 28,340 articles of Nobel laureates, which receive more than 20 citations by the year of 2011. The low percentages of flashes in the pan and sleeping beauties remained them rare phenomena.

Field-Normalized Citation Impact Indicators and the Choice of an Appropriate Counting Method

Ludo Waltman and Nees Jan van Eck

Centre for Science and Technology Studies, Leiden University, Leiden (The Netherlands)

Abstract
Bibliometric studies often rely on field-normalized citation impact indicators in order to make comparisons between scientific fields. We discuss the connection between field normalization and the choice of a counting method for handling publications with multiple co-authors. Our focus is on the choice between full counting and fractional counting. Based on an extensive theoretical and empirical analysis, we argue that properly field-normalized results cannot be obtained when full counting is used. Fractional counting does provide results that are properly field normalized. We therefore recommend the use of fractional counting in bibliometric studies that require field normalization, especially in studies at the level of countries and research organizations.

Conference Topic
Citation and co-citation analysis; Indicators

Introduction
In discussions on bibliometric indicators, two topics that receive a considerable amount of attention are field normalization and counting methods. Field normalization is about the problem of correcting for differences in citation practices between scientific fields. The challenge is to develop citation-based indicators that allow for valid between-field comparisons. Counting methods are about the way in which co-authored publications are handled. For instance, if a publication is co-authored by two countries, should the publication be counted as a full publication for each country or should it be counted as half a publication for each country?

The topics of field normalization and counting methods are usually discussed separately from each other. However, we argue that there is a close connection between the two topics. Our argument is that proper field normalization is possible only if a suitable counting method is used. In particular, we claim that properly field-normalized results cannot be obtained when one uses the popular full counting method, in which co-authored publications are fully assigned to each co-author. The fractional counting method, which assigns co-authored publications fractionally to each co-author, does provide properly field-normalized results. The problem of full counting basically is that co-authored publications are counted multiple times, once for each co-author, which creates a bias in favor of fields in which there is a lot of co-authorship and in which co-authorship correlates with additional citations. This is the essence of the argument that we present in this paper. Our argument builds on an earlier paper (Waltman et al., 2012), but in the present paper we elaborate the argument in more detail and we also present an extensive empirical analysis.

This paper is a shortened version of a more extensive working paper (Waltman & Van Eck, 2015). The working paper includes additional empirical analyses comparing different counting methods at the level of institutions and countries. Furthermore, the working paper considers different variants of fractional counting and also studies first author and corresponding author counting methods.

Counting methods

Our focus is on the comparison between full counting and fractional counting. In the case of full counting, a publication is fully assigned to each co-author. For instance, a publication co-authored by four countries counts as a full publication for each of the four countries. In the fractional counting case, a publication is fractionally assigned to each co-author. The weight with which a publication is assigned to a co-author indicates the share of the publication allocated to that co-author. The sum of the weights of all co-authors of a publication equals one. An example of fractional counting is the situation in which a publication co-authored by four countries is assigned to each country with a weight of 1 / 4 = 0.25.

There is a quite extensive literature on counting methods. Because of space limitations, we mention only a few selected studies. A systematic terminology for counting methods is proposed by Gauffriau, Larsen, Maye, Roulin-Perriard, and Von Ins (2007). They refer to full counting as whole counting and to fractional counting as normalized counting. Gauffriau, Larsen, Maye, Roulin-Perriard, and Von Ins (2008) present a comparison of counting methods at the country level. They also provide an overview of earlier literature on counting methods. Another country-level comparison is reported by Aksnes, Schneider, and Gunnarsson (2012). At the institution level, Waltman et al. (2012) present a comparison between full and fractional counting. Interesting work on counting methods can also be found in various papers by Ruiz-Castillo and colleagues, who propose the idea of a so-called multiplicative counting method (e.g. Albarrán, Crespo, Ortuño, & Ruiz-Castillo, 2010).

Relation between counting methods and field normalization

Our aim in this section is to demonstrate the close connection between counting methods and field normalization. In particular, we aim to make clear that full counting is fundamentally inconsistent with the idea of field normalization. We argue that full counting yields results that suffer from a bias in favor of fields in which there is a lot of co-authorship and in which co-authorship correlates with additional citations. This bias is caused by the fact that co-authored publications are counted multiple times in the case of full counting, once for each co-author.

We present our argument by providing two simple examples. Both examples take countries as the unit of analysis and focus on the mean normalized citation score (MNCS) indicator (Waltman, Van Eck, Van Leeuwen, Visser, & Van Raan, 2011). However, the underlying ideas of the two examples are more general, and similar examples can be given with authors or organizations as the unit of analysis and with other field-normalized indicators.

Table 1. Example involving a single field.

	Authors	No. of cit.	Norm. cit. score
Publication 1	Country A	3	0.6
Publication 2	Country A	6	1.2
Publication 3	Country B	1	0.2
Publication 4	Country A; Country B	10	2.0

Example involving a single field

We consider a world in which there are just four publications. These publications have been produced by two countries, labeled as country A and country B. Table 1 shows for each publication the countries by which the publication is authored and the number of citations the publication has received. The table also shows the normalized citation score of each publication. For simplicity, it is assumed that all four publications are in the same field. The normalized citation score of a publication is therefore obtained simply by dividing the number of citations of the publication by the average number of citations of all four publications. The

average number of citations of the four publications equals (3 + 6 + 1 + 10) / 4 = 5, and therefore the normalized citation score of for instance publication 1 equals 3 / 5 = 0.6. Of course, the average of the normalized citation scores of the four publications equals one.
We now calculate both for country A and for country B the MNCS. Using full counting, we obtain

$$\mathrm{MNCS}_\mathrm{A} = \frac{0.6 + 1.2 + 2.0}{3} = 1.27 \text{ and } \mathrm{MNCS}_\mathrm{B} = \frac{0.2 + 2.0}{2} = 1.10.$$

On the other hand, using fractional counting, we get

$$\mathrm{MNCS}_\mathrm{A} = \frac{1.0 \times 0.6 + 1.0 \times 1.2 + 0.5 \times 2.0}{1.0 + 1.0 + 0.5} = 1.12 \text{ and } \mathrm{MNCS}_\mathrm{B} = \frac{1.0 \times 0.2 + 0.5 \times 2.0}{1.0 + 0.5} = 0.80,$$

where publication 4 has been assigned with a weight of 0.5 to country A and with a weight of 0.5 to country B.
The important thing to observe in this example is that in the case of full counting country A and country B both have an MNCS above one. One of the main ideas of field-normalized indicators such as the MNCS indicator is that the value of one can be interpreted as the world average. Under this interpretation, country A and country B both perform above the world average. Since there are no other countries in our example, the conclusion would be that all countries in the world perform above the world average. There are no countries with a below-average performance. In our opinion, the conclusion that everyone is above average does not make much sense. Moreover, this conclusion is fundamentally different from the conclusion that is reached in the case of fractional counting. Using fractional counting, country A has a performance above the world average while the performance of country B is below the world average.
Looking a bit more in detail at our example, we observe that in the fractional counting case we have

$$\frac{2.5 \times \mathrm{MNCS}_\mathrm{A} + 1.5 \times \mathrm{MNCS}_\mathrm{B}}{2.5 + 1.5} = \frac{2.5 \times 1.12 + 1.5 \times 0.80}{2.5 + 1.5} = 1.$$

Hence, the weighted average of the MNCS of country A and the MNCS of country B, with weights given by each country's fractional number of publications, equals exactly one. This is a general property of fractional counting. The weighted average of the MNCSs of all countries in the world will always be equal to exactly one.
In the full counting case, the weighted average of the MNCS of country A and the MNCS of country B equals

$$\frac{3 \times \mathrm{MNCS}_\mathrm{A} + 2 \times \mathrm{MNCS}_\mathrm{B}}{3 + 2} = \frac{3 \times 1.27 + 2 \times 1.10}{3 + 2} = 1.20,$$

where the weight of each country is given by the number of publications of the country obtained using full counting. So in the full counting case the world average at the country level does not equal one but instead equals 1.20. Taking 1.20 as the world average, we conclude that country A, with an MNCS of 1.27, has an above-average performance while

country B, with an MNCS of 1.10, performs below average. This is in agreement with the conclusion reached using fractional counting.

So in our example there is a difference of 1.20 – 1 = 0.20 between the world average obtained using full counting and the world average obtained using fractional counting. We refer to this difference as the full counting bonus. In principle, the full counting bonus can be either positive or negative, but we will see that in practice the bonus is usually positive. The full counting bonus is caused by the fact that publications co-authored by multiple countries are counted multiple times in the case of full counting, and therefore the citation impact of multi-country publications relative to single-country publications determines whether the full counting bonus is positive or negative. The bonus will be positive if publications co-authored by multiple countries receive more citations than publications authored by a single country. Conversely, a negative bonus will be obtained if multi-country publications are cited less frequently than single-country publications. As can be seen in Table 1, in our example the only publication co-authored by multiple countries is publication 4, and this is also the most highly cited publication. In the full counting case, publication 4 is fully assigned both to country A and to country B. Hence, the most highly cited publication in our example is counted two times, once for country A and once for country B. This double counting of publication 4 explains why both countries have an MNCS above one and why the full counting bonus is positive.

Example involving multiple fields

In the example discussed above, all publications are in the same field. We now consider an example that involves more than one field. This example is presented in Table 2. There are six publications, three in field X and three in field Y, and there are four countries. Countries A and B are active only in field X, while countries C and D are active only in field Y. The three publications in field X have all received the same number of citations, and therefore these publications all have a normalized citation score of one. This is not the case in field Y, in which publication 6, co-authored by countries C and D, has received more citations than publications 4 and 5, which are single-country publications. Of course, the average normalized citation score of the publications in field Y equals one, just like in field X.

Table 2. Example involving multiple fields.

	Field	Authors	No. of cit.	Norm. cit. score
Publication 1	Field X	Country A	10	1.0
Publication 2	Field X	Country B	10	1.0
Publication 3	Field X	Country A; Country B	10	1.0
Publication 4	Field Y	Country C	4	0.8
Publication 5	Field Y	Country D	4	0.8
Publication 6	Field Y	Country C; Country D	7	1.4

Using fractional counting, the four countries all have an MNCS of exactly one. For countries A and B this is immediately clear. In the case of countries C and D, the MNCS is calculated as $(1.0 \times 0.8 + 0.5 \times 1.4) / (1.0 + 0.5) = 1$. So fractional counting tells us that all four countries perform at the world average. This is indeed the outcome that we would expect to obtain. The publications of countries A and B have all been cited equally frequently as the average of their field, so countries A and B obviously perform at the world average. In the case of countries C and D, we observe that these countries have exactly the same performance and that they are the only countries active in field Y. Based on these two observations, it is natural to conclude that the performance of countries C and D is at the world average.

We now consider the full counting case. Using full counting, countries A and B have an MNCS of one, while countries C and D have an MNCS of $(0.8 + 1.4) / 2 = 1.10$. The full

counting results seem to suggest that countries C and D have a better performance than countries A and B. However, a more careful analysis shows that this is not a correct interpretation of the results. To see this, we calculate both for field X and for field Y the average of the MNCSs of the countries active in the field. The average MNCS of the countries active in field X equals one, while the average MNCS of the countries active in field Y equals 1.10. Hence, both countries A and B active in field X and countries C and D active in field Y perform at the world average of their field. Like in the fractional counting case, we conclude that all four countries have an average performance. Countries C and D have a higher MNCS than countries A and B only because they are active in a field with a higher full counting bonus. Field Y has a full counting bonus of $1.10 - 1 = 0.10$, while the full counting bonus in field X equals zero.

Conclusions based on the examples

Based on the above examples, two important conclusions can be drawn. The first conclusion is that there is a need to carefully distinguish between two field normalization concepts. We refer to these concepts as weak field normalization and strong field normalization. Weak field normalization requires the average of the normalized citation scores of all publications in a field to be equal to one. Strong field normalization is more demanding. It requires the weighted average of the MNCSs of all countries active in a field to be equal to one, where the weight of a country is given by its number of publications in the field.

As shown in the above examples, full counting yields results that are in agreement with the idea of weak field normalization, but these results may violate the idea of strong field normalization. For instance, in the first example discussed above, the average normalized citation score of the four publications equals one (weak field normalization), but the average MNCS of the two countries does not equal one (no strong field normalization). Fractional counting results, on the other hand, satisfy not only the idea of weak field normalization but also the idea of strong field normalization. Using fractional counting, the weighted average of the MNCSs of all countries active in a field will always be equal to one.

When citation-based indicators are calculated using full counting, there is a risk of misinterpretation. People may confuse the concepts of weak and strong field normalization, and they may fail to understand that the idea of strong field normalization does not apply in the case of full counting. In the second example presented above, they may for instance draw the incorrect conclusion that countries C and D perform above the world average. In the fractional counting case, people will not draw such an incorrect conclusion, because fractional counting results are in agreement with the idea of strong field normalization.

We now turn to the second conclusion that follows from our examples. The fact that full counting yields results that are incompatible with the idea of strong field normalization may in itself be regarded as just a minor issue. Instead of having a world average of one, the average of all countries in the world may for instance be equal to 1.10 or 1.20. Although a world average of one might be somewhat more convenient, the exact value of the world average may in the end seem to be of limited importance.

However, our second conclusion is that deviations of the world average from one actually do have serious consequences, at least when making comparisons between fields. This is what is shown in the second example given above. Using full counting, the average MNCS of the countries active in field X equals one, while the average MNCS of the countries active in field Y equals 1.10. So in field X the world average equals one, while in field Y we have a world average of 1.10. Direct comparisons of the MNCSs of the countries active in field X and the countries active in field Y therefore do not yield valid conclusions. Based on their MNCSs, the countries active in field Y seem to perform better than the countries active in field X, but

taking into account the fact that field Y has a higher world average than field X, it actually should be concluded that all countries perform at the same level.

Essentially, the second conclusion that we draw based on our examples is that full counting is fundamentally inconsistent with the idea of field normalization. Citation-based indicators calculated using full counting yield results that do not allow for valid comparisons between fields, and this is the case even when field-normalized indicators, such as the MNCS indicator, are used. When full counting is used in the calculation of field-normalized indicators, countries that focus their activity on fields with a high full counting bonus have an advantage over countries that are active mainly in fields with a low full counting bonus. Fractional counting does not suffer from this problem. Fractional counting results are compatible with the idea of strong field normalization, and these results therefore do allow for proper between-field comparisons.

Empirical analysis of the full counting bonus

In the previous section, we have introduced the idea of the full counting bonus and we have illustrated this idea using theoretical examples. In this section, we present a large-scale empirical analysis of the full counting bonus. This analysis for instance makes clear which fields benefit most from the full counting bonus, and the analysis shows the differences between fields caused by the bonus.

Calculation of the full counting bonus

We first explain in more detail the way in which we calculate the full counting bonus. For simplicity, we assume that our interest is in the full counting bonus at the level of countries. However, the full counting bonus can be calculated in a similar way at the level of for instance authors or organizations.

Suppose we have a set of n publications. This could be for instance the set of all publications in a specific field and in a specific year. For each publication i, we have a citation score c_i. The citation score of a publication can be defined in different ways. It may be simply the number of times a publication has been cited, but it may also be something more advanced, for instance a field-normalized citation score. We also know for each publication the countries by which the publication has been co-authored. We use m_i to denote the number of countries that have co-authored publication i.

In order to obtain the full counting bonus, we first calculate for each country the average citation score of its publications. We perform this calculation both using full counting and using fractional counting. Next, we calculate a weighted average of the average citation scores of all countries. In the case of full counting, we use the number of publications of a country obtained using full counting as the weight of the country. In the case of fractional counting, we use a country's number of publications obtained using fractional counting as the country's weight. Finally, we calculate the full counting bonus as the difference between the weighted average in the full counting case and the weighted average in the fractional counting case.

The above approach to calculating the full counting bonus is somewhat complicated. However, a mathematically equivalent but much simpler approach is available. In this approach, the full counting bonus is calculated as

$$\mathrm{FCB} = \frac{\sum_{i=1}^{n} m_i c_i}{\sum_{i=1}^{n} m_i} - \frac{\sum_{i=1}^{n} c_i}{n},$$

where the first term equals the above-mentioned weighted average in the full counting case while the second term equals the weighted average in the fractional counting case. In the first term, the citation score c_i of publication i co-authored by m_i countries is counted m_i times. This is because in the full counting case publication i is fully assigned to each of the m_i countries. In the second term, the citation score c_i of publication i is counted only once, regardless of the number of countries m_i by which publication i has been co-authored. This is because in the fractional counting case the total weight with which publication i is assigned to the m_i countries equals one.

In our empirical analysis, we consider two definitions of the citation score of a publication. Both definitions include a normalization for field. In the first definition, the citation score of a publication is obtained by dividing the number of citations of the publication by the average number of citations of all publications in the same field and in the same year. Averaging the citation scores of multiple publications then gives us the MNCS indicator. This indicator was also used in the theoretical examples presented in the previous section. In the second definition of the citation score of a publication, we determine whether a publication belongs to the top 10% most frequently cited publications of its field and publication year. A publication belonging to the top 10% has a citation score of one, while a publication belonging to the bottom 90% has a citation score of zero. When this second definition is used, averaging the citation scores of multiple publications yields the $PP_{top\ 10\%}$ indicator, where $PP_{top\ 10\%}$ stands for the proportion of top 10% publications (Waltman et al., 2012; Waltman & Schreiber, 2013). When the full counting bonus is calculated for the set of all publications in a specific field and in a specific year, the second term in the above equation for the full counting bonus will be equal to one in the case of our first definition of the citation score of a publication. This term will be equal to 0.1 (or 10%) in the case of our second definition.

Empirical results

We perform our analysis using the Web of Science (WoS) database. The analysis is based on publications in the period 2009–2010. Only publications of the WoS document types 'article' and 'review' are taken into account. A four-year citation window is used, including the year in which a publication appeared. For the purpose of the calculation of the field-normalized citation scores of publications, fields are defined by the WoS journal subject categories.

We consider three units of analysis: Authors, organizations, and countries. To determine the number of organizations and the number of countries by which a publication has been co-authored, we take into account both the regular addresses of the publication and the reprint address. The number of organizations and the number of countries of a publication is obtained by counting the number of distinct organization names and the number of distinct country names mentioned in the addresses of the publication.

The full counting bonus depends on two factors. On the one hand, it depends on the variation among publications in the number of authors, organizations, or countries. For instance, if all publications have the same number of authors, there can be no full counting bonus at the level of authors. On the other hand, the full counting bonus also depends on the relation between the number of authors, organizations, or countries of a publication and the citation score of the publication. There can for instance be no author-level full counting bonus if publications with different numbers of authors on average all have the same citation score.

Figure 1 presents the distribution of publications based on their number of authors, organizations, and countries. Not surprisingly, the figure shows that the variation among publications in the number of authors is largest while the variation among publications in the number of countries is smallest. Figure 2 presents the relation between the number of authors, organizations, and countries of a publication and the average citation score given by the MNCS indicator. In general, an increasing relation can be observed between the number of

authors, organizations, and countries of a publication and the average citation score. The relation is strongest for countries and weakest for authors. In fact, when the number of authors is between two and five, there is hardly any dependence of the average citation score of a publication on the number of authors. Publications with three or four authors on average even have a slightly lower citation score than publications with two authors. Results for the $PP_{top\ 10\%}$ are not shown, but are similar to the results for the MNCS indicator.

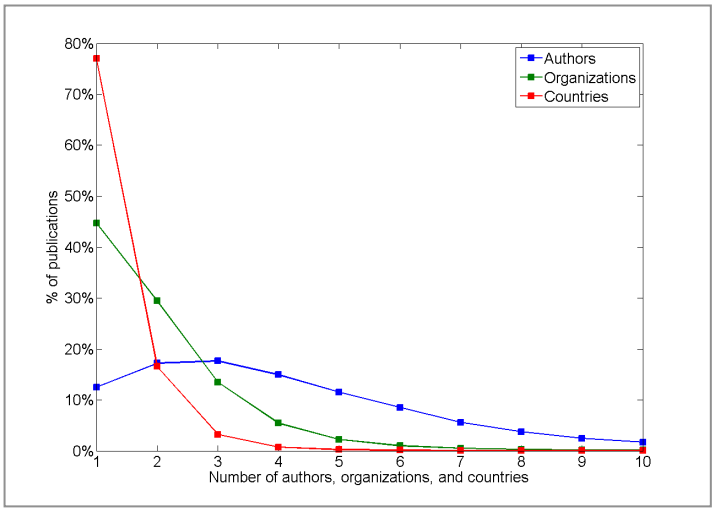

Figure 1. Distribution of publications based on their number of authors, organizations, and countries.

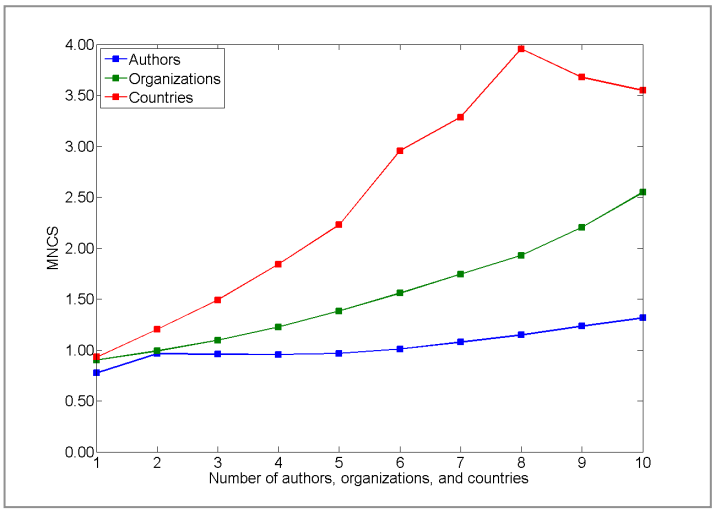

Figure 2. Relation between the number of authors, organizations, and countries of a publication and the MNCS indicator.

Figures 1 and 2 make clear that publications often have multiple co-authors and that the citation impact of a publication tends to increase with the number of co-authors. Co-authored publications are counted multiple times in the case of full counting, and our expectation based on Figures 1 and 2 therefore is to observe full counting bonuses that are positive and of significant size. This is indeed what is reported in Tables 3 and 4. The tables show the full counting bonus at the level of authors, organizations, and countries for five broad fields of science and also for all fields of science taken together. Table 3 relates to the MNCS indicator, while Table 4 relates to the $PP_{top\ 10\%}$ indicator. In order to facilitate comparison between the results obtained for the two indicators, the full counting bonus is presented as a percentage of the average value of the indicator. For instance, in the case of the MNCS

indicator, we obtain a full counting bonus of 0.248 at the level of authors for all fields of science. The average value of the MNCS indicator equals one, and therefore the full counting bonus is reported as 0.248 / 1 = 24.8% in Table 3. Likewise, the $PP_{top\ 10\%}$ indicator has an average value of 0.1 (or 10%), and therefore a full counting bonus of 0.0304 (or 3.04%) is reported as 0.0304 / 0.1 = 30.4% in Table 4.

Table 3. Full counting bonus for the MNCS indicator at the level of authors, organizations, and countries, including a breakdown into five broad fields of science.

	Authors	Organizations	Countries
All fields	24.8%	21.1%	12.6%
Biomedical and health sciences	20.9%	26.8%	16.7%
Life and earth sciences	14.7%	16.2%	12.7%
Mathematics and computer science	8.2%	8.0%	6.9%
Natural sciences and engineering	35.2%	19.3%	10.8%
Social sciences and humanities	14.7%	11.2%	5.6%

Table 4. Full counting bonus for the PPtop 10% indicator at the level of authors, organizations, and countries, including a breakdown into five broad fields of science.

	Authors	Organizations	Countries
All fields	30.4%	26.5%	17.1%
Biomedical and health sciences	24.9%	34.5%	22.6%
Life and earth sciences	22.8%	24.3%	19.7%
Mathematics and computer science	11.3%	11.3%	9.7%
Natural sciences and engineering	43.3%	20.6%	13.0%
Social sciences and humanities	21.3%	17.2%	8.3%

Based on the results for the MNCS indicator presented in Table 3, a number of conclusions can be drawn. At all three analysis levels (i.e., authors, organizations, and countries), there turns out to be a full counting bonus that is positive and of significant size. In general, the bonus is highest at the level of authors and lowest at the level of countries. We have seen in Figure 2 that the number of countries of a publication has a much stronger effect on a publication's citation score than the number of authors, but apparently this is offset by the fact that publications with a large number of countries occur much less frequently than publications with a large number of authors, as shown in Figure 1. The full counting bonus at the level of organizations is generally in between the country-level and author-level bonuses, although there are two main fields (i.e., 'Biomedical and health sciences' and 'Life and earth sciences') in which the organization-level bonus is higher than the author-level one.

The results reported in Table 3 also indicate that at the levels of authors and organizations the full counting bonus is lowest in the 'Mathematics and computer science' main field. At the country level, 'Social sciences and humanities' is the main field with the lowest bonus. The 'Natural sciences and engineering' main field has the highest bonus at the level of authors, while the highest bonus at the organization and country level can be found in the 'Biomedical and health sciences' main field.

The results for the $PP_{top\ 10\%}$ indicator reported in Table 4 are quite similar to the MNCS results presented in Table 3. However, full counting bonuses turn out to be consistently higher for the $PP_{top\ 10\%}$ indicator than for the MNCS indicator.

More detailed results at the level of 250 WoS journal subject categories can be found in an Excel file that is available at www.ludowaltman.nl/counting_methods/. The Excel file also indicates how the five main fields listed in Tables 3 and 4 are defined in terms of the WoS journal subject categories. There turn out to be rather large differences between subject categories in the full counting bonus. For instance, the subject categories with the highest MNCS full counting bonus at the level of organizations and countries are 'Medicine, general

& internal' and 'Physics, nuclear'. The subject categories have bonuses of, respectively, 148% and 176% at the organization level and 89% and 70% at the country level. Other subject categories have bonuses that are close to zero or even negative. Examples of such subject categories include 'Chemistry, organic' and 'Ergonomics'.
It is important to be aware of the consequences of the large differences between subject categories in the full counting bonus. Consider a university that has a full counting MNCS of 2.50 in the 'Medicine, general & internal' subject category and a full counting MNCS of 1.00 in the 'Chemistry, organic' subject category. What should we conclude based on these values? The obvious conclusion may seem to be that in terms of citation impact our university is performing much better in the 'Medicine, general & internal' subject category than in the 'Chemistry, organic' subject category. However, this conclusion does not take into account the effect of the full counting bonus. As mentioned above, the 'Medicine, general & internal' subject category has an organization-level full counting bonus of almost 150%, while the full counting bonus for the 'Chemistry, organic' subject category is close to zero. Taking into account the effect of the full counting bonus, we need to conclude that in both subject categories our university performs around the average level of all organizations worldwide.

Commonly used arguments in favor of full counting

In practice, most bibliometric analyses use full counting instead of fractional counting. Below we list three arguments that are often given to argue against the use of fractional counting and to justify the use of full counting. We also provide a response to each argument.

Argument 1: The different co-authors of a publication usually have not contributed equally. By giving equal weight to each co-author, fractional counting fails to properly represent the contributions made by the different co-authors. Hence, giving equal weight to each co-author is arbitrary and lacks a sound justification.

It is true that there can be large differences between co-authors in the contribution they have made to a publication. At the level of an individual publication, fractional counting may therefore significantly misrepresent the contributions made by individual co-authors. However, at the level of a large set of publications, for instance all publications of an organization or a country, we believe that it is reasonable to assume that the error will be within an acceptable margin. This is because errors at the level of individual publications are likely to cancel out. The contribution of an organization or a country to certain publications may be overestimated, but most probably there will then be other publications for which the contribution of this organization or this country is underestimated.
Furthermore, the argument that giving equal weight to each co-author of a publication is arbitrary may equally well be used as an argument against full counting. Like fractional counting, full counting gives the same weight to each co-author of a publication.

Argument 2: Fractional counting provides an incentive against collaboration, which is often considered undesirable.

We believe that citation impact and collaboration represent different dimensions of scientific performance and that in general these dimensions can best be measured separately from each other. Citation-based indicators should be assessed based on the degree to which they measure citation impact in an accurate way. In this respect, we believe that for many purposes fractional counting performs better than full counting. If in addition to citation impact one also considers collaboration to be a relevant dimension of scientific performance, then additional indicators should be used to measure this dimension. If one desires to do so, these indicators can then be used to provide an incentive to collaboration. By assessing citation-

based indicators based on the effect they may have on collaboration, one fails to make a proper distinction between the citation impact dimension of scientific performance and the collaboration dimension.

Argument 3: Fractional counting is more difficult to understand and less intuitive than full counting.

To a certain degree, we agree with this argument. Fractional counting yields non-integer publication and citation counts. These non-integer counts are more difficult to understand and require more explanation than the integer publication and citation counts provided by full counting. Fractional counting may also be less intuitive than full counting. For instance, consider a researcher who has produced some of his publications on his own while he has produced other publications with one or two co-authors. The researcher may feel that his co-authored publications are of similar importance to his oeuvre as his single-author publications. However, fractional counting gives less weight to the co-authored publications of the researcher than to his single-author publications. This is not in agreement with the feelings the researcher has about the importance of the different publications in his oeuvre, and therefore from the point of view of the researcher fractional counting can be regarded as less intuitive than full counting.

On the other hand, from a different point of view, it can also be argued that fractional counting is actually more intuitive than full counting. Earlier in this paper, we have given two examples showing that field-normalized citation impact indicators calculated using full counting can easily be misinterpreted. Field-normalized indicators calculated using fractional counting are much more easy to interpret in a correct way. As we have explained, this is because indicators based on fractional counting yield results that are compatible with the idea of strong field normalization. Unlike full counting indicators, fractional counting indicators therefore allow comparisons between fields to be performed in an easy and intuitive way. So from this point of view indicators based on fractional counting can be considered more intuitive than their full counting counterparts.

Conclusions

In this paper, we have presented a new perspective on the choice between different counting methods, leading to an important new argument in favor of fractional counting. Building on our earlier work (Waltman et al., 2012), this argument is based on the observation that the problem of choosing an appropriate counting method is closely connected to the problem of field normalization of citation-based indicators.

We have argued that from a field normalization point of view fractional counting is preferable over full counting. As we have shown, properly field-normalized results cannot be obtained using full counting, and field-normalized indicators calculated using full counting can easily be misinterpreted. Fractional counting does provide properly field-normalized results, and these results can be interpreted in a much more straightforward way than results obtained using full counting. Essentially, the problem of full counting is that co-authored publications are counted multiple times, once for each co-author, which creates an unfair advantage to fields with a lot of co-authorship and with a strong correlation between co-authorship and citations. For instance, the average full counting MNCS of all organizations or all countries active in these fields is significantly higher than one. On the other hand, fields in which co-authorship is less common or in which co-authorship does not correlate with citations are disadvantaged. Full counting yields results that are biased against organizations and countries whose activity is focused on these fields. Fractional counting does not suffer from this problem. In the case of fractional counting, each publication is counted only once, regardless

of its number of co-authors, and this ensures that comparisons between fields can be made in an unbiased way.

What are the practical implications of the analysis presented in this paper? In our view, this depends on the level of aggregation at which a bibliometric study is performed. In the case of a study at a high aggregation level, such as the level of countries or organizations (e.g., university rankings), we consider it absolutely essential to use fractional counting instead of full counting. At this level, there is a serious risk of misinterpretation of full counting results. Moreover, we believe that arguments in favor of full counting, such as the ones discussed in the previous section, are of limited relevance at a high aggregation level.

The situation is more difficult at a low level of aggregation, for instance at the level of researchers or research groups. At this level, we believe that reasonable arguments can be given in favor of both full and fractional counting. Especially the third argument discussed in the previous section plays an important role at this level. As pointed out in this argument, full counting is in agreement with the intuitive idea that all publications of a researcher or a research group should be considered of equal importance.

However, there is a more fundamental reason why the argument presented in this paper in favor of fractional counting is less relevant at a low level of aggregation. The argument depends on the connection between counting methods and field normalization, but the entire idea of field normalization may be seen as problematic at a low aggregation level. Field-normalized indicators have a limited accuracy (e.g., Van Eck, Waltman, Van Raan, Klautz, & Peul, 2013), and it is questionable whether these indicators are sufficiently accurate for applications at a low aggregation level. If the accuracy of field-normalized indicators at a low aggregation level is considered insufficient, the argument presented in this paper in favor of fractional counting has no relevance at this level.

In this paper, we have not shown how results obtained using full and fractional counting differ in practice. We refer to our working paper (Waltman & Van Eck, 2015) for an extensive comparison of full and fractional counting in bibliometric studies at the level of institutions and countries. The working paper also considers different variants of fractional counting, and it studies first author and corresponding author counting methods.

Abstract
This paper describes a multidisciplinary study and development effort to analyze full text and metadata of scientific articles and patents for indicators of new disruptive and game-changing technical breakthroughs. The system we are developing can scan millions of documents in two languages, English and Chinese, and extract meaningful trends and predictions. Whereas traditional approaches to innovation analytics rely on citation analysis to analyze impact or identify the most influential patents or researchers in the field, our system takes a step further and combines these methods with an analysis of text in order to identify and characterize emerging technologies. The paper describes the indicators and forecasting models, as well as presents the results of applying these indicators to forecast levels of interest in a particular technology based on the analysis of English and Chinese patents. It further shows how the indicators we developed can provide insights into the nature and the lifecycle of emerging technologies.

Conference Topic
Indicators

Introduction
This paper describes Abductive Reasoning Based on Indicators and Topics of EmeRgence, or ARBITER, an automated system whose purpose is to identify and characterize emerging technologies and emerging fields in science. It does so by processing very large collections of scientific publications and patents in multiple languages and identifies trends, associations, and predictions more rapidly than with current methods. Unlike previous approaches to detecting emergence, which are based on the citation analysis of papers and patents (e.g. Bettencourt et al., 2008; Shiebel et al., 2010; Roche et al., 2010), we are extracting information from the text of publications and patents, identifying authors, their affiliations, addresses, as well as classifying types of organizations and publications. Moreover, we apply natural language processing technologies to extract scientific terminology from the full text of the documents, to identify different types of relationships between citations, authors, terms, and organizations, including contrast, opinion, and related work, and to characterize maturity and other properties of terms based on their contextual patterns. This diverse set of features enables us to efficiently process multiple collections and various types of data without dependency on the presence of a specific feature in a collection. For example, our approach is not hampered by the lack of prior art references in Chinese patents, which is a problem for a standard, citation-based analysis of innovative technologies.

To define indicators of emergent technologies and scientific fields, we have developed a pragmatic theory of technoscientific emergence, described in Brock et al. (2012), which builds on Actant Network Theory (Latour, 2005). An Actant Network is a heterogeneous network of human and non-human elements, including people, institutions, funders, meetings, documents, and scientific terminology, interconnected by disparate relationships. The membership of elements within such a network, and the nature and extent of the relationships

[1] Approved for public release; unlimited distribution.

between these elements, is dynamic and constantly changing. To model emergence, we have developed indicators that measure the character and evolution of Actant Networks, including

- Extent of different types of elements in a network, including prolific and prominent entities
- Number of relationships and the volume of traffic in a network
- Growth of entities and relationships, including average growth rate and slope measures
- Novelty of elements and relationships
- Prevalence of the marketplace actant
- Extent of patenting activities
- Amount of disagreements and uncertainties.

In our previous work, we have shown how these indicators can be applied to characterize communities of practice (Babko-Malaya et al., 2013a), identify the presence of the debate in the community (Babko-Malaya et al., 2013b), as well as determine whether practical applications exist for research fields (Thomas et al., 2013). This paper presents the results of applying these indicators to forecast prominence of technology terms, as measured by a significant increase in term frequency. Whereas ARBITER processes both scientific articles and patents, the results presented in this paper are limited to the analysis of patents.

This paper contains three further sections. First, we give an overview of metadata and full text features, describe different categories of indicators designed to identify emerging technologies, as well as demonstrate how the indicators are combined via Bayesian networks into a forecasting model. The next section presents the results of the correlation analysis of indicators with future term prominence for English and Chinese patents, which measures the ability of our indicators to forecast a significant increase in term usage. The final section outlines how the system can be applied to characterize the nature and the lifecycle of the technology.

System Description

Feature Extraction

ARBITER extracts features from the metadata and full text of scientific papers and patents, including Lexis-Nexis Patent data, which includes granted patents and published patent applications from United States and Chinese national patent offices, and Thomson Reuters Web of ScienceTM (abstracts of journals and conference proceedings for the same time period, ~40M records). The features we extract from these sources include metadata features (such as title, author, author affiliation, patent assignees, etc.), as well as features that are based on the analysis of text. All feature extraction capabilities, including language features, are developed for two languages: English and Chinese. A summary of our features is shown in Figure 1. The entities we extract include people, organizations, documents, and scientific terminology, interconnected by different types of relationships.

To analyze persons, we extract authors from scientific articles and inventors from patents. In order to be able to count unique mentions of researchers, we developed a disambiguation component, which groups them into equivalence classes. Our analysis of researchers builds on features such as researcher impact, including Hirsch index and prolificness (measured by patent/paper productivity), as well as co-authorship and citation graphs.

To identify organizations, we extract author affiliations and patent assignees from metadata, as well as funding organizations from the text of acknowledgements and footnotes of scientific papers. All organizations are classified into three classes: Commercial, Academic, and Government/Nonprofit. The organization classification component allows us to evaluate

the extent and changes in the Academic vs. Commercial involvement in a certain field, as well as the diversity of researchers and organizations.

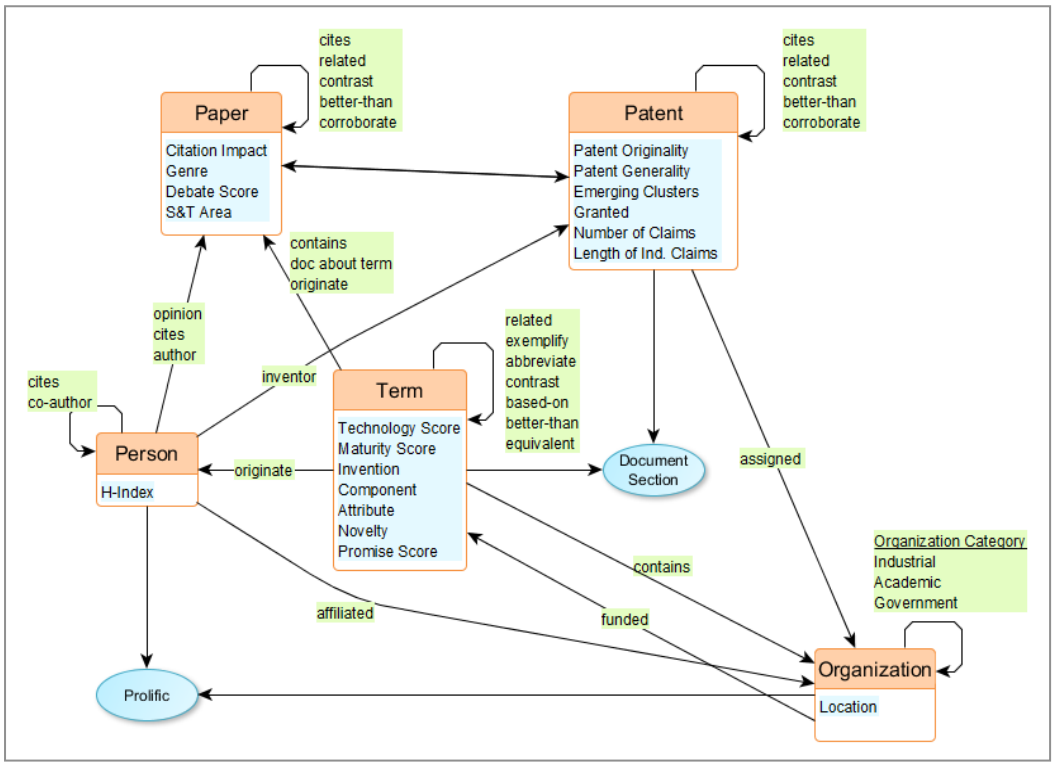

Figure 1. Actant Network extracted from metadata and text.

Our analysis of documents uses citation-based metrics developed by one of our team partners to measure generality, originality, and membership in "emerging clusters" (Breitzman & Thomas, 2015). We further measure mean citation impact of papers and patents, and analyze the structure and length of patent claims.

Our other partners have developed several modules for linguistic processing of text in English and Chinese. For example, to identify scientific terminology, we apply a technology described in Meyers et al. (2010) that extracts scientific noun phrases from the text of papers and patents. The extracted terms are noun phrases that tend to occur frequently in a set of articles from a specific field, but rarely occur in more general or popular articles.

In order to characterize these terms, we score terms based on the extent to which the term behaves like a technology (Anick et al., 2014), as well as assign a maturity score based on how often the term is mentioned in text as being used.

To analyse documents, we apply a genre classifier to evaluate the types of documents that are being published in a certain field, such as review articles or product reviews, as well as to classify documents based on the extent of the debate in the community (Babko-Malaya et al., 2013b). Using the document structure parser, we further identify different sections of documents and categorize claims in patents. To support Chinese extraction, we have adapted a tool to support word segmentation and part of speech tagging to scientific literature and patents (Li & Xue, 2014).

All entities we extract are linked by various types of relations. Whereas some relations are extracted from metadata (e.g. affiliated, invented, assigned, cites, co-author), many relations are extracted from text using information extraction techniques. These relations include opinion relations as well as relations like abbreviate, exemplify, and related work (based on,

better than, contrast, etc), which are described in more detail in Meyers (2013) and Meyers et al. (2014) and are illustrated below.

All entities and relations extracted from full text were evaluated against manually created gold standard corpora. Performance of extraction components is generally comparable across English and Chinese with the f-score above 70-75% in both languages.[2]

Indicators

Using this network, we have developed over 200 indicators that measure different characteristics and changes in the network associated with particular technologies and concepts. The indicators we developed are driven by our pragmatic theory, which defines emergence as the growth in the robustness of actant networks (Brock et al., 2012). The indicators we apply to identify potential disruptive technologies are therefore designed to analyze the relationships between the target entity and other elements in the actant network, including the extent and nature of these relationships, their novelty, dynamic changes, as well as impact, prominence and diversity. Other indicators we explore relate technology emergence to their practicality, as well as the presence of the debate in a community.[3]

Term Momentum Indicators. Our first set of indicators measures momentum in the usage of a particular term. These indicators are time series of annual counts, such as counts of term usage by inventors and organizations, with a further focus on prolific inventors and organizations. In addition, our 'section-based' indicators analyze term usage in independent claims, summary of invention, and abstract sections of patents. The rationale behind an analysis of term usage in specific sections is that these indicators can better measure the extent of the acceptance of the term by the community. For example, if a term occurs in independent claims of patents, it means that it has been legally accepted.

Term Characterization. Beyond indicators based on the momentum associated with individual terms, we also developed indicators that examine different characteristics of these terms. These characteristics include (1) the likelihood that the term describes a technology, (2) the maturity of the technology described by the term, (3) the degree to which the term functions as a description of an invention, and (4) the degree to which a term refers to a component of another technology.

Term characterization scores are calculated by collecting and aggregating evidence from the term's context. For example, to compute maturity scores, we define a set of 'usage' patterns, i.e. patterns that indicate that a term was used or applied: *We used [term] for …, [term] was used for …, employ [term], …* The maturity score is then derived from the number of times these 'usage' patterns are applied to the term. Likewise, the degree to which the term is used as a component is computed based on term usage in 'component'-specific contexts, as illustrated by the sentence *"A typical RFID tag consists of/contains an RFID antenna and RFID chip"*. The terms *RFID antenna* and *RFID chip* are tagged as components in this context, given that they occur as the objects of verbs *consist of* or *contains*. Our expectation is that a time series analysis of maturity of technologies, including their usage as an invention or a component, might be indicative of a change in the lifecycle of a technology, and therefore can be used to identify potentially disruptive technologies (Arthur, 2009).

Semantic Relations. Another class of language-based indicators is based on semantic relations we extract from text. These relations include Opinion, Abbreviate, Exemplify,

[2] Although performance is comparable, there is some variation in the frequency and the type of relations that we extract in the two languages. Some relations are very sparse in Chinese (such as Abbreviations, Contrast, Exemplify (Term1 is an example of Term2). Another difference is that text processing in Chinese is significantly slower than in English due to word segmentation.

[3] The indicators described in this section are focused on the analysis of patents. Similar indicators have also been developed for the analysis of scientific articles, but their analysis is beyond the scope of this paper.

Originate, and different types of Related Work, including Contrast, Based On, and Better Than (Meyers et, 2014). For example, Practical relations represent the author's view that the technology is either being used specially or is useful in some way. Therefore, the indicator that measures the number of Practical relations attached to a term may identify an increase in interest to using a given technology, or its new application. Meanwhile, the relation Abbreviate, which links scientific terms to their abbreviations, can be used to detect the timeline of the acceptance of the term by the community. Finally, relations like Contrast may help to identify the early stages of technology development, given that scientists developing innovative concepts tend to contrast their work with existing research, whereas as the technology becomes more accepted, the number of contrast relations declines.

Document and Inventor Characteristic indicators. This class of indicators measures characteristics of the papers or patents that are using the term. Some of these indicators measure citations to papers containing a given term, or the impact factor of the journals in which the term appears. Others compute dispersion of term usage across technologies or countries, or the number of prior art references in patents.

Inventor Characteristic indicators. In addition to characteristics of documents, we also analyse the inventors and patent assignees who use the term in patents. Examples include the Hirsch index of an inventor or the impact of prior patents granted to inventors or patent assignees.

Novelty. Term Novelty indicators measure the first appearance of a term anywhere in a patent document, as well as the first appearance of a term in specific sections of a patent, such as in the independent claims. Another Novelty indicator computes the first time a term appears with an abbreviation attached. These indicators are thus designed to analyse the timeline of the acceptance of the term by the community.

Most of the indicators described above are time series of annual counts or scores, such as a "number of prominent inventors per year using term in patents." To simplify the modelling process, we reduced each time series to a single value by applying three different methods:

(1) Find the slope of the regression line of indicator values against time (a measure of how fast the indicator is increasing over time);

(2) Calculate the average growth rate for the indicator value over the period selected for the time series;

(3) Compute the sum of indicator values for three years prior to the reference period.

We also experimented with (a) the x2 coefficient of the best-fitting, second-order polynomial for indicator value as a function of year (a measure of curvature, or rate of acceleration), and (b) the two-year prediction of this best-fitting polynomial. These indicators, while sometimes informative, were usually redundant with slope.

Forecasting Models

Our models are tree-augmented Naive Bayes networks (Friedman et al., 1997). Such networks have a structure like that of the network shown in Figure 2. For clarity, we display only a fragment of the model; a complete model may contain 30 to 50 indicator variables.

Bayesian networks provide a factorized representation of a joint probability distribution over a set of variables, and efficiently update the distribution, given evidence in the form of values for variables. In our models, there is a unique root node that represents the unobserved future prominence of an entity. In the above model, this is the node labeled "Prominence3." Prominence is normalized to be between 0 and 1, with a special value of -1 for cases in which the usage of the term decreases. As evidence is entered into the net, the probability distribution over the possible values of prominence is updated.

Bayesian Networks have shown good performance as classifiers (Friedman et al., 1997). We use a version of a Bayesian classifier in which links between indicator variables capture

synergistic effects among those variables – i.e. information about two or more variables tells us more about prominence than the sum of the information value of the individual variables. Capturing synergistic effects has been shown to improve classifier performance (Friedman et al., 1997).

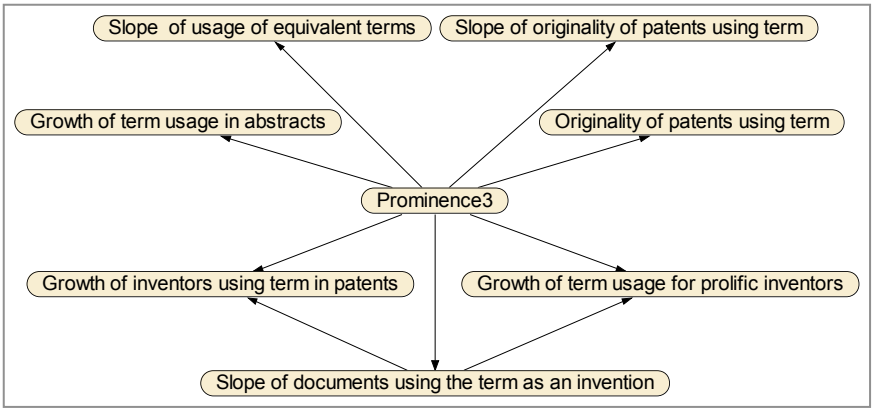

Figure 2. Fragment of model for predicting term prominence.

We chose to use Bayesian networks for several reasons. First, we executed a performance comparison between Bayesian networks (looking at common confusion matrix measurements such as the true and false positive rate, F1 score, etc.) and other classifiers such as JRip, J48, SVM, and meta-classifiers wrapping these, including Bagging and AdaBoostM1. Second, we chose Bayesian networks due to their flexibility and ease of interpretation. Finally, Bayesian networks provide insight into the contribution of indicator variables by supporting the computation of information-theoretic quantities such as mutual information and conditional mutual information.

We use a fine-grained discretization of prominence values instead of a binary prominent/not-prominent variable. This allows more precise computation of information-theoretic relations between indicator variables and prominence than does a binary variable. For example, some variables may be good at predicting very high prominence, while others merely discriminate prominent from non-prominent entities.

Although the prominence variable has a fine-grained discretization, it can be used as a binary classifier by choosing a threshold for prominence. The threshold is chosen through the multi-objective optimization process, described below.

Model Generation and Optimization

Automated model generation must answer the following questions in order to create the desired Bayes net:

- Which indicator variables should be included?
- Which indicator variables should be linked?
- How should continuous variables be discretized?
- How much weight should the training algorithm give to the training data relative to the untrained prior distribution so as to avoid over fitting?
- What threshold for predicting prominence provides the best trade off between recall, precision, and other performance goals?

All of these questions are answered by an optimization loop. This optimization loop uses a multi-objective elitist genetic algorithm (NSGA-II) to search the model parameter space (i.e. answers to the above questions) and rewards solutions that score well relative to specified recall and precision goals. The optimizer uses stratified 10-fold cross validation to compute metrics (e.g. recall and precision) for various combinations of system and ground truth

prominence thresholds. This process leverages the recall ↔ precision trade-off parameter. Finally, the optimizer promotes and further explores solutions that perform relatively well via: (1) uniform crossover, (2) Gaussian mutation for continuous variables, and (3) random flip mutation for discrete variables. The end result is an answer to the above questions that is optimized to the specified objectives.

Indicator Analysis

The analysis described below measures how well the indicators and models can forecast future term prominence, where a term is considered prominent if it has achieved a significant increase in usage.[4] To perform this analysis, we computed indicator values and generated models by processing all documents up to a given year (called the reference period), and then compared system outputs against a ground truth variable measuring an increase in term usage three years after the reference period. This analysis measures the ability of our models to forecast a significant increase in term frequency three years into the future.

By using automated model generation process described above, we generated domain-specific models for different technology areas in English and Chinese patents, including Computer Science, Communications, Biotechnology, and Semiconductors. The performance was higher for Chinese than for English, with the average recall of 0.49 and 0.52 for English patents and recall of 0.47 and precision of 0.61 for Chinese patents. The higher precision for Chinese patents is most likely due to Chinese patents containing a higher percentage of prominent terms than English patents.

To analyze individual indicators, we computed rank correlations between indicators and term prominence. Table 1 illustrates the performance of our indicators for English patents for the domain of Computer Science using Spearman's rank correlation coefficient (Rho) and three approaches to summarizing time series: slope, growth, and sum. For example, in Table 1, Rho slope for the indicator "Number of organizations per year using term in patents" shows the rank correlation for the indicator "the slope of the regression line fitted to the number of organizations using a selected term each year leading up to the reference period."

Table 1 reveals that indicators are significantly correlated with prominence for at least one computation (slope, growth, or sum), with the exception of one — the number of significant opinion relations. This is not unexpected, since opinion relations rarely occur in patents.[5] It also shows that term momentum indicators have the strongest rank correlations with prominence, i.e. measuring past momentum is particularly useful for predicting future prominence. Given that the other classes of indicators are conceptually very different from term momentum indicators, we expect that their effect on the forecasting model is additive to the momentum indicators, rather than duplicative. To test this hypothesis, we computed the partial correlations of non-momentum indicators with prominence, after the most basic term momentum has been accounted for (prior term usage in patents).

[4] One of the limitations of our system is that our analysis applies to individual terms, rather than sets of terms that are representative of technologies or research areas. This limitation is due to the problem of generation of ground truth data for training of our statistical models. In the future, we plan to extend this approach to analyse clusters of related terms, which are representative of technologies and scientific fields.

[5] Our analysis of scientific articles has shown that opinion-type relations (such as positive, standard, and negative opinion) are very infrequent in scientific literature as well, which suggests that opinion-based indicators are not particularly useful for the analysis of scientific literature and patents.

Table 1. Spearman rank correlations with future increase in term usage in English patents.

	Time Series indicators	Rho-Slope	Rho-Growth	Rho-Sum
Term Momentum Indicators	Number of unique organizations per year using term in patents	0.48	0.26	0.47
	Number of prolific organizations per year using term in patents	0.47	0.25	0.46
	Number of unique inventors per year using term in patents	0.50	0.13	0.47
	Number of prolific patenting inventors per year using term in patents	0.45	0.30	0.50
	Number of times per year term is used in patents	0.50	0.26	0.47
	Number of times per year equivalent terms are used in patents	0.48	0.25	0.45
	Number of times per year term is used in summary of invention section	0.52	0.26	0.51
	Number of times per year term is used in Independent claims	0.46	0.38	0.51
	Number of times per year term is used in Abstract section	0.47	0.33	0.52
	Number of industrial assignees using term per year	0.49	0.19	0.46
	Number of academic patent assignees using term per year	0.21	0.26	0.30
Term Characteristics	Annual technology score	N/S	N/S	0.19
	Annual maturity score	0.11	0.13	0.33
	Term usage as an invention	0.12	0.18	0.19
	Term usage as a component	0.23	0.25	0.27
Semantic relations	Annual counts of Exemplify relations	0.33	0.35	0.37
	Annual counts of Practical relations	0.33	0.33	0.37
	Annual counts of Opinion Significant relations	N/S	N/S	N/S
	Term usage with an abbreviation	0.19	0.23	0.24
	Annual counts of Contrast relations	0.20	0.26	0.26
	Annual counts of Based on relations	0.23	0.18	0.24
	Annual counts of Better than relations	0.17	0.13	0.18
Document Characteristic	Originality of patents using the term	N/S	N/S	0.19
	Average citation impact of documents about the term	N/S	N/S	0.31
	Term frequency in an emerging cluster	0.18	0.12	0.42
	Number of prior art references	0.02	-0.12	0.22
	Citations to high impact patents	N/S	N/S	0.31
	Dispersion of term usage across technologies	0.12	N/S	0.46
Inventor Char.	Number of patent inventors using the term as invention	0.12	0.17	0.19
	Hirsch index of the inventor	N/S	N/S	0.19
	Citation impact of prior patents granted to inventor(s)	N/S	N/S	0.29

Table 2 lists the indicators in the descending order of their partial correlations with prominence. An interesting finding is that the indicators that provide information over and above term momentum indicators include the ones that are based on language features, such as Practical and Exemplify relations, as well as term characterization. The indicators that have low or even negative correlations include document- and inventor-based indicators, such as the Hirsch index of the inventor, or the average citation index of document using the term. Having said that, it is important to note that document and inventor indicators are consistently selected by our forecasting models, which indicates that they are not really replaceable by other indicators.

Table 2. Partial correlation of indicators with prominence, controlling for momentum indicator.

Indicator	Partial Correlations
Annual counts of Practical relations	0.199
Term usage as an invention	0.170
Annual counts of Exemplify relations	0.169
Term usage as a component	0.159
Citations to high-impact patents	0.149
Annual maturity score	0.134
Annual technology score	0.129
Annual counts of Based_on relations	0.120
Annual counts of Contrast relations	0.114
Originality of patents using the term	0.101
Term usage with an abbreviation	0.098
Annual counts of Better_than relations	0.080
Citation impact of prior patents granted to inventor(s)	0.019
Average citation impact of documents about the term	-0.023
Number of prior art references	-0.042
Term frequency in an emerging cluster	-0.057
Hirsch index of the inventor	-0.074

Comparing indicators with different rationale, such as practicality versus discursive interest, one interesting finding is that the indicators focusing on the practicality of a field have the strongest correlations with prominence. These indicators include maturity scoring, usage as a component, Practical relations, and term usage by industrial patent assignees. Indicators focused on discursive interest in the term, such as Contrast relations, Better Than relations, and term usage by academic researchers in the field, have weaker (although still significant) correlations with prominence (as shown in Table 1 above). This suggests that, while both practicality and discursive interest are useful characteristics for the analysis of patents, the former is of particular value in forecasting the future prominence of terms.

Our further analysis of indicators focused on trying to identify indicators with complementary strengths. For example, we discovered that many of our indicators are good at predicting whether term usage will increase or decline/remain stable, but there are only a few indicators that are good at predicting different degrees of positive changes in term usage. This is illustrated by Table 3, which shows rank correlations between indicators and future changes in term usage coded as positive versus non-positive (Rho+/), as well as rank correlations considering positive values only (Rho-Pos).

As Table 3 shows, the correlations for the classification problem (Rho+/-) are generally higher, which suggests that it is more straightforward for an indicator to forecast whether or not a term will have a positive prominence, versus forecasting different degrees of positive prominence. It also reveals that some indicators might have particular strengths. For example, while momentum indicators and some document characteristic indicators perform best for delineating between positive and non-positive cases, the best indicator for distinguishing between different levels of positive prominence is “the proportion of granted patents using term relative to published documents”.

Table 3. Spearman correlations for indicators based on different conditions.

	Time Series indicators	Rho+/-	Rho-Pos
Term Momentum Indicators	Number of unique organizations per year using term in patents - Slope	0.50	0.21
	Number of prolific patenting organizations per year using term in patents - Slope	0.49	0.19
	Number of unique inventors per year using term in patents - Slope	0.52	0.22
	Number of prolific patenting inventors per year using term in patents - Slope	0.52	0.22
	Number of times per year term is used in patents - Slope	0.53	0.22
	Number of times per year equivalent terms are used in patents - Slope	0.51	0.20
	Number of times per year term is used in summary of invention section - Sum	0.54	0.24
	Number of times per year term is used in Independent claims section - Sum	0.53	0.25
	Number of times per year term is used in Abstract section - Sum	0.55	0.26
	Number of industrial assignees using term per year - Slope	0.51	0.21
	Number of academic patent assignees using term per year - Sum	0.33	0.09
Term Character ization	Annual technology score - Sum	0.21	0.05
	Annual maturity score - Sum	0.33	0.14
	Term usage as an invention - Sum	0.17	0.12
	Term usage as a component - Sum	0.27	0.13
Semantic relations	Annual counts of Exemplify relations - Sum	0.36	0.19
	Annual counts of Practical relations - Sum	0.37	0.18
	Term usage with an abbreviation - Sum	0.22	0.15
	Annual counts of Contrast relations - Sum	0.24	0.15
	Annual counts of Based_on relations - Sum	0.21	0.15
	Annual counts of Better_than relations - Sum	0.14	0.14
Document Characteristic	Originality of patents using the term - Sum	0.21	0.07
	Average citation impact of documents about the term- Sum	0.30	0.03
	Term frequency in an emerging cluster - Sum	0.46	0.15
	Number of prior art references - Sum	0.27	0.05
	Citations to high-impact patents - Sum	0.33	0.16
	Dispersion of term usage across technologies - Sum	0.50	0.18
Inv- entor Char.	Number of patent inventors using term as invention-Sum	0.18	0.10
	Hirsch index of the inventor - Sum	0.30	-0.02
	Citation impact of prior patents granted to inventor(s) - Sum	0.36	0.07
Single value	Proportion of granted documents using term relative to published documents	0.39	0.29
	The year the term first appeared in a patent	-0.15	0.01
	The year the term first appeared with an abbreviation	0.25	0.17

We further evaluated performance of indicators across one-, two- and three-year gap periods and observed a significant difference. All indicators tend to perform better in predicting longer forecasts (such as three-year gap) than shorter periods (such as one- or two-year gap). This may be because a three-year forecast smoothed out some of the year-by-year volatility in term usage.

Table 4. Spearman correlations for term prominence indicators in Chinese patents.

Time Series indicators	Rho-Slope	Rho-Growth	Rho-Sum
Number of unique inventors per year using term in patents	0.50	N/S	0.46
Number of prolific patenting inventors per year using term in patents	0.50	N/S	0.46
Number of times per year term is used in patents	0.50	0.06	0.46
Number of times per year term is used in Independent claims section	0.50	0.16	0.44
Number of unique organizations per year using term in patents	0.48	N/S	0.43
Number of prolific patenting organizations per year using term	0.48	N/S	0.44
Number of times term is used in summary of invention section	0.18	N/S	0.11
Annual maturity score	0.08	0.08	0.28

Finally, Table 4 shows correlation analysis for some of the indicators that were applied to Chinese Computer Science patents. It is important to note that citations rarely occur in Chinese patents, so indicators that are based on citation metrics cannot be used for the analysis of term prominence in Chinese. A comparison of correlations for English and Chinese (Tables 1 and 4) reveals that the general patterns across two collections are very similar, with Slope and Sum term momentum indicators performing particularly well, along with the Sum version of the Maturity Score.

Future Plans: Term Characterization

In addition to predicting future levels of interest to a technology, we expect that the indicators we developed can also provide some insights into the nature of the technology, its lifecycle, and other term characteristics. An example of this type of analysis is illustrated by 10 computer science terms, shown in Table 5.

Table 5. An analysis of 10 computer science terms.

Term	Pe	Term Characterization Analysis
RFID antenna	0.60	a device, becoming widely used in diff applications in 2007
Instant messaging	0.47	a technology or method, innovative, not a component
Robotics	0.31	a branch of technology, not a specific device, mature
XML	0.31	technology name, active area of research
Speech recognition	0.31	widely accepted technology, but best practice is being debated
Cellular telephone	0.31	a widely used standalone device, still of interest
RDF	0.31	technology name, becoming more widely used
Linux operating system	0.31	a widely accepted mature technology
GPS	0.30	a technology, widely used, mature, active area of research
Quantum computing	0	a principle or concept, innovative, no practical applications

The Pe column shows our predictions for the future changes in term usage, as described above, where zero value indicates that term usage will remain stable or decline in the future, whereas positive values predict that there will be an increased community interest in the term. The terms were analysed using 2007 as the reference period, forecasting term usage in 2010. The most interesting terms in this list include *RFID antenna* and *instant messaging*, the other terms, except for *quantum computing*, have slightly lower positive Pe values, indicating that there will be some growth in their usage between 2007 and 2010. The fact that quantum computing has zero value is not unexpected, considering that the data processed for this analysis included patent literature only, and this term has rarely been used in patents until 2007.

In addition to identifying terms with high prominence, we expect that the indicators described in the paper can also be used to characterize technologies, as illustrated in Table 5. For example, by using individual indicators or groups of indicators, we can potentially identify

widely accepted and mature technologies, terms that function as components of other technologies, active areas of research, as well as areas where best practice is being debated.

For example, Figure 3 reveals the values for the indicator that computes the average growth rate of term usage by academic institutions. This indicator can be used to identify innovative technologies that attract a growing attention from academia. Out of the 10 terms, technologies with the highest growth of academic assignees include *RFID antenna, instant messaging*, and *RDF*.

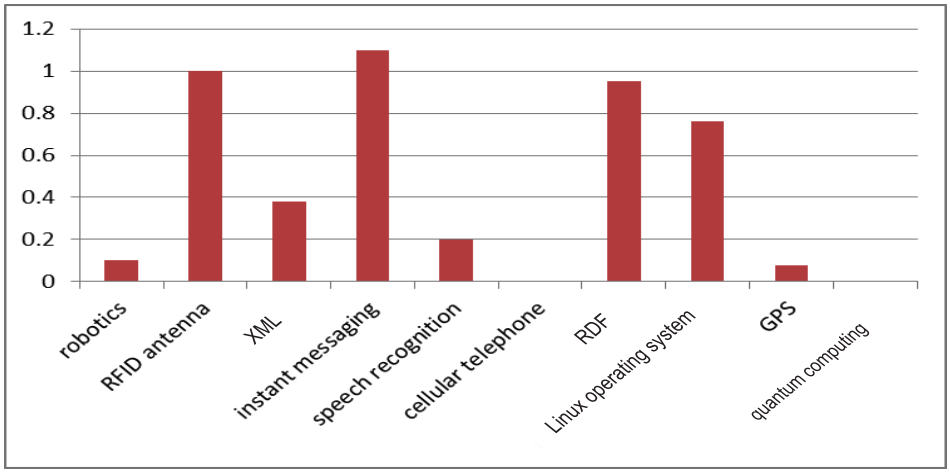

Figure 3. The average growth rate of academic assignees using term from 2002 to 2007.

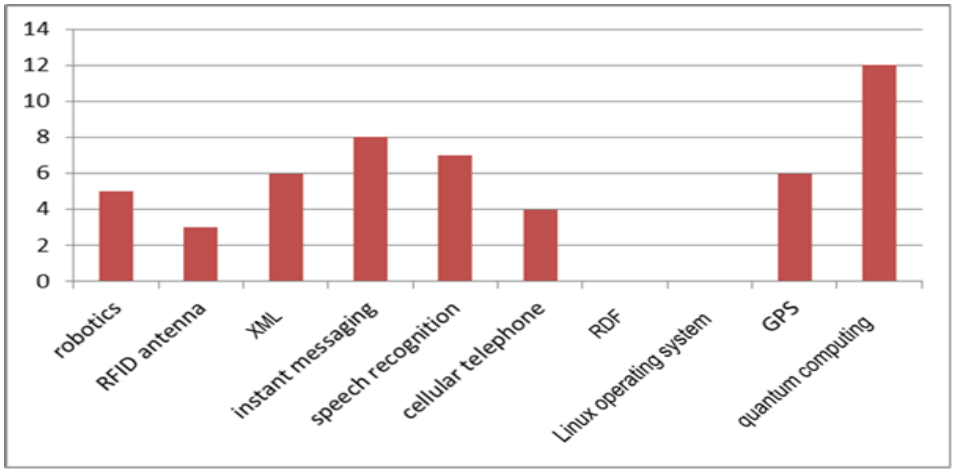

Figure 4. The number of inventors using term as an invention from 2005 to 2007.

Figure 4, on the other hand, illustrates the indicator values for "the number of inventors that were using the term as a description of an invention". Interestingly, the term that has the highest indicator value in this case is *quantum computing*. The terms with the higher values in Figure 3, *RDF and RFID antenna* have the lowest indicator values in Figure 4. This example suggests that individual indicators or groups of indicators may be used to detect different types of emerging technologies and that these differences might be related to their nature or lifecycle. It further illustrates that individual indicators can help to identify newer terms like *quantum computing*, and that high values of specific indicators may be indicative of the future potential of the term.

Conclusion

The system presented is capable of scanning millions of technical documents, extracting key indicators from both text and metadata, and forecasting meaningful trends and predictions from the extracted metrics. In particular, the extracted indicators are useful in predicting levels of interest in particular technologies. We also showed how the indicators provide insight into the nature and the lifecycle of emerging technologies, including their maturity, practicality, stages of development, and acceptance by the community.

Abstract
Many existing metrics to evaluate scholars consider their scientific impact without considering the importance of breadth of research. In this paper, we define a new metric for breadth of research based on the generalized Stirling metric that considers multiple aspects of breadth of research. We extract research topics in computer science using concept extraction and clustering from the literature in the ACM dataset. We then assign authors a distribution over these research topics, from which we calculate scores of breadth of research for each author. We design five simulation experiments that evaluate the ability of a metric to measure breadth of research and use these experiments to compare our new metric to traditional metrics. The results show how these metrics perform in different experiments, concluding that no metric consistently outperforms the others. We test the relationship between our new metric and scientific impact and find a weak correlation between them. Finally, we find that the variation of the metric over time illustrates a possible publication pattern for scholars.

Conference Topic
Indicators

Introduction
An increasing number of scholars are engaged in interdisciplinary research (Porter, Cohen, David Roessner, & Perreault, 2007; Wagner et al., 2011). Some of this is due to the emergence of new scholarly "disciplines" that are inherently multi-disciplinary such as information science, while some arises from scientific problems such as climate change that require expertise from multiple fields. Meanwhile, scholarly impact and influence continues, by and large, to be measured by indices that ignore breadth of research and may even penalize scholars who diversify their research portfolio. For example, H-index, which is used extensively to measure scholarly impact, and which has been criticized for its limited focus (Weingart, 2005), may be unfair when comparing scholars with different degrees of breadth of research. Ultimately, a metric or a set of metrics is needed that accounts for breadth of research, so that breadth of research can be measured and be included in an evaluation system of scholars' scientific influence.

In this paper we describe research that explores the area of scholarly impact metrics and breadth of research. The contributions of our work are as follows. We design a new metric to measure scholars' breadth of research that builds on traditional metrics. We develop a multi-stage method for extracting topics from a corpus (in our case computer science papers) and calculate the scores of breadth of research for authors who have published papers in computer science conferences. We design five simulation experiments that compare the relative performance of existing metrics and our new metric for measuring breadth of research. We measure the relationship of breadth of research and H-index for scholars who are authors in our corpus. Finally, we explore the variation of breadth of research for scholars over time to observe their paper publication behavior over their careers.

The structure of this paper is as follows. The next section describes related work in the areas relevant to our work. Following that, we report on the dataset we used in our research. We

then describe our process of dictionary extraction, topic extraction, paper assignment and author assignment to topics. In the subsequent section we illustrate our new metric and compare it to traditional metrics. The penultimate section describes simulation experiments to show the performance of the new metric, the relationship between the new metric and metrics of research impact, and the variation over time of breadth of research for scholars. Our conclusions and possible future work are listed in the final section.

Related Work

There is a variety of existing literature relevant to the area of breadth of research. The areas covered by this literature include topic extraction, topic relationship extraction, metrics design and the relationship between different aspects of research evaluation systems.

There are many methods to associate topics to publication. The simplest one is to use the classification codes in a dataset, such as ISI subject categories in Web of Science, as the set of topics. But these categories are too coarse-grained and hide intra-disciplinary variability. Another method is to use unsupervised learning algorithms to extract some topics according to the content of papers or the citation network of papers. Topic modelling (Blei, Ng, & Jordan, 2003) is one of the popular unsupervised learning algorithms based on content of papers. This model has been used to identify the disciplines that comprise interdisciplinary work funded by NSF (Nichols, 2014). The ACT model (author-conference-topic) (Li et al., 2010) is an adaptation of Blei's model. Another approach is to use community detection in networks as a basis for finding topics. One example is the use of two-round clustering (Rosvall & Bergstrom, 2008) over the citation network to extract topic-associated communities (Velden & Lagoze, 2013). Another method using both the citation network and the word distribution of abstracts (Jo, Hopcroft, & Lagoze, 2011) finds temporally-ordered topics from a corpus of scientific literature, such as the ACM dataset.

Understanding the relationship between topics is also an important step after topic extraction, because the calculation of the similarity of topics is necessary for understanding the breadth of research. Some researchers have extracted the relationships and used information visualization techniques to represent the relationship between different topics. For example, Yan (2013) detects the path between different disciplines to find the evolution of some areas. Another paper describes a new method to find the diversity subgraph in a multidisciplinary scientific collaboration network (He, Ding, Tang, Reguramalingam, & Bollen, 2013). An interesting visualization method leverages the circle of science to visualize the relationship between disciplines in one dimension (Boyack & Klavans, 2009).

Many metrics have been designed to measure factors related to scientific influence. The most common metrics are impact factor and H-index, which measure the number of citations of scholars' papers. Although these metrics have many problems such as lack of universality between different disciplines (Kaur, Radicchi, & Menczer, 2013), they are still widely used in systems like Google Scholar. Some alternative metrics also use the number of citations to measure the scientific influence of scholars (Ruscio, Seaman, D'Oriano, Stremlo, & Mahalchik, 2012). They offer advantages over simple metrics such as H-index, but they also focus solely on the citation count of papers. Other metrics based on the centrality of scholars in a network (e.g., co-authorship) like PageRank and betweeness centrality (Bollen, Van de Sompel, Hagberg, & Chute, 2009) are also widely used. However, the correspondence of centrality to actual influence is unknown.

As mentioned earlier, commonly used metrics of scholarly influence fail to consider breadth of scholars' research. In response a number of researchers have created some metrics for the degree of interdisplinarity and more generally breadth of research. The report of quantitative metrics and context in interdisciplinary scientific research (Wagner et al., 2011) is a good survey for metrics for interdisciplinarity. Specialization and integration (Porter et al., 2007)

are good metrics of interdisciplinarity because they consider similarity between disciplines when measuring interdisciplinarity. They can be modified easily in the context of a diversity of research topics. Some papers discuss different dimensions of interdisplinarity (Rafols & Meyer, 2010; Rafols, Leydesdorff, O'Hare, Nightingale, & Stirling, 2012): diversity, coherence and intermediation. They define diversity as a combination of variety, balance and disparity. Coherence means link strength between different disciplines. Intermediation is based on the network structure and is measured by betweenness centrality, clustering coefficient and average similarity. Other papers describe metrics based on these dimensions. Cassi, Mescheba, and de Turckheim (2014) divides the Stirling metric into "within component" and "between component" to measure the diversity of articles. Jensen & Lutkouskaya (2013) defines six indicators based on the dimensions and measure the breadth of research at two levels (article and laboratory). Karlovčec and Mladenić (2014) defines a new diversity metric based on Generalized Stirling. The metric incorporates connectedness of the citation graph into the original metric and applies it in exploratory analysis of the research community in Slovenia. Roessner, Porter, Nersessian, and Carley (2012) validates the interdisciplinarity metrics with ethnographic materials (field observations and unstructured interviews).

Finally, some research has focused on the relationship between breadth of research and other factors considered in scientometrics (not just scientific influence). One interesting paper finds that the papers with an average degree of interdisciplinarity will get higher impact than papers with too high or too low degree of interdisciplinarity (Sternitzke & Bergmann, 2008). The results are convincing but metrics used in this paper are quite simple (Jaccard similarity and cosine similarity). Two papers find that interdisciplinary papers have potentially lower impact than more focused papers. One of them finds that multidisciplinary papers are not frequently cited in contrast to the disciplinary papers (Levitt & Thelwall, 2008). The other explains how high-ranked journals suppress interdisciplinary research (I Rafols & Meyer, 2010). Other papers describe some factors that can encourage researchers to be involved in interdisciplinary research work (Carayol & Thi, 2005; van Rijnsoever & Hessels, 2011). They provide some theories to explain why scholars choose interdisciplinary projects. Some findings support that there are no correlations between citation ranks and ranked interdisciplinarity indices (Ponomarev, Lawton, Williams, & Schnell, 2014). In contrast, other researchers confirm that the degree of interdisciplinarity is strongly correlated with the impact factor (Silva, Rodrigues, Oliveira, & da F. Costa, 2013).

Dataset

We extract abstracts, full text and other metadata from the ACM digital library for proceedings of major conferences in computer science. From these proceedings we select authors whose names are unambiguous and who have published at least five papers. The standard for unambiguity is whether using the full name as the query sent to Google Scholar returns only one researcher profile with the same name. We extract the citation numbers and H-indexes by crawling over Google Scholar. Overall we crawled H-indexes and citation numbers for 8911 authors from Google Scholar in August 2014. We also used the Wikipedia dataset to extract important terms in computer science.

Topic Extraction and Assignment

Both traditional metrics and the new metric designed in this paper require a distribution over different topics or areas for authors. In order to generate topic distributions, we leverage the text data in the papers of ACM digital library and implement three steps to form distributions: dictionary extraction, topic extraction and author assignment.

Dictionary Extraction

How to define topics is the first problem to be solved in the topic extraction and assignment. In our work, we extract a dictionary of n-grams in computer science and cluster them into topics using the Affinity Propagation algorithm (Frey & Dueck, 2007). Three different sources of dictionaries are used in this paper: grams that are frequently used in papers, grams that can be matched to their abbreviations in the papers, and entries in Wikipedia.

Dictionary extraction follows these steps:

1. Extract bigrams and trigrams that occur frequently in papers using a threshold of more than 10 times for bigrams and more than 5 times for trigrams. The threshold helps to eliminate noisy grams with low frequency.
2. Extract grams from papers that conform to the pattern "n-grams (abbreviation)", e.g. machine learning (ML).
3. Intersect the results of step 1 and step 2 (3816 terms in total).
4. Build a network of entries in Wikipedia according to hyperlinks between them in the website.
5. Make use of grams in step 3 and search their neighbours in the network of Wikipedia terms. If their neighbours also occur frequently in papers (with frequency higher than the thresholds mentioned above), add the terms into the final dictionary (6100 terms)

The top 5 bigrams and top 5 trigrams in the final dictionary are shown in Table 1:

Table 1. Grams with top frequency

Grams	*Frequency*
User Interface	2372
Software development	2102
Programming language	2042
Software engineering	1988
Operating system	1761
Wireless sensor network	586
World wide web	467
Graphical user interface	305
Support vector machine	300
Discrete event simulation	287

Topic Extraction and Assignment

After extracting the dictionary, we count the co-occurrence measure for every pair of terms. We then calculate the similarity between different terms by:

$$Sim_{ij} = \log \frac{Cooccur_{ij} + 1}{Max(Cooccur_{ij}) + 2}$$

The logarithm calculation makes the distribution of similarity more uniform and avoids the influence of outliers of co-occurrence numbers. We weight co-occurrences of terms in abstracts of papers more than those in full text based on the intuition that abstracts generally have a stronger “topic signal”. Using the computed similarity matrix of terms, we then run Affinity Propagation to cluster together similar terms and choose an exemplar for every cluster. The benefits of Affinity Propagation are that there isn’t a need to parameterize the number of clusters and that the exemplars for every cluster provide a straightforward explanation of what these clusters are about. More than two hundred clusters, or topics, are generated. Here are two examples of the clustering results:

Exemplar: digital library

Terms:
citation analysis, citation index, community building, digital earth, digital library, digital library software, digital preservation, digital reference, discourse analysis, dublin core.
Exemplar: machine learning
Terms:
active learning, adaptive control, bayes classifier, belief propagation, clinical trial, computational learning theory , concept learning, conditional random field.
We then assign every paper a probabilistic assignment to the different topics according to their respective frequency of n-grams associated with the particular topic. Therefore, every paper will have a distribution over topics.

Author Assignment

Using the clusters of grams in computer science and the topic distributions for every paper, we assign authors into different topics according to their papers. Every author is represented by a distribution over topics, which are used to calculate scores of metrics. There does not exist a "gold standard" list of researchers that ranks breadth of research that we can use to evaluate how reasonable our topic assignments are. We list below some topic distributions for well-known computer scientists to demonstrate our assignment.

John Koza	
1 genetic programming	0.567
2 programming language	0.083
3 knowledge base	0.063
Peter Denning	
1 memory management	0.107
2 computer systems	0.093
3 information systems	0.050
Eric Horvitz	
1 user interface	0.082
2 information retrieval	0.067
3 machine learning	0.051
4 speech recognition	0.047

Breadth of Research Measurement

With the author distribution of topics established, the key question is how to translate this into a measure of breadth of research for authors. As mentioned in the section describing related work, many metrics have been used to measure the "degree of interdisciplinarity". Compared to previous metrics to measure breadth of research, we design a new metric that considers the topic distribution, similarity distribution and coherence within research topics.

Summary of Old Measurements

There are many measurements of diversity or interdisciplinary, like entropy (Weaver, 1949), Simpson's index (Simpsons, 1949) and generalized Stirling (Stirling, 2007). Each of these is computed as follows. Denote p_i as the probability of topic distribution for an author over topic i, d_{ij} as the distance between topic i and topic j.

$$Entropy = \sum_{i=1}^{n} -p_i \times \log_n (p_i)$$

$$Simpson = 1 - \sum_{i=1}^{n} {p_i}^2$$

$$Generalized\ Stirling = \sum_{i,j} d_{ij}^{\alpha}\ (p_i \times p_j)^{\beta}$$

Comparing them, only generalized Stirling considers not only the distribution of topics but also the similarity between topics. The further the distance between topics in which an author publishes papers, the more diverse will the author's research interest be. However, the traditional metrics do not consider the notion of differing *coherence* between different research topics. And the degrees of influence of topics with small proportions are very limited. The new measurement is a modified version of the generalized Stirling metric and it incorporates the coherence of topics and value of *minor topics* (topics with small proportions).

New Measurement

The new metric for breadth of research is defined as follows.

Denote d_{ij} as the distance between two topics, which are defined as the average distance (inverse of similarity defined above) between terms in the two topics, p_i as the probability of an author's paper belong to topic i, coh_i as the *coherence* of topic i. Coherence of each topic is the proportion of authors for whom the respective topic is their major research topic, which is an important signal to illustrate whether a research topic concentrate on some core research questions. Parameters α, β, γ are used to control the relative weights of different components.

$$Breadth\ of\ Research = \sum_{i,j} d_{ij}^{\alpha}\ (p_i + p_j)^{\beta} (Coh_i \times Coh_j)^{\gamma}$$

We modify the product of p_i and p_j in generalized Stirling to summation of p_i and p_j because the summation will give minor topics more chances to be counted into the measurement of breadth of research. We add the coherence term into the metric because different topics have different "density" within themselves. For example, some topics like digital library are less coherent topics because there are many diverse subtopics in these topics. But for topics like operation systems, researchers concentrate on several narrow subtopics. A researcher focusing on digital library should have larger breadth of research than operating systems researchers if other variables are controlled (so the gamma should have a negative value).

The new metric leverages properties of papers (topic distribution), properties of topics (coherence) and properties of relationship (topic similarity). The tunable parameters give the metric more flexibility to balance between different aspects of breadth of research.

Experiments

Simulation Experiment

There is no established standard for determining the quality of metrics of breadth of research. Furthermore, there is no ground truth to show the rankings of scholars' breadth of research with which to validate the various metrics. We propose an alternative evaluation method based on a set of axioms concerning breadth of research and then test how the metrics perform according to these axioms.

In addition to the definition of d_{ij} and coh_i defined in the previous section, the following definitions relate to the axioms.

- Denote A_i as the article i, $C=\{ A_1, A_2 ... \}$ as a *collection* of articles, and N_C as the number of articles in collection C.
- Denote t_i as the topic i, $D_A(t)$ as the topic distribution of article A over topic t. $(\sum_t D_A(t) = 1)$

- Denote $D_C(t)$ as the topic distribution of collection C over topic t. $D_C(t) = \frac{1}{N_C}\sum_{A_i \in C} D_{A_i}(t)$. $(\sum_t D_C(t) = 1)$
- Denote *score(C)* as the score of a metric over the collection of articles C

Axiom1: Publish in Old Topics

If an author publishes a paper in a topic in which she has published many papers before, her breadth of research should decrease.

Choose t, s.t. $t = arg\,max_t\, D_C(t)$, construct a new article A_{new}, s.t. $D_{A_{new}}(t) = 1$. $C' = C \cup \{A_{new}\}$. Then *score(C') < score(C).*

Axiom2: Publish in New Topics

If an author publishes a paper in a new topic in which she has never published, her breadth of research should increase.

Choose t, s.t. $D_C(t)=0$, construct a new article A_{new}, s.t. $D_{A_{new}}(t) = 1, C' = C \cup \{A_{new}\}$. Then *score(C') > score(C).*

Axiom3: Publish in New Topics Twice

If an author publishes papers in two new topics in a sequence, the increase of breadth of research in the second time should be smaller than the increase of that in the first time.

Choose t_1 and t_2, s.t. $D_C(t_1)=0$, $D_C(t_2)=0$, $t_1 \neq t_2$,construct two new articles A_{new1} and A_{new2}, s.t. $D_{A_{new1}}(t) = 1$ and $D_{A_{new2}}(t) = 1$. $C' = C \cup \{A_{new1}\}$, $C'' = C' \cup \{A_{new2}\}$. Then *score(C')-score(C) > score(C'')-score(C').*

Axiom4: Publish in Close Topics

If an author publishes a paper in a new topic close to the author's research interest, the improvement of her breadth of research should be less than that of publishing a new paper in a randomly chosen topic.

Randomly Choose t_1 s.t. $D_C(t_1)=0$, construct a new article A_{new1}, s.t. $D_{A_{new1}}(t_1) = 1$. $C' = C \cup \{A_{new1}\}$. Choose t_2 s.t. $D_C(t_2)=0$ and $arg\,min_t(inf_{t_0 \in \{t|D_C(t)>0\}} d_{t_0 t_1})$. Construct a new article A_{new2}, s.t. $D_{A_{new2}}(t_2) = 1, C'' = C' \cup \{A_{new2}\}$. Then *score(C'') < score(C')*

Axiom5: Publish in Coherent Topics

If an author publishes a paper in a new topic with high coherence, the improvement of her breadth of research should be less than that of publishing a new paper in a randomly chosen topic.

Randomly Choose t_1 s.t. $D_C(t_1)=0$, construct a new article A_{new1}, s.t. $D_{A_{new1}}(t_1) = 1$. $C' = C \cup \{A_{new1}\}$. Choose t_2 s.t. $D_C(t_2)=0$ and $t_2 = arg\,max_t\,(Cohe_t)$. Construct a new article A_{new2}, s.t. $D_{A_{new2}}(t_2) = 1, C'' = C' \cup \{A_{new2}\}$. Then *score(C'') < score(C').*

We implemented five simulation experiments based on the original dataset with 8911 authors to test how the traditional metrics and our new metric conform to the axioms. The results are shown in Table 2.

Table 2. Probability that metrics satisfy of the axioms

	Entropy	*Simpson's*	*GL Stirling* $(\alpha = 2; \beta = 0.3)$	*New Metric* $(\alpha = 1, \beta = 0.5, \gamma = -0.5)$
Axiom1	0.99	0.99	0.97	0.88
Axiom2	0.89	0.97	0.86	0.86
Axiom3	0.97	0.94	0.50	0.50
Axiom4	0	0	0.76	0.70
Axiom5	0	0	0.54	0.62

The results show that entropy and Simpson's perform well in the first three axioms because they don't consider distances between topics and introduce less noise. Because every new topic will be regarded equally for these metrics, they cannot follow Axiom4 and Axiom5. Generalized Stirling and our metric perform reasonably well in Axiom1 and Axiom2, but worse than entropy and Simpson's. They perform relatively badly in Axiom3 because relatively bad performance on publishing a paper in new topic (Axiom2) will aggregate when testing the performance of publishing two papers in two new topics. But they perform well in Axiom4 because of the consideration of distances. Also we find our metric performs better than generalized Stirling in Axiom5, which means coherences of topics and greater weights on minor topics are beneficial when we consider variation of metrics when people publish in topics with different coherence levels.

Parameter Sensitivity

The performance of new metric is influenced by the value of parameters α, β and γ. We tested the performance of the new metric with different settings. The results are shown in Table 3, Table 4 and Table 5.

Table 3. Average Prob of satisfying the axioms with different α.

	$\alpha = 0.1$	$\alpha = 1$	$\alpha = 10$	$\alpha = 100$
Axiom1	0.40	0.42	0.48	0.62
Axiom2	0.33	0.38	0.44	0.55
Axiom3	0.34	0.32	0.24	0.22
Axiom4	0.38	0.57	0.66	0.64
Axiom5	0.63	0.61	0.57	0.52

Table 4. Average Prob of satisfying the axioms with different β.

	$\beta = 0.1$	$\beta = 1$	$\beta = 10$	$\beta = 100$
Axiom1	0.86	0.67	0.30	0.08
Axiom2	0.69	0.57	0.24	0.16
Axiom3	0.40	0.40	0.29	0.05
Axiom4	0.57	0.57	0.59	0.53
Axiom5	0.61	0.61	0.59	0.52

Table 5. Average Prob of satisfying the axioms with different γ.

	$\gamma = 0.1$	$\gamma = 1$	$\gamma = 10$	$\gamma = 100$
Axiom1	0.58	0.47	0.45	0.45
Axiom2	0.24	0.39	0.47	0.48
Axiom3	0.09	0.26	0.34	0.38
Axiom4	0.49	0.57	0.59	0.59
Axiom5	0.62	0.66	0.58	0.53

The tables show that the metric is very sensitive to the α, β and γ. In order to find the best parameter setting, we calculated the average performance over five different simulation experiments for every parameter settings. We selected the settings with highest average performance and a minimum threshold of at least 0.5 in every experiment. The best setting for Generalized Stirling is $\alpha = 2, \beta = 0.3$. The best setting for the new metric is $\alpha = 1, \beta = 0.5$ and $\gamma = -0.5$. They are used in the comparison of metrics in Table 2.

Summation Modification

One of important modifications of our metric is the replacement of product with summation in the second term of metric. We test the effect of this. If we control the distance term and coherence term in the metric to be the same for every topic and set $\beta = 1$. The metric using summation will definitely follow Axiom2 but not follow Axiom1 and Axiom3.

Let *n* represents the number of topic.

Axiom1: Publish in Old Topics

$$score(C) = \sum_{i,j} d^{\alpha}\ (p_i + p_j)(\text{coh} \times \text{coh})^{\gamma} = (n-1)d^{\alpha}(coh)^{2\gamma}$$

$$= \sum_{i,j} d^{\alpha}\ (p_i{}' + p_j{}')(\text{coh} \times \text{coh})^{\gamma} = score(C')$$

Axiom2: Publish in New Topics

$$score(C) = \sum_{i,j} d^{\alpha}\ (p_i + p_j)(\text{coh} \times \text{coh})^{\gamma} = (n-1)d^{\alpha}(coh)^{2\gamma}$$

$$< \sum_{i,j} d^{\alpha}\ (p_i{}' + p_j{}')(\text{coh} \times \text{coh})^{\gamma} = (n)d^{\alpha}(coh)^{2\gamma} = score(C')$$

Axiom3: Publish in New Topics Twice

$$score(C) = (n-1)d^{\alpha}(coh)^{2\gamma}$$

$$score(C') = (n)d^{\alpha}(coh)^{2\gamma}$$

$$score(C'') = (n+1)d^{\alpha}(coh)^{2\gamma}$$

$$score(C'') - score(C') = score(C') - score(C)$$

From the derivation above, the performance of new metric in Axiom 1 and Axiom 3 should be worse than the metric with product. The performance of Axiom 2 should be better than the metric with product. So we construct a metric using product in the second term and compare the performance of it with the new metric in different parameter settings.

$$Breadth\ of\ Research = \sum_{i,j} d_{ij}^{\alpha}\ (p_i \times p_j)^{\beta}(Coh_i \times Coh_j)^{\gamma}$$

The results in Table 6 shows that the metric using summation outperforms product in Axiom 2, and metric using product outperforms summation in Axiom1, which is consistent with the results of derivation. But the results for the other three axioms are close between the two metrics, which means the interaction between different terms in the metric (distance term, distribution term and coherence term) will influence the results of simulation.

Table 6. Comparison between metric with summation and production.

Metric	*Parameter setting*	*Axiom1*	*Axiom2*	*Axiom 3*	*Axiom4*	*Axiom5*
Production	$\alpha = 0.1\ \beta = 0.1 \gamma = -0.1$	0.99	0.85	0.45	0.22	0.59
	$\alpha = 100\ \beta = 1 \gamma = -1$	0.82	0.62	0.47	0.69	0.53
	$\alpha = 1\ \beta = 1 \gamma = -10$	0.83	0.40	0.39	0.55	0.76
Summation	$\alpha = 0.1\ \beta = 0.1 \gamma = -0.1$	0.97	0.89	0.45	0.22	0.59
	$\alpha = 100\ \beta = 1\ \gamma = -1$	0.69	0.69	0.50	0.69	0.55
	$\alpha = 1\ \beta = 1 \gamma = -1$	0.69	0.47	0.41	0.54	0.77

Relationship between breadth of research and scientific impact

We tested the Pearson correlation between metrics of breadth of research and H-indexes of scholars. Our results (Table 7) show that some metrics have a positive relationship with H-index. Others have weak negative relationship. Because publication numbers may influence

the correlation between breadth of research and scientific impact i.e. the increase of numbers of publications may bring increase of breadth of research and increase of H-index simultaneously to make them positively correlated to each other, we test the partial correlation between metrics of breadth of research to H-index controlling publication numbers (Table 7). They are weaker than Pearson correlations. And all the weak partial correlation scores don't illustrate strong correlation between metrics for breadth of research and H-index for scholars.

Table 7. Correlation between breadth of research and H-index.

	Pearson Corr.	*Partial Corr.*
Entropy v.s. H-index	-0.1722	-0.0769
Simpson's v.s. H-index	0.2102	0.0922
GL Stirling v.s. H-index	0.4283	0.1820
New Metric v.s. H-index	0.4337	0.1832

The Variation of metrics over publication years

We illustrate in Figure 1 the variation of average scores of metrics for all the scholars over publication years. Simpson's, generalized Stirling and our new metric initially increase and then level off, which explains a possible publication pattern of scholars: scholars' breadth of research may increase with the increase of publications in the early stage of their career. But because of accumulation of publications, their accumulative breadth of research will not change dramatically in the late years. For the entropy metric with base n, it is normalized by topic number. So it keeps in a stable level over year, which shows a different pattern compared to other metrics.

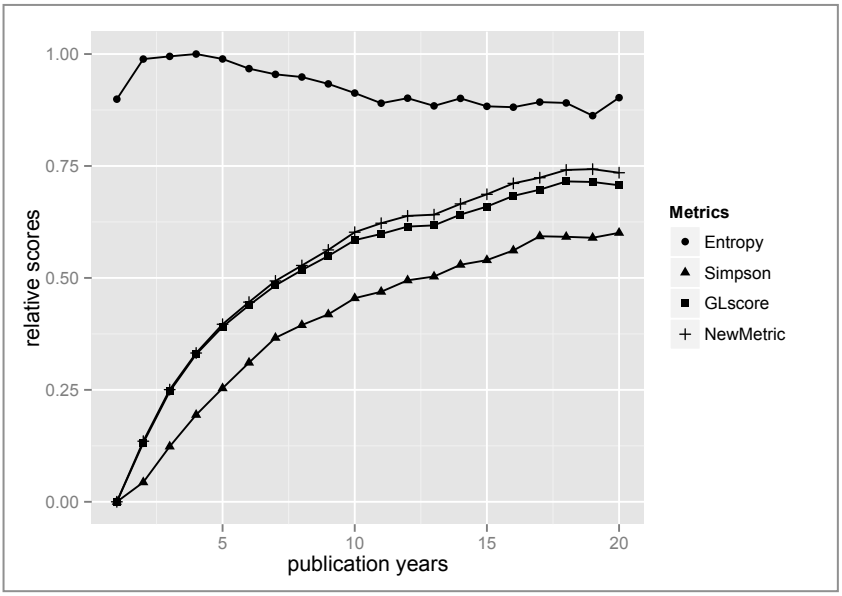

Figure 1. Variation of metrics over publication years.

Conclusion and Future Work

In this paper, we describe a new metric based on generalized Stirling to evaluate breadth of research for scholars in computer science. The metric makes use of topic distribution, similarity between topics, and coherence of topics and it can capture the diversity aspects of breadth of research. The simulation experiments show that traditional metrics can perform well in some axiom, but they don't perform well when coherence within topics and similarity between topics are considered. In contrast, generalized Stirling metric and the new metric for

breadth of research work better in the simulation related to similarity between topics and coherences but perform worse in the experiments of adding new topics. It is a trade-off between the simplicity of metrics and the concern of topic similarity and coherence.

With the new metric for breadth of research, we find the correlation between breadth of research and scientific metrics are weak, especially when we control publication numbers. From our study, there's no evidence to show whether the increase of breadth of research will influence the impact of scholars' publication. Also, after testing the variation of the new metric over years, we find a possible publication pattern of scholars: Breadth of research increases in the beginning with the increase of publications. But they increase slowly when publications have been accumulated.

There are a number of research questions that arise from the work described in this paper. The first one is finding alternative methods to generate research topics. Unsupervised learning models based on both text contents and citation information may be helpful to extract topics and show topic variation for authors. The second question is how to improve the simulation results for the new metric. The new metric performs better than general Stirling and other traditional metrics in some aspects. But if more information from co-author and citation network can be incorporated into the metric, the performance may be better and interpretable.

Transforming the Heterogeneity of Subject Categories into a Stability Interval of the MNCS

Marion Schmidt[1] and Daniel Sirtes[1*]

iFQ Institute for Research Information and Quality Assurance, Schützenstr. 6a, D-10117 Berlin (Germany)

Abstract
The internal homogeneity of research disciplines in subject categories (SC) of the Web of Science database (WoS) regarding their publication and citation practices is an essential precondition for the field-normalization of citation indicators. This imperative of underlying homogeneity seems not to be met throughout all categories, as has been shown in former research. A keyword-based clustering method displays both the diversity of research areas included in an SC and that the clusters' mean citation rate differ substantially. This proof-of-concept paper on the basis of one country set and two SCs presents a bootstrapping method, which allows quantifying the degree of heterogeneity within subject categories as a stability interval. The MNCS 95% stability interval of our set has a range of 6.7% and 7.3% compared to its score. This kind of robustness measure could be implemented for future evaluative citation analysis in order to convey the coarseness of bibliometric point estimates.

Conference Topics
Methods and techniques; Citation and co-citation analysis; Indicators

Introduction
Field-normalized citation indicators such as the MNCS (Waltman, Eck, Leeuwen, Visser, & Raan, 2011) normalize the citation rate of a given publication corpus based on expectancy values of subject categories which correspond to the respective average citation rates within a research field (Vinkler, 1986; Mcallister, Narin, & Corrigan, 1983). Field normalization has been developed in order to neutralize the obvious diversity of publication and citation practices between field and subfields, as a corrective to otherwise unfair comparisons between the citation impact results of corpora with varying subject distributions.
Various methods for field delineation have been proposed (Glänzel & Schubert, 2003; Glänzel, Thijs, Schubert, & Debackere, 2009; Ruiz-Castillo & Waltman, 2014) including many proposals for clustering methods and arguments to determine the correct levels of aggregation. So far, however, no classification systems other than those provided by the database vendors could be established as standard throughout the bibliometrics community.
However, it is easily observable that the classification of the WoS subject categories diverges in size and specificity. Van Eck et al. (2013) provide furthermore strong evidence of heterogeneity within the medical subject categories along the characteristics of clinical and experimental research: After terms have been extracted from titles and abstracts, substructures are made visible by a term cloud procedure. These substructures can be assigned intellectually to clinical or experimental research and differ significantly in their citation rates along these dimensions. An intuitive explanation for this phenomenon would be the assumption that clinical researchers cite experimental studies, but that experimental researchers cite clinical studies only to a lesser extent.
Van Eck et al. (2013) draw the conclusion that the impact of clinical research is structurally underestimated by classical normalized citation indicators. The substructures made visible correspond to a facet that can be seen as transverse to a valid and comprehensible classification according to medical fields such as Clinical Neurology, Cardiac &

[*] The order of authorship is merely alphabetical.

Cardiovascular Fields, etc. Further theoretical issues beyond classification or clustering criteria seem to be not yet solved: If, for example, publications in so called hot topic areas are compared only with similar publications, even only with those who share not only the same topic, but also the same instruments, etc.? This could be seen as an over-normalization (Sirtes, 2012b; Sirtes, 2012a). Or is it legitimate to aggregate hot topics with less active research areas and thereby highlight the former as particularly successful? With the latter attitude the strategic decision of a researcher for a high impact research fields would be gratified while at the same time an implicit premise would be set that not all delineable areas in a functionally differentiated research landscape would be of equal value, insofar impact differences, which are effects of the functional differentiation, would not be neutralized.

By introducing finer classification systems these issues are addressed, although not answered based on theoretical reasons, as only further normalization options are created, whereas the resulting differences are not directly interpretable. Besides, in-house classifications systems are not easily compatible with a desirable trend towards greater standardization and reproducibility in the bibliometric community.

In the present paper we introduce a concept for quantifying heterogeneity differences within subject categories and thus maintain the WoS subject categories as basis for the field normalization, as they provide community-wide comparability and mutual reproducibility. Heterogeneity differences between subject categories are quantified and used to construct error or stability intervals, which can be integrated into the calculation of the total impacts of an institution or a country as before. The approach thus combines two advantages: on the one hand, we continue to work at the level of a standard classification system and on the other hand, underlying structures on a secondary level are made transparent.

Methods and Data

Keyword terms of all articles, reviews and letters published in journals of two medical subject categories (Parasitology (P), Otorhinolaryngology (O)) of the publication year 2008 have been extracted.[1] WoS keywords are not a controlled vocabulary like, e.g., Medical Subject Headings in PubMed/Medline and are therefore not per se complete and normalized. Table 1, however, shows that the amount of publications that have not assessed with keywords is relatively small. Keywords have, on the other hand, the advantage of simple accessibility; it is not necessary to exclude i.e. filler words. In order to accomplish a basic normalization, a stemming procedure is carried out which neutralizes different inflexions.

All distinct keyword terms are normalized with an Oracle Text stemming function and coupled by the *contains* function, again as provided in Oracle Text. Stemmed terms must therefore not be necessarily identical, but one term can contain the other, respectively. This also applies to keywords, which are phrases and may contain single keywords and be thus coupled with them. These keyword pairs are used for a coupling procedure of the corresponding publications; Salton's Cosine is used to neutralize differing amounts of keywords.

With the aim to reproduce the visual substructures of Van Eck et al. (2013) in a first step with our cluster procedure, these two subject categories have been chosen as they display different types of sub-structures in the discussed work. Parasitology displays quite distinct structures with three visible clusters seemingly characterized by significant differences in citation levels whereas Otorhinolaryngology displays a more fuzzy structure.[2]

[1] All calculations are processed in an Oracle database of WoS raw data (SCI, SSCI, A&HCI, CPCI-S, CPCI-SS) frozen in the 17th calender week 2013.

Table 1: Share of publications with keywords.

	Parasitology	*Otorhinolaryngology*
JARL 2008 (all)	3727	5122
JARL 2008 (percentage of publications with keywords)	98.0%	90.6%

The ratio of realized to theoretical possible relations between all items gives an impression about the broadness of the empirical basis of the coupling results. Table Table 2 gives the percentage of realized to theoretically possible relations of all publications (JARL = Articles, Letters and Reviews with publication type Journal Article) in 2008.

Table 2: Ratio realized relations to possible relations.

	Parasitology	*Otorhinolaryngology*
JARL 2008 (all)	18.2%	11.3%
JARL 2008 (only with keywords)	19.0%	13.8%

The resulting distance measures for publication pairs are imported into the statistical program R, converted into dissimilarity values and the clustering method Ward is used. Ward as a standard hierarchical-agglomerative clustering procedure was chosen, because it is crucial for our approach to have a clustering procedure which does not require a fixed number of clusters as parameter. Furthermore, single linkage with its well-known tendency to dilated cluster structures seems to impose to weak requirements on the clusters' homogeneity and complete linkage too strong requirements.
The usual cut-off-value of 5 was determined manually; however in future iterations of the procedure the optimal cut off value will be estimated.
As shown in Table 2 not all publications in the respective sets are actually assigned with keywords, thus we have added a non-keyword cluster with its mean citation rate in order to represent all publications in our dataset. This appears as a legitimate solution given that fact that non-keyword items have considerably smaller mean citation rates compared to the whole subject category and have to be taken into account in order to appropriately represent the SC.

Results

The visualization for the subject category parasitology as resulting from (Van Eck et al.., 2013) indicates a distribution of three discernable substructures which are clearly different in citation level. With our method, we arrive at eleven clusters. Table 3 shows four of the top keywords[3] and the respective mean citation rates, whereas Figure 1 gives the frequency distribution of the clusters (as the width of the bars) and the mean citation rates in a histogram. The topics of the clusters can only partially confirm Van Eck et al.'s conclusion. The keywords of cluster 5, 6, and 7 have all clear connection to experimental laboratory research, however only 5 (with the most distinctly molecular biology focus) has a very high citation rate compared to the rest. It is possible, that parasitology is rather a special case compared to other medical SCs, as it also encompasses topics such as classical biology (cluster 1), epidemiology (clusters 2 and the more clinical 4), a veterinary cluster (8), and clusters that are joined by common parasites (3, 9,10, and 11).

[3] All keywords were in the top 10 most frequent ones. Redundant keywords (like 'plasmodium' and 'plasmodium falciparum') and keywords that were not informative in understanding the topic of the cluster (like 'parasites') were excluded.

Table 3 - Top keywords and mean citation rate of keyword clusters in parasitology (ordered by cluster size).

Cluster	Top Keywords				Mean Citation Rate
1	Phylogeny	Evolution	Ecology	Morphology	3.91
2	Infection	epidemiology	Seroprevalence	Antibodies	5.76
3	Malaria	plasmodium falciparum	infected erythrocytes	cerebral malaria	6.25
4	Transmission	Children	Resistance	Efficacy	7.02
5	Expression	in-vitro	Protein	gene-expression	7.57
6	Mice	in-vivo	dendritic cells	immune-response	6.69
7	Identification	PCR	linked-immunosorbent-assay	Antibodies	5.50
8	Sheep	Cattle	haemonchus-contortus	Ivermectin	4.11
9	Disease	trypanosoma cruzi	chagas disease	risk-factors	6.09
10	Diptera	Culicidae	aedes-aegypti	anopheles-gambiae	5.32
11	Cryptosporidium	Parvum	Giardia	Genotypes	7.88

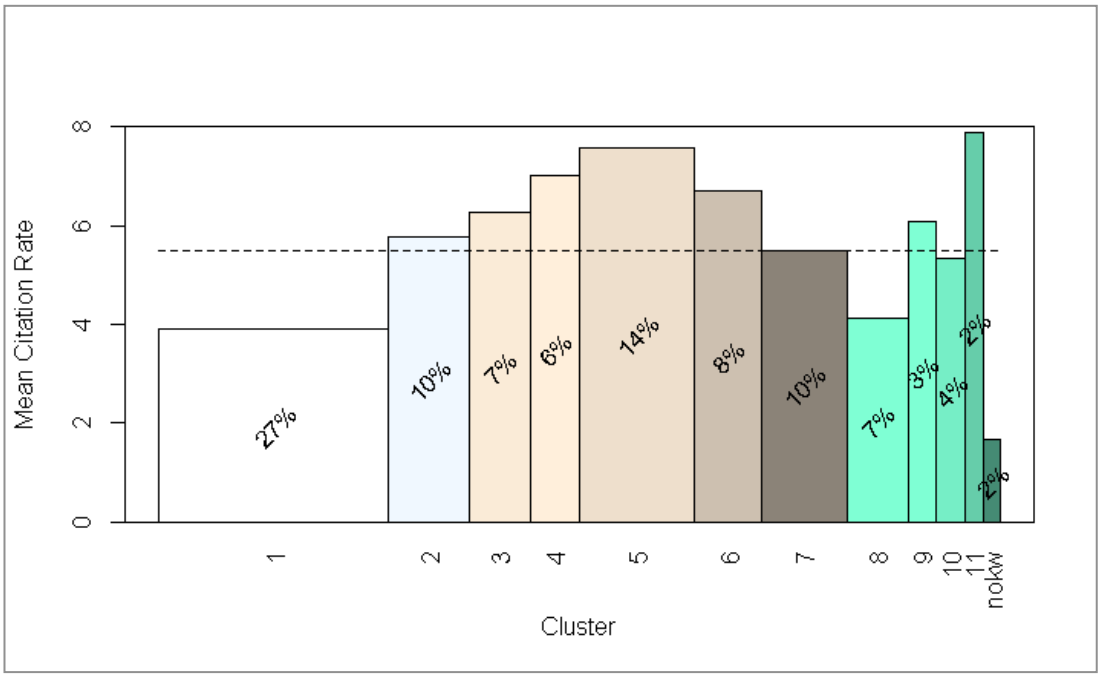

Figure 1: Share and Mean Citation Rate of Parasitology Clusters. The dotted line represents the MCR of the whole SC.

In the second case of otorhinolaryngology, the structure shown by (Van Eck u. a., 2013) is quite fuzzy and less-structured, which is mirrored by our cluster distribution. It consists of one larger and a considerable amount of very small cluster. There are also significant variations between mean citation levels ranging from around 2 to larger than 4, it is however more difficult to interpret the cluster's respective keyword frequencies.

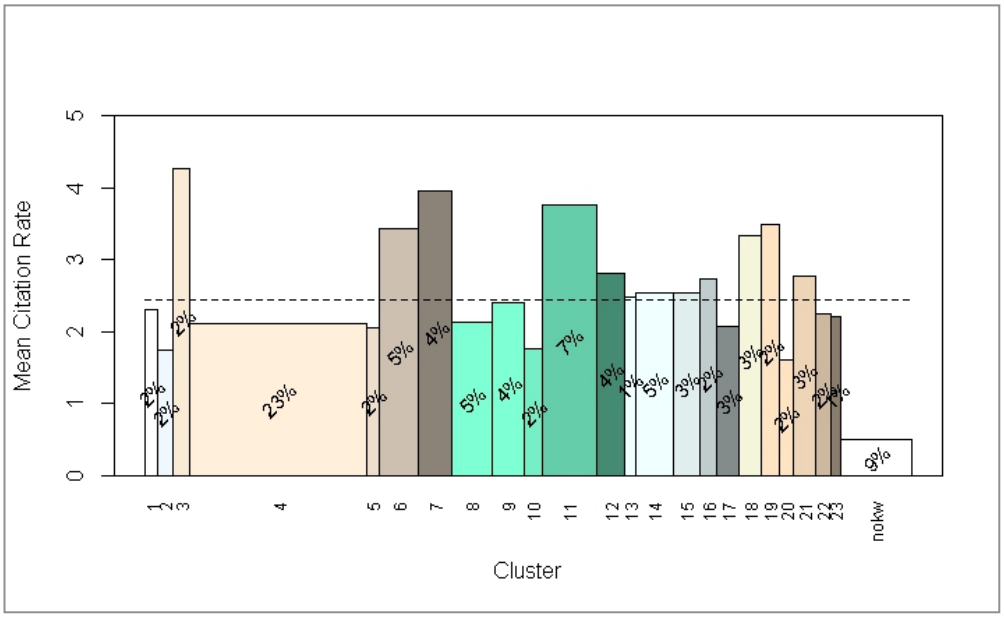

Figure 2: Share and Mean Citation Rate of Otorhinolaryngology Clusters. The dotted line represents the MCR of the whole SC.

In order to calculate the MNCS and its stability, sets of publications with an affiliation in Germany have been selected. The size of the sets were 208 (P) and 486 (O) publications respectively.

On the basis of the resulting cluster distributions, a bootstrapping approach has been utilized.

A set of MCR clusters equal to the size of the German set has been drawn with replacement from the clusters' MCRs with the probabilities equal to the clusters' share. The arithmetic mean of this combination has been calculated and served as the Expected Citation Score (ECS_i). Each raw citation score of the German papers was then divided by the ECS_i and the arithmetic mean of the results delivered the $MNCS_i$. 10'000 iterations of this procedure have been executed. The distribution of the scores are depicted in Figure 3.

Finally, the 2.5% and 97.5% quantiles of this distribution have been calculated.

The resulting MNCS 95% stability interval of the German set for parasitology ranges from 1.35 to 1.46 with an MNCS of 1.40 and for otorhinolaryngology from 0.87 to 0.93 with an MNCS of 0.9. Thus, although parasitology displays a much wider distribution, as can also be seen in Figure 3, the relative deviance of the MNCS ([95% range of $MNCS_i$]/MNCS) is quite similar with 7.3% and 6.7%, respectively.

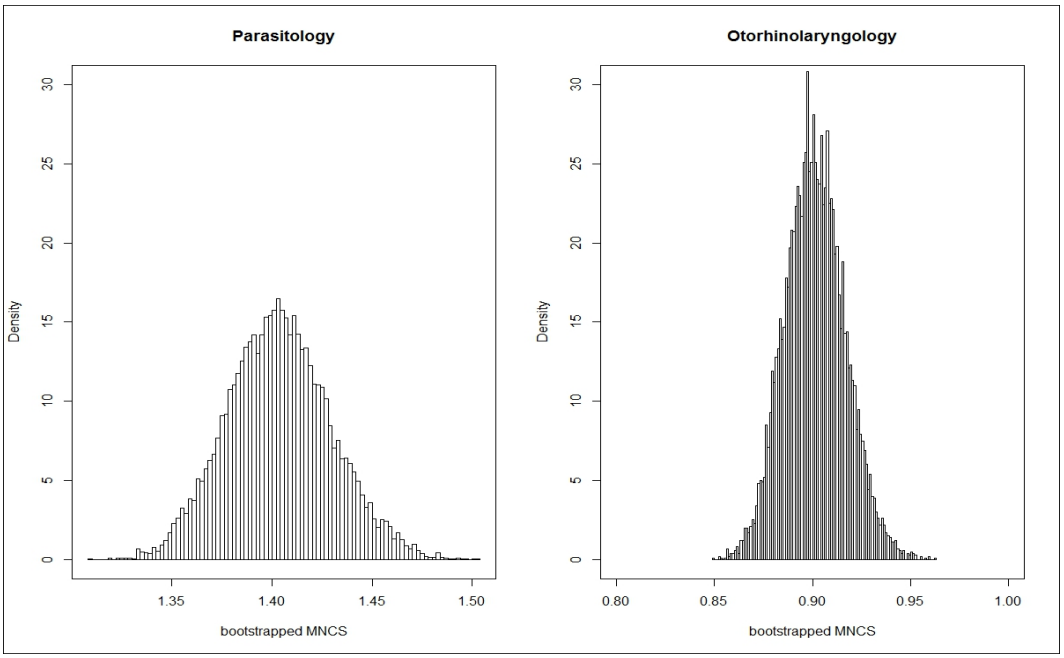

Figure 3: Distribution of $MNCS_i$ for German publications.

Discussion

These preliminary results show in the case of parasitology that clusters can be delineated and differing topical foci can be identified as well. While a dimension clinical versus experimental research is perceivable, other facets also occur: It may be the case that parasitology is a special SC as the clusters have also rather unusual topics compared to other medical disciplines such as classical biology, veterinary sciences and epidemiology. The Mean Citation Rates vary massively with a total range of MCRs of 3.97 citations per publication In the second case of otorhinolaryngology, the cluster distribution is less harmonic, more frayed out and not easily interpretable (confirming here the results of (Van Eck et al., 2013)). The coupling procedure succeeded on a relatively smaller amount of publications and many more clusters have been created. Furthermore, the citation levels are all much lower and the range of MCRs, the publications without keywords notwithstanding, have only a total range of 2.6 citations per publication.

The hitherto work was intended as a proof of concept: We were able to show that subject category substructures with different citation levels exist. Differences in citation homogeneity are however not in both cases concordantly attributable to topical structures. For the current state of this work, some simplifications have been applied: Citation rates should be processed and normalized document type-specific as articles, letters and reviews are cited differently. However, citation level differences in our results are so clear and dominant that they couldn't possibly only be caused by different document type patterns in the clusters. For a final implementation of this method, the calculations will be processed document type-specific and the expansion of the method to sets of multiple SCs, including an SC fractionalization will be developed. An exclusion of letters might be contemplated as for example about half of the publications without keywords in otorhinolaryngology are letters (about three quarters of all letters in this SC). Furthermore, parameters of the study like the clustering method and definition of cut off-values will be systematically varied and analyzed. It is even conceivable to calculate such stability intervals on the basis of percentile based indicators, which are less sensitive to outliers than the MNCS. However, already as it stands this method shows promise in circumventing to problem of calculating normalized citation scores on non-standard classification schemes while taking into account the heterogeneity of research areas in the

classical WoS SC classification. This method could also be combined with already existing bootstrapping methods of the publications sets themselves as implemented for example in the Leiden Ranking (www.leidenranking.com). Together they could account for both the robustness of the citation scores given the size and distribution of the publication sets themselves, as well as the underlying uncertainty of the expected citation rates. We believe that such methods that display the coarseness of bibliometric point estimates, which especially clients of evaluative bibliometric analyses are prone to disregard and thus revel or despair at minute changes of their scores and ranks, are an important step to the correct interpretation of bibliometric indicators and crucial for the development of bibliometrics into a mature science.

Measuring Interdisciplinarity of a Given Body of Research

Qi Wang

Abstract
Identifying interdisciplinary research topics is an essential subject, not only for research policy but also research funding agencies. Previous research was constructed on measuring interdisciplinarity mainly at the macro level of research, such as Web of Science subject category and journal. However, these studies lack analysis at the micro level of the current science system. It means few studies have analyzed interdisciplinarity at the level of publications. To cover this gap, we introduce an approach for measuring interdisciplinarity at the level of micro research topics. The research topics are clustered by direct citation relations in a large scale database. According to the characteristics of boundary-crossing research, we provide an alternative approach to measure interdisciplinarity. Comparing with the widely used Rao-Stirring indicator (Integration score), we found that the results obtained by two indicators of interdisciplinarity have a strong correlation, thus we believe that this approach could effectively identify boundary-crossing research topics.

Conference Topic
Indicators

Introduction
In bibliometric and scientometric research, measuring interdisciplinarity is a difficult yet important topic. However, although it has been widely recognized that interdisciplinary research solves complex problems, promotes scientific developments and innovations, there is still no consensus on how to define and measure this type of research. Specifically, a variety of definitions on boundary-crossing research have been proposed, such as interdisciplinary multidisciplinary, transdisciplinary and cross-disciplinary; however the definitions of each term as well as discriminations among them are quite ambiguous (for more details see Huutoniemi K. et al., 2010; Wagner C.S. et al., 2011). In a broad sense, these concepts all refer to the research that cross boundaries between disciplines. We do not intend to explore the nuances among the concepts in this study. Thus, at the very beginning of this article we need to emphasis that, for the purpose of this research, the term *interdisciplinary research topics* used to refer to all type of boundary-crossing research, in other words, it covers all type of research with interdisciplinarity.

Furthermore, due to the controversy in defining research with interdisciplinarity at the conceptual level, there is no consensus on how to measure interdisciplinarity in practices. Various approaches are utilized to analyze interdisciplinarity, including both quantitative methods such as bibliometric indicators, text-mining and qualitative methods such as interviews and surveys. In particular, bibliometric approaches have been widely applied to measure and identify interdisciplinarity, such as citation-based indicators (Porter & Chubin, 1985; Leydestorff, 2007; Porter, Roessner & Heberger, 2008; Porter & Rafols, 2009; Rafols & Meyer, 2010; Leydestorff & Rafols, 2011; Rafols et al., 2012; Lariviere & Gingras, 2014), author-based indicators (Qin et al., 1997; Schummer, 2004; Abramo et al., 2012), as well as similar indicators but relying on a variety of classification systems of science (Tijssen, 1992; Morillo, Bordons, & Gomez, 2001; 2003; Braun & Schubert, 2003; Sugimoto, 2011;

Sugimoto et al., 2011). Additionally, a few studies have applied text-mining approaches, LDA for example, to explore interdisciplinarity of a given issue (Wang et al., 2013; Nichols, 2014).

In this article, we explore a citation-based measurement for identifying interdisciplinary research topics at the level of publications. We also use the Web of Science (WoS) classification system, but with a different approach. More specifically, we first construct micro research topics based on the direct citation relations among individual publications. Meanwhile, the publications are assigned into one or several subject categories on the basis of the journal where the publication has appeared and of WoS classification system. It implies that a research topic constructed might belong to one or several WoS subject categories according to publications within the cluster. In other words, WoS subject categories that attached to publications are regarded as traditional boundaries of scientific disciplines, whereas micro research topics constructed on the relatedness among publications might break the existing knowledge boundaries. We assume, then, that a cluster can be regarded as an interdisciplinary research topic if there is a considerable number of within-cluster citations spanning distant WoS subject categories. The indicator proposed in this article combines knowledge diversity with knowledge integration, in which heterogeneity and connectedness of subject categories within research topics are taken into account. It provides an alternative approach to measure interdisciplinarity and simplifies the previous citation-based approaches.

Data and Methodology

This study was based on data from the in-house WoS database of the Centre for Science and Technology Studies (CWTS) of Leiden University. The database used in this study covers the period from 2002 to 2013, a 10-year period. The total number of publications in our database is about 9 million. The methodology that we introduce for measuring interdisciplinarity of micro research topics can be divided into three steps.

Step 1 Clustering publications into micro research topics

The clustering method is mainly based on the previous studies by Waltman & van Eck (2012; 2013). First, the relatedness of publications was measured by the normalized direct citation relation among individual publications (for details see Waltman & van Eck, 2012). Furthermore, based on the relatedness matrix, an improved Louvain algorithm (Blondel et al., 2008), namely a 'Smart Local Moving algorithm' (SLM) was applied to cluster individual publications (for details see Waltman & van Eck, 2013). Labels of each cluster were selected from titles and abstracts of publications within cluster (for details see Waltman & van Eck, 2012).

Measuring interdisciplinarity on the level of micro research topics, constructed based on the citation relations, is one of the most important distinctions between this study and previous research. There are two reasons for measuring the degree of interdisciplinarity in this approach. First, WoS subject categories attached to journals cannot properly describe publication itself. For instance, although *Journal of the Association for Information Science and Technology* belongs to two categories, INFORMATION SCIENCE & LIBRARY SCIENCE and COMPUTER SCIENCE, it does not necessarily mean that all publications appeared in this journal span the two categories. More generally, some publications associated with the category of INFORMATION SCIENCE & LIBRARY SCIENCE and others related to the category of COMPUTER SCIENCE. The second reason is that WoS assigned journals such as *Nature*, *Science*, and *Plos One* as MULTIDISCIPLINARY SCIENCE. Instead of focusing on a specific scientific field, this sort of journals covers almost the full range of scientific disciplines. When measuring interdisciplinarity on the level of journals, this sort of journals may have high interdisciplinarity scores. However, although the journals are composed of publications

spanning over different scientific disciplines, it does not necessarily mean the integration of knowledge from various sources exists.

In order to avoid the problems mentioned above, we constructed micro research topics based on the relatedness of individual publications, which are expected to provide a more accurate body of research topics within the current science system.

Step 2 Calculating a similarity matrix of ISI subject categories

Porter and Rafols (2009) analyzed a sample of more than 30,000 WoS publications and their cited references, in which publications were assigned to subject categories on the basis of the WOS classification of journals the publications appeared. They constructed a matrix of subject categories using the relations of articles and their cited references, and then applied Salton's cosine (Salton & McGill, 1983) to obtain the similarity matrix of subject categories. The similarity value s_{ij} is high if subject category i and j are cited a lot by the same publications.

However, in this study, two subject categories are considered to be strongly related if they both cite a lot to the same subject categories. Specifically, the construction of a similarity matrix of subject categories is done in two steps.

In the first step, for each pair of a citing subject category i and a cited subject category j, the number of citations from publications in subject category i to publications in subject category j is counted. We use c_{ij} to denote the number of citations from publications in subject category i to publications in subject category j. Note that according to the WoS classification system, one journal might be attributed into multiple subject categories. Therefore a fractional counting strategy is adopted to handle publications belonging to more than one subject category.

The second step is to construct a similarity matrix of subject categories based on the citation matrix created in the first step. The cosine similarity measure is used for this purpose. Hence, the similarity of two subject categories i and j is given by

$$s_{ij} = \frac{\sum_k c_{ik} c_{jk}}{\sqrt{\left(\sum_k c_{ik}^2\right)\left(\sum_k c_{jk}^2\right)}}$$

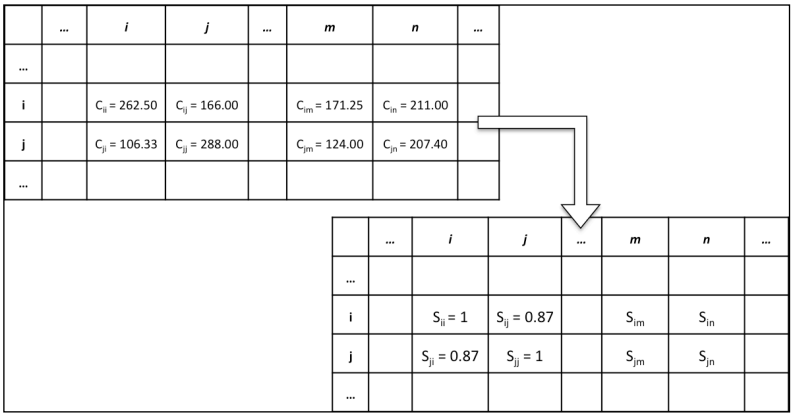

Figure 1. An example of the formula for calculating similarity.

Figure 1 can be used as an example to illustrate how the formula of similarity applied. The top left table is the matrix of citation relations among subject categories, which is not symmetric. Since a fractional counting strategy is used in this study, the numbers of citations are not always integers. As we mentioned above, c_{ij} means the number of citations from subject category i to j. Moreover, according to the above formula, we obtained the symmetric

similarity matrix of subject categories, which is shown in lower right of figure 1. In this case, subject category *i* and *j* are all cite a lot to the categories *i*, *j, m* and *n.* Therefore, the similarity between *i* and *j* is quite high, that is 0.87.

In short, using the cosine similarity measure, s_{ij} is high if publications in the two categories tend to cite the same categories. If publications in two subject categories tend to cite completely different categories, the similarity between the categories is low.

Step 3 Determining the degree of interdisciplinarity

As mentioned above, we suppose that a research topic could be regarded as an interdisciplinary research topic should satisfy two criteria; one is that it contains distant subject categories, the other is there are citation relations among different subject categories within this topic. In short, a cluster that is consisted with citation relations spanning different subject categories might be an interdisciplinary research topic.

Following the criterion discussed above, we explore the indicator to measure interdisciplinarity, whose formula is as follows:

$$Interdisciplinarity = \frac{1}{n\_cit}\sum_i^k \sum_j^k n\_cit_{ij} d_{ij},$$

where $d_{ij} = 1 - s_{ij}$. Within a cluster, n_cit_{ij} is the number of citations between subject categories i and j, and n_cit is the sum of citations obtained by $n\_cit = \sum_i^k \sum_i^k n\_cit_{ij}$. The indicator includes three attributes: *variety*, the number of subject categories within a cluster (denoted as *k*), *connectedness*, the number of cross-citations (denoted as n_cit_{ij}) and *distance*, the degree of distinctiveness between subject categories (denoted as d_{ij}). In short, a research topic can be considered to be more interdisciplinary if the citation relations within that cluster cross various WoS subject categories.

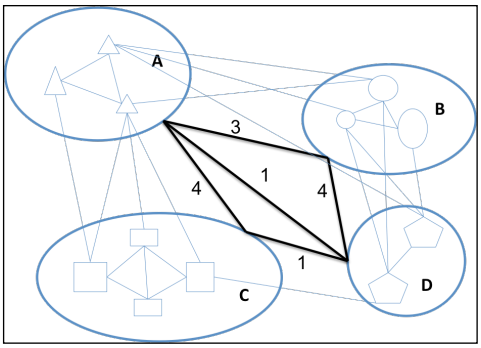

Figure 2. An example of the citation relations within a research topic.

Figure 2 shows a research topic including 12 publications that belong to 4 subject categories. The black lines represent the citation relations among different subject categories, and the blue lines are the links within the same category. In our measurement, the citations crossing subject categories (black lines in the Figure) and distances of subject categories are taken into account.

Results

Clustering analysis

Table 1 provides the basic statistic results of original and restricted database. The restricted database was constructed based on two criteria. First, we expect to analyze research topics with a relatively large number of publications only. Therefore, we set a restriction on the number of publications of each cluster so that clusters with more than 100 publications could

be advanced in the next step. Second since the accuracy of measurement is highly related to the quality of clustering results, we reviewed the clusters with the indicator, *mean citation score*. It obtained by using the total number of citations divided by the total number of publications within a cluster. If the number of citations is less than the number of publications of a cluster, publications belong to the cluster are connected loosely, resulting in the emergence of clusters with poor qualities. In this case, we found 667 clusters with low mean citation scores (defined as less than 2), which accounted for 7% of the total. Thus, it turns out that most of clusters have relatively strong interconnections. The analysis in the following sections is performed base on the restricted database.

Table 1. Basic statistic results of original and restricted database.

	# of pubs	# of topics	Average pubs	Max pubs	Min pubs	St.d pubs
Original	9,146,302	9,565	956	10744	1	1026
Restricted	8,930,360	7,864	1,135	10744	100	1040

Similarity matrix

Using Salton's cosine (Salton & McGill, 1983), we obtained a similarity matrix of WoS subject category, the range of similarity values is between 0 and 1. It implies that the similarity s_{ij} is zero if subject category i and j never cite to the same categories, whereas s_{ij} approaches one if they both cite a lot to the same categories. To test the accuracy and reliability of our similarity matrix, we have compared it with the one obtained by Porter & Rafols (2009), whose method have been introduced above. As expected, the result shows there is positive correlation between the two matrices ($r = 0.7405$). In general, we believe that the results obtained from the two approaches with slight differences are consistent.

Interdisciplinarity of research topics

The average interdisciplinarity score of each research topic is about 0.42 with a standard deviation of 0.11. The largest score is 0.72 associated with the research on respiratory system, while the lowest is close to 0.0086. The distribution of research topics over the interdisciplinarity score is shown in figure2. As can be seen, the majority of research topics have interdisciplinarity scores between 0.35 and 0.55.

In order to better interpret the results, we aggregated the WoS subject category into five main fields according to the Leiden Ranking 2013. Table 2 lists the five main fields. Specifically, a publication appearing in one or several main fields is based on the journal where it has been published. When a publication has appeared in a journal of multi-assignation and these subject categories are assigned into different main fields, the publication is expected to appear in more than one field (more details see CWTS Leiden Rank 2013, pp4). Thus, a research topic might be assigned into several main fields if the publications within this topic belong to more than one field.

Before turning to the interdisciplinarity score, we emphasize that it is quite difficult and almost impossible to define a clear cutting-off point between interdisciplinary and non-interdisciplinary research topics. Considering the difficulty, we selected the research topics with an interdisciplinarity score greater than 0.6143, which account for around 1% of the total. For the purpose of understanding the knowledge integration across main fields in the macro level, we applied following strategy. Regarding a research topic, if the number of publications in one main field is larger than 50% of the total, then the topic is assigned into this main field. Otherwise, the research topic would be assigned into its two dominant main fields. In doing so, the select topics (top 1% of the total) are tabulated in Table 3, in which each row is the main field with the most number of publications and each column is the main field holding the second number of publications. For instance, in the first row, 1 means there

is one research topic whose publications mostly appear in main fields 1 and 2, as well as main field 1 has the most number of publications.

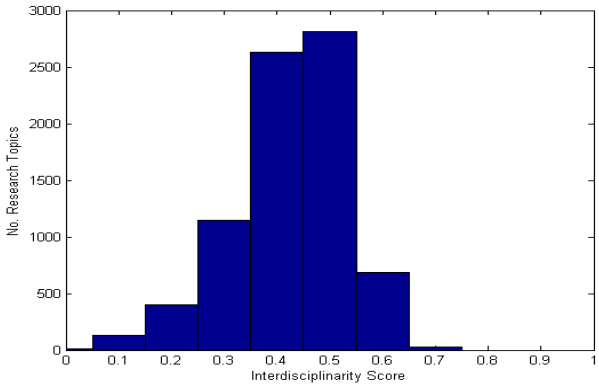

Figure 3. Distribution of research topics over interdisciplinarity score.

Table 2. Labels of main fields.

ID	*Labels of Main Fields*
Main Field -1	Social sciences & humanities
Main Field -2	Biomedical &health sciences
Main Field -3	Natural sciences & engineering
Main Field -4	Life & earth sciences
Main Field -5	Mathematics & computer science

Table 3. Distribution of research topics over the main fields.

	Main field-1	Main field-2	Main field-3	Main field-4	Main field-5	Total
Main field-1	11	1	0	0	0	12
Main field-2	1	33	6	1	2	43
Main field-3	0	2	25	1	0	28
Main field-4	0	0	1	8	0	9
Main field-5	0	2	1	0	5	8

As can be seen, most research topics in the top 1% of the total belong to the main field 2, that is BIOMEDICAL & HEALTH SCIENCES. Meanwhile, among the research topics that across two main fields, the topics whose publications mainly appear in the main field 2 contribute the largest proportion. Primarily, this is because the most number of research topics fall into this main field. In addition, the research conducted by Porter & Rafols (2009) have demonstrated that subject categories MEDICINE- RESEARCH & EXPERIMENTAL and NEUROSCIENCES have high degrees of interdisciplinary according to the Integration score (aka, Rao-Stirling's diversity) (more details see Porter & Rafols, 2009, pp723). In our classification system, the two subject categories both belong to main field 2, which is partially verified that the main field of BIOMEDICAL &HEALTH SCIENCES has relatively high interdisciplinarity. Main field 5, that is MATHEMATICS & COMPUTER SCIENCE, holds the smallest number of research topics with high interdisciplinarity, as shown in table 3. This result is also consist with the research by Porter & Rafols (2009), in which they showed subject category MATHEMATICS that is assigned into main field 5 in our study has the lowest integration score between 1975 and 2005.

For the purpose of examining the quality of the indicator, we now take a more derailed look at research topics. In doing so, we randomly select 5 research topics from the top 1%, one from

each main field. For each research topic, Table 4 gives the three most important subject categories and the two most cited publications.

Table 4. Selected research topics with high interdisciplinarity.

Cluster ID	Information of Publication	
4323	Main field (R_pubs) T_pubs Rank Subject Categories (N_pubs) Title (Times cited)	Main Field -1 (53%); Main Field -4 (27%) 705 56 VETERINARY SCIENCES (244); SOCIOLOGY (225); PUBLIC, ENVIRONMENTAL & OCCUPATIONAL HEALTH (47) Rijken M et al. Magnetic zenith enhancement of HF radio-induced airglow production at HAARP (45)
8434	Main field (R_pubs) T_pubs Rank Subject Categories (N_pubs) Title (Times cited)	Main Field -5 (55%); Main Field -3 (34%) 108 99 ROBOTICS (49); COMPUTER SCIENCE, ARTIFICIAL INTELLIGENCE (34); INSTRUMENTS & INSTRUMENTATION (22) Vergassola M. et al. (2007) 'Infotaxis' as a strategy for searching without gradients (103) Yoerger D.R. et al. (2007). Techniques for deep sea near bottom survey using an autonomous underwater vehicle (38)

Take two clusters as examples, cluster 3644 and cluster 4083 are randomly selected from BIOMEDICAL & HEALTH SCIENCES and NATURAL SCIENCES & ENGINEERING respectively; however, the two most frequent main fields of both clusters are the same. Apart from that, as can be concluded from table 4, most publications of both clusters belong to the

subject category of NUCLEAR SCIENCE & TECHNOLOGY. Hence we infer that the two research topics are similar at a certain degree. Observing the detailed information of publications in each cluster, we found that both clusters are related to the research on nuclear medicine, that is "a medical specialty involving the application of radioactive substances in the diagnosis and treatment of disease"[1]. However, there is a considerable difference in terms of the degree of interdisciplinary score. Cluster 3644 is much more interdisciplinary than cluster 4083 as shown from table 4. To understand the differences, we visualized the two clusters using the map of subject categories.

The map of subject categories can represent the position of a cluster in the global map of science, as well as show whether the cluster has the characteristics of interdisciplinary research. For instance, we can observe from the map of subject categories whether clusters are dispersed over many distant subject categories. The software VOSviewer (van Eck & Waltman, 2010) was used to construct the map of subject categories. In this study, the baseline map was generated by the citations between WoS subject categories using publications from 2002 to 2013. Figure 4 and 5 were generated by overlaying on the baseline map with circles, in which size of circles represents the number of publications in each WoS subject category, nodes represent subject categories, as well as links shows citations among them.

Comparing the two figures, we found that cluster 3644 are more diverse that it contains citations spanning various subject categories with larger distances (i.e. COMPUTER SCIENCE THEORY AND METHOD, ENGINEERING ELECTRICAL AND ELECTRONIC), as well as its number of publications in various subject categories are quite even. Thus, it is reasonable that cluster 3644 has a higher interdisciplinary score than cluster 4083, although they have a similar research topic. Meanwhile, it can be inferred that the two clusters have different research focuses since the subject categories with the most number of publications of the two clusters are quite different. That also explains why publications with a similar research topic were classified into two clusters.

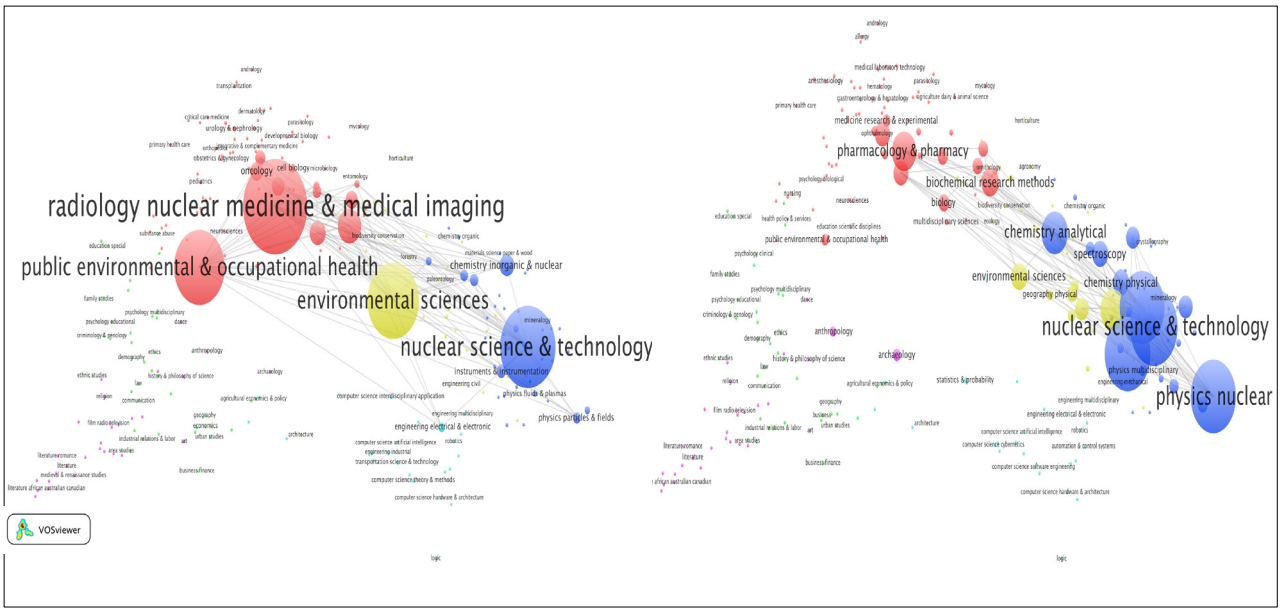

Figure. 4. A map of subject categories (note: the left panel is cluster 3644; the right panel is cluster 4083).

An example of Information Science and Library Science. Readers of this paper might be familiar with research in the field of information and library science; therefore, we now take a specific look at a cluster in this subject category. To give an example, we select the cluster that holds the highest interdisciplinarity value among all the clusters whose most publications belong to this subject category. In doing so, we obtained cluster 4982, which ranks 72 among the top 1% most interdisciplinary clusters. The detailed information of this cluster is shown in table 6.

As can be seen, the cluster includes 565 publications, and most of them belong to main fields of SOCIAL SCIENCES AND HUMANITIES and MATHEMATICS AND COMPUTER SCIENCE, that fit what figure 10 shows. Moreover, it also can be seen that this research topic covers various subject categories, such as computer science research, ergonomics, business, laws, and psychology. Furthermore, based on the most cited publications and the figure of citation network of this cluster, we can estimate that this research topic is rated to the research on information privacy. This is probably in line with what our cognition, that research on information privacy involves studies on either information or computer technology, or social science research such as law and psychology, or studies which overlap the two types of research.

To find more evidence, we searched the courses related to information privacy in MIT OpenCourseWare, using "information privacy" as the key words. Then, 1150 results have been obtained. The courses include from *The Economics of Information*, *Communications and Information Policy* to *Biomedical Computing*, *Information and Entropy*. That proves the research topic of information privacy is interdisciplinary in character.

Table 5. Publication information of cluster 4982.

Cluster ID	Information of Publication	
4982	Main field (R_pubs)	Main Field -1 (52%); Main Field -5 (44%)
	T_pubs	565
	Rank	72
	Subject Categories (N_pubs)	COMPUTER SCIENCE, INFORMATION SYSTEMS (141); BUSINESS (108); INFORMATION SCIENCE & LIBRARY SCIENCE (107)
	Title (Times cited)	Malhotra N.K., Kim S.S. & Agarwal J. (2004). Internet users' information privacy concerns (IUIPC): The construct, the scale, and a causal model (169)
		Nissenbaum H. (2004). Privacy as contextual integrity (110)

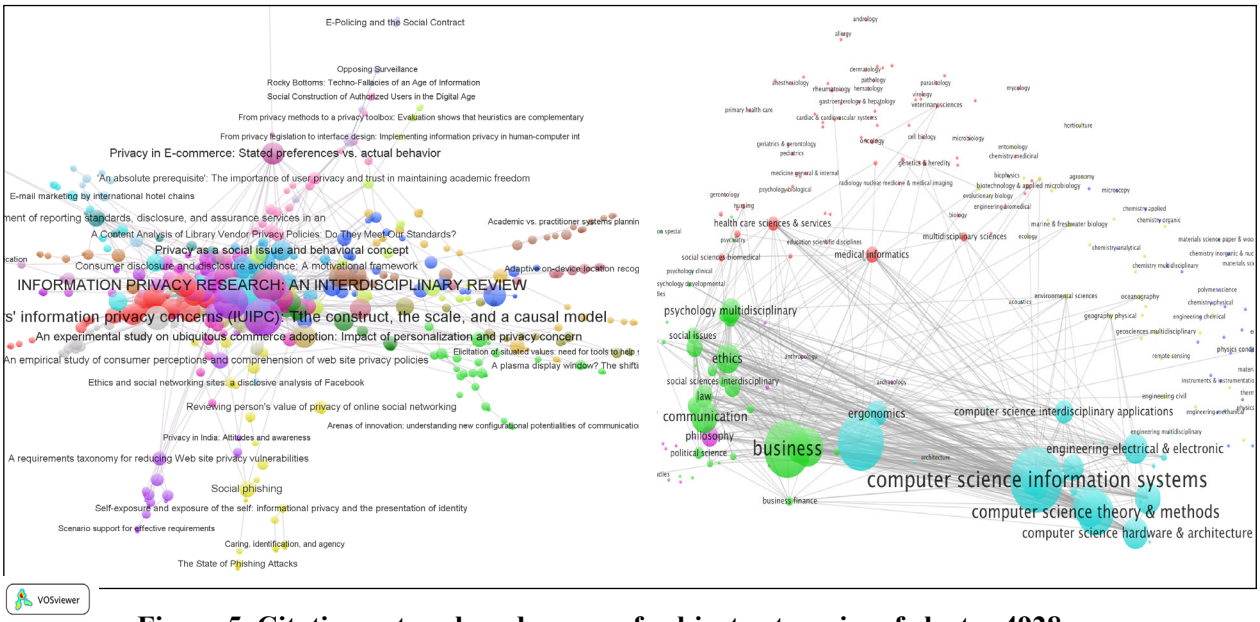

Figure 5. Citation network and a map of subject categories of cluster 4928.

Discussion and Conclusion

In this article, we proposed an alternative approach to investigate interdisciplinarity. The measurement is based on a publication-level and direct citation relations based classification system. Hence, several interdisciplinarity research topics were identified with the new interdisciplinarity score in the current science system.

The interdisciplinarity score proposed not only takes citation relations among various WoS subject categories within a cluster into consideration, but it incorporates a measure of how distant the subject categories. As mentioned above, the indicator proposed in this article is similar, to some extent, with the widely used indicator of interdisciplinarity, that is Rao-Stirling index or Integration score (Porter & Rafols, 2009). The most crucial distinction between the two indicators of interdisciplinarity is that, for each research topic, we use the number of citations among subject categories instead of the number of publications in different subject categories. We consider that the number of citations among subject categories can reflect both how diverse as well as how compact a cluster is. Furthermore, to test the robust of this approach, we estimated Pearson's correlation between the two indicators. The correlation coefficient is 0.9552, which high correlation suggests that there is no difference between the original Rao-Stirling index and the variant proposed in this article.

Another distinction with previous research is that our study is based on a publication-level and direct citation relations based classification system, in which publications were assigned into different research topics according to their citation relations. It implies the research topics constructed can more closely match the current structure of scientific research and provide more detailed information of the research content per se (Waltman & van Eck, 2012). There are 250 WoS subject categories in total, providing a coarse description of science. On the contrary, we worked on a classification with around 10,000 research topics, deriving from large-scale clustering. While the clusters in this study are small compared with WoS classification, it is important and necessary to explore interdisciplinary research topics at different level of classification system of science.

Moreover, we need to emphasis the concept of 'interdisciplinary research topic' that we used in this article again. Here, this term is related to all types of crossing boundary research topics, which can be considered as a loose standard. Since there is a gradual transition from

mono-disciplinary to interdisciplinary research, it is somewhat impossible to define a clear line to distinguish mono-disciplinary and interdisciplinary related research.

In summary, we have introduced an alternative approach for identifying interdisciplinary research topics. By in-depth analysis of some randomly selected topics, especially based on citation networks and overlay maps, we believe that they are boundary-crossing research topics. Since most research on the measurement of interdisciplinarity have conducted based on an existing classification system of science, such as journal and WoS subject category, we expect this study could provide another perspective on the current science system. The identified research topics could more accurately reveal interdisciplinary research within the current structure of scientific research.

Acknowledgments

This paper was written during a research stay at the Centre for Science and Technology Studies (CWTS) of Leiden University. I acknowledge the support of CWTS. I would like to thank Ludo Waltman for the extremely helpful discussions and suggestions on this study. I also appreciate Ulf Sandström for his comments on the early version.

How often are Patients Interviewed in Health Research? An Informetric Approach

Jonathan M. Levitt[1] and Mike Thelwall[2]

[1]J.M.Levitt@wlv.ac.uk, [2]m.thelwall@wlv.ac.uk
Statistical Cybermetrics Research Group, University of Wolverhampton, Wolverhampton WV1 1LY (UK)

Abstract
In recent years research funding bodies have increased their emphasis on the engagement between researchers and the public. As part of this increased emphasis, the UK's National Institute for Health Research aims to promote a research-active population. A way in which patients can be research-active is by participating in research interviews. In order to assess the past levels of this type of contribution of patients to research, this paper investigates the extent to which health research refers to patient interviews. Co-word indicators for the interviewing and qualitative interviewing of patients are used to gauge how the levels of interviewing and qualitative interviewing in Web of Science (WoS) articles have varied over time, between science and social science and between WoS categories. The results indicate that the level of interviewing of patients, referred to in WoS articles, rose steadily between 1991 and 2013. Moreover, the amount of interviewing and qualitative interviewing varied substantially between health-related fields, with a marked tendency for more interviews in social science research and fewer in science research.

Conference Topic
Indicators

Introduction
Over the past few years research funding bodies have increased their emphasis on public involvement in health research. For example, the UK's National Institute for Health Research, in a recent strategic plan, listed as a key objective, "Citizens helping to identify and deliver research of the highest quality" (NIHR, 2014), adding that citizen participation health research "is contributing to a 'research active' nation focused on best health for all." In particular, those who are ill seem to be particularly important because they can provide first-hand understanding of the specific illness being researched. In order to understand the potential contribution of ill people to health research, it helps to understand their past contribution to health research. This paper addresses two aspects of past contribution: the extent to which this contribution has varied over time and the extent to which this contribution has varied between subjects. This paper also introduces and demonstrates a novel technique: the use of co-word metrics to gauge the levels of both interviewing and qualitative interviewing of patients, and applies it to Web of Science (WoS) articles.

Background
Informetric techniques Although the individual words in abstracts can be irrelevant to the content of the articles, analyses of the words in academic publications have been used extensively. Collections of articles have been mapped, based on the words in their titles (Leydesdorff & Zaal, 1988; Milojević et al., 2011), their titles and keywords (Whittaker, 1989), their titles and abstracts (Peters & van Raan, 1993), their titles with references used for context (van den Besselaar & Heimeriks, 2006), or their full text (Glenisson et al., 2005). However, other research with similar goals has ignored the text in articles and used subject headings instead (An & Wu, 2011). Automatic analyses of the text of articles have also been used to identify, or differentiate between, different types of methods used. For instance, this approach has been used to track the evolution, over time, of computing technologies within library and information science research and to identify articles that used specific statistical

techniques (Thelwall & Wilson, in press). One particularly relevant study searched for a set of methods-related keywords (e.g., cohort study) in the titles of health-related articles in the Web of Science, and then compared the citation impacts of the articles found for each method (Patsopoulos, Analatos, & Ioannidis, 2005).

Patient involvement in research

In addition to often being involved in decisions about their own care (Charles, Gafni, & Whelan, 1997), patients are routinely the subjects of medical research to investigate the causes of, or cures for, their maladies. Patients can also be more actively involved in research by giving their opinions in open-ended questionnaires, or in interviews, or focus groups and by participating in steering groups for the co-ordination of research. Patients may also be involved in developing or promoting informational material to fellow sufferers (Greenfield, Kaplan, & Ware, 1985) or even in developing research policies (Nilsen et al., 2006). Gaining the patient's perspective can be helpful for research, for example, to get insights into the extent to which symptoms, in practice, vary from the norm (Cotrell & Schulz, 1993) and to understand and prioritise the problems that sufferers believe to be the most important to address (Serrano-Aguilar et al., 2009). Seeking the views of patients is sufficiently widespread for systematic reviews of this practice to be published for specific ailments (Morton et al., 2010). Nevertheless, the apparently widespread knowledge of the importance of patient involvement does not ensure that it occurs for all conditions.

Research questions

This paper investigates a contribution that ill people have made to health research, namely the extent to which health research has interviewed patients. The research questions are:

1. To what extent has the level of the research interviewing (and in particular the qualitative interviewing) of patients varied over time?
2. To what extent has the level of the research of interviewing (and in particular the qualitative interviewing) of patients varied between subject categories?

Method

The main data used to address the research questions is the approximate number of articles that refer to patient interviews and approximate number of articles that refer to qualitative patient interviews. This data, obtained for different WoS databases and subject categories, must be normalised to allow comparisons between findings for different years and subjects.

A simple way of normalising is to calculate the rate of interviewing and qualitative interviewing in each subject category would be to divide by the number of articles in the dataset investigated. For some subject categories only a small proportion of articles are closely related to patients, however, and so this ratio would be flawed. For instance, less than one fifth of Pharmacology Pharmacy articles refer to ‘patient’ in the topic.

In order to normalise the interview metric, this paper divides instead by the number of articles that refer to patients. This interview metric indicates the extent to which articles that refer to also refer to interviews. This choice is based on the reasonable assumption that studies on patient interviews will in generally refer to patient in their abstracts. In order to normalise the qualitative interview metric, this paper divides by the number of articles that refer to patients and interviews. This qualitative interview metric indicates the extent to which articles that refer to patient interviews also refer to the interviews being qualitative. This metric was chosen in order to limit the metric to research that plausibly could qualitatively interview patients (i.e., where patients and interviews are mentioned).

In order to calculate the interview metric and qualitative interview metric the following data was extracted from WoS: (a) the number of articles that contain ‘patient*’ in the topic (patient frequency), (b) the number of articles that contain ‘patient*’ and ‘interview*’ in the topic

(patient interview frequency), and (c) the number of articles that contain 'patient*', 'interview*' and at least one of 'qualitative*', 'open-ended', 'in-depth', ''semi structured' and 'semistructured' in the topic (patient interview qualitative frequency). The interview metric was defined as 1000*patient interview frequency/patient frequency; the qualitative interview metric was defines as 100*patient interview qualitative frequency/patient interview frequency. The multipliers of 1000 and 100 were chosen in order for most of the findings to be expressed between 10 and 100. The definition of the qualitative interview metric was preferred to the alternative definition of 10000*patient interview qualitative frequency/patient frequency as it indicates how the proportion of interviews that are qualitative varied over time and between subjects.

A possible source of inaccuracy in the interview metric is that articles with patient and interview in the topic do not necessarily refer to patient interviews. The accuracy of the interview metric was gauged through content analysis of a random sample of 50 WoS articles containing 'patient*' and 'interview*' in the topic; 90% of the records referred to interviews of patients or people associated with their illness. A possible source of inaccuracy in the qualitative interview metric is that articles with patient, interview and an indicator of qualitative in the topic do not necessarily refer to qualitative patient interviews. The accuracy of the qualitative interview metric was gauged through a content analysis of a random sample of 50 WoS records containing 'interview*' and at least one of ''qualitative*', 'open-ended', 'in-depth', ''semi structured' and 'semistructured'; 96% of the records indicate that the interviews were qualitative. Other possible sources of inaccuracy in these metrics are false positives (e.g., 'patient' can be used in sense not related to health, i.e., not impatient) and omissions (e.g., the list of terms for qualitative research is unlikely to be exhaustive).

As a high proportion of the search terms are in the article abstracts, it is important to confine the study to periods in which a high proportion of WoS records contain abstracts. A total of 84% of the records, of a random sample of 50 WoS articles published in 1991, contain abstracts, whereas the figure for WoS articles published in 1990 is only 8% (for 2013 the figure is 100%). Consequently, this study does not investigate years prior to 1991.

Results

In this paper, ''Patient incidence' denotes the number of articles with 'patient*' in the topic, 'Interview incidence' denotes the number of articles with 'interview*' in the topic per 1,000 articles with 'patient*' in the topic, and 'Qualitative interview incidence' denotes the number of articles with the indicators of qualitative in the topic per 100 articles with 'interview*' in the topic, 'SCI only' denotes articles in the Science Citation Index (SCI) and not in the Social Sciences Citation Index (SSCI), 'SCSI only' denotes articles in the SSCI and not in the SCI, 'SCI & SSCI' denotes articles in both the SCI and SSCI, and 'A&HCI' denotes articles in the Arts & Humanities Citation Index.

Table 1: Patient, interview and qualitative interview incidences for five WoS datasets.

Datasets	*Articles containing patient* in the topic*	*Interview articles per 1000 patient articles*	*Qualitative interview articles per 100 interview articles*
WoS	2,570,556	23.7	26.0
SCI only	2,309,924	11.0	16.5
SSCI only	67,088	134.5	35.1
SCI & SSCI	192,749	137.1	32.1
A&HCI	2,810	74.4	35.9

As can be seen in Table 1, for both SSCI only and SCI & SSCI the incidences of interviews are over 12 times the incidence for SCI only and the incidence of qualitative interviews is 90% higher than the incidence for SCI only. These differences are likely to be partly due to the different sizes of the databases and partly due to differences in the proportion of articles that mention patients. The table also indicates that interviews are relatively prevalent in social science research relating to patients and rare in science research relating to patients. Because of the small number of A&HCI articles that contain 'patient*' in the topic, this paper does not further investigate this dataset.

In response to Question 1 (variation over time) the incidence of interviews for WoS rose by 175% between 1991 and 2013 (Figure 1, left). The incidence for SCI only undulated between 1998 and 2013, (10.2 in 1998, 11.1 in 2013), whereas, during the same period, the levels of SSCI only and SCI & SSCI rose steadily (the 2013 levels are respectively 48% and 36% higher than the 1998 levels). Thus, the use of interviews in patient-related research seems to have risen more rapidly in the social sciences than in science, despite the lower initial prevalence of interviews in science research. The use of qualitative methods in interviews appears to have risen substantially in all the areas investigated. However, the increase is more rapid in social sciences research than in science research (Figure 1, right).

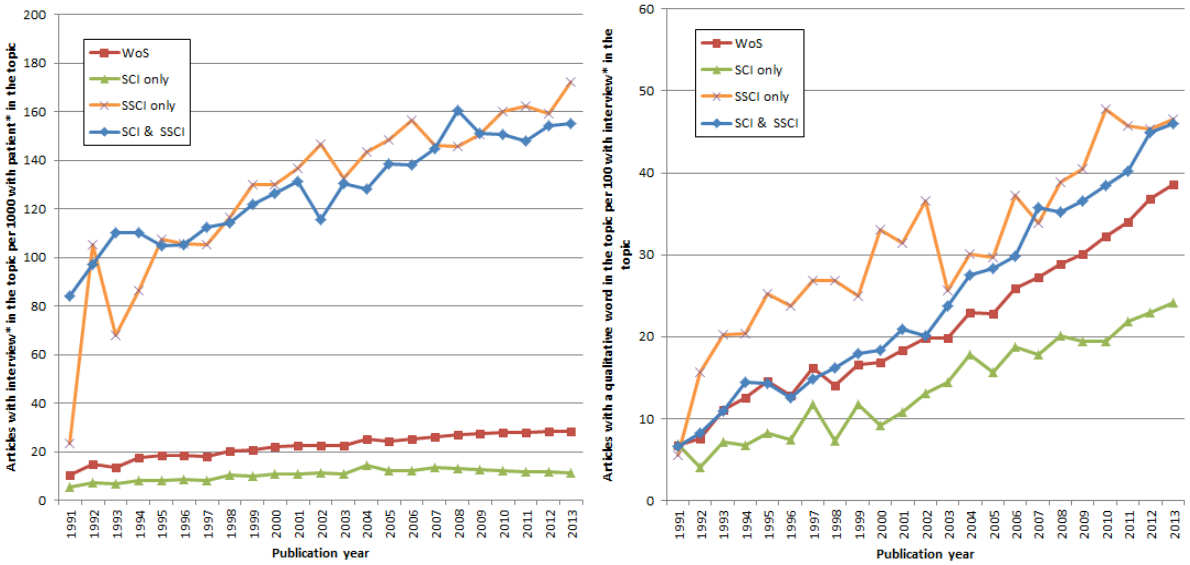

Figure 1. Annual incidence of interviews (left) and qualitative interviews (right).

In order to analyse disciplinary differences in more detail (Question 2), WoS categories were identified for each of the datasets SCI only, SSCI only and SCI & SSCI with at least 50 articles containing patient* and interview* in the topic. The ten categories identified were Clinical neurology, Health care sciences services, Health policy services, Nursing, Oncology, Pharmacology pharmacy, Psychiatry, Psychology, Public environmental occupational health and Rehabilitation. The incidence of interviews varies greatly between the ten categories, in addition to between science and social science research in the same category. The most extreme case is oncology, for which interviews are rare in science, but common in social science research (Table 2).

The incidence of qualitative interviews differs between science and social science in each individual category; qualitative interviews are more prevalent in social science research in 8 out of 10 categories (Table 2). For SCI only, the incidence of interviews is substantially lower for Clinical neurology, Oncology and Pharmacology pharmacy (average 12.0) than for the other seven categories (average 59.6). The incidence of qualitative interviews is also much lower for Clinical neurology, Oncology and Pharmacology pharmacy (average 14.0)

compared with the other seven categories (30.7). Hence, there are substantial disciplinary differences in the incidences of interviews and qualitative interviews within science.

Table 2: Incidence of interviews for ten WoS categories.

	Interviews			*Qualitative interviews*		
WoS category	*SCI*	*SSCI*	*Both*	*SCI*	*SSCI*	*Both*
Clinical neurology	16.5	65.1	107.3	11.9	25.0	17.6
Health care sciences services	92.2	99.9	157.5	41.4	30.3	46.5
Health policy services	76.0	182.7	125.4	31.6	47.6	39.0
Nursing	81.5	199.9	196.4	51.8	53.5	61.0
Oncology	7.2	226.3	195.2	15.0	47.7	45.7
Pharmacology pharmacy	12.3	199.2	67.6	15.2	58.0	17.8
Psychiatry	36.0	136.6	139.7	12.9	21.8	14.4
Psychology	46.0	102.2	115.5	25.9	17.7	19.4
Public environmental occupational health	53.3	219.8	170.6	20.0	44.3	37.0
Rehabilitation	32.5	86.7	137.9	31.0	34.5	52.4
Mean	**45.3**	**151.8**	**141.3**	**25.7**	**38.0**	**35.1**

For Clinical neurology, Oncology and Pharmacology, the percentage of articles in SCI only with patient* in the topic is particularly high: the percentage (in terms of articles in SCI or SSCI with patient* in the topic) for Clinical neurology is 89.3%, for Oncology is 96.4% and for Pharmacology pharmacy is 93.8%, whereas the average percentage for the other seven categories is 30.7%. There is a statistically significant Spearman correlation of -.81 between the interview incidence of SCI only and the percentage of articles with patient* in the topic that are in SCI only. This correlation reflects science categories having few interviews.

Limitations and conclusions

A limitation is that some studies with 'patient*' and 'interview*' in the topic do not interview patients (e.g., they interview physicians or carers of patients) and some studies with 'interview*' or indicators of qualitative in the topic do not conduct qualitative interviews (e.g., they combine quantitative interviews with qualitative analysis of patient records). But, as this research is comparative and the variations over time and between subjects are substantial, it seems likely that this limitation would not greatly affect the overall findings. Another limitation is that the results rely on the WoS journal subject classifications for journals. This may have a significant impact on the results for individual subject categories, as individual journals may have a substantial minority of the articles in a category. It would be useful to apply the techniques here to the full text of papers to help assess how often patient are involved in research but this is not discussed in the abstract of a paper.

After adjusting for the increase in the number of articles with 'patient*' in the topic, the number of WoS articles with 'interview*' in the topic increased by 175% from 1991 to 2013, suggesting that the use of patient interviews has increased substantially over the past 23 years. This may reflect a general trend towards involving patients more frequently in research, or an increase in the amount of research published, or indexed in WoS in research areas that typically involve patient interviews, such as nursing. In addition, after adjusting for the increase in the number of articles with 'patient*' and 'interview' in the topic, the number of articles that also had an indicator of qualitative in the topic increased by 511% from 1991 to 2013. This suggests that qualitative approaches are increasingly prevalent in health interviews, or that the qualitative nature of the research is more frequently specified. An

alternative explanation is that the amount of research published, or covered in WoS, has expanded in areas in which qualitative interviews are particularly common.

The incidences of interviews were particularly low amongst articles that were in SCI only; for 1991-2013 the incidence is less than one twelfth of the incidence for SSCI articles. When confining the study to categories present in both the SCI and the SSCI, there was a very marked difference between the datasets; however, the difference was substantially lower when excluding categories in which over 85% of the articles are in the SCI.

In the context of the NIHR aim of promoting a research-active population, the increased prevalence of patient interviews and qualitative interviews is encouraging, but categories with low percentages of interviews (e.g., Clinical neurology, Oncology and Pharmacology pharmacy) need to be further investigated to check whether individual subject areas are giving too little credence to patient interviews. Finally, this paper indicates that the technique of using simple co-word metrics based on the presence of words in the topic of WoS records can be applied usefully to informetric tasks. However, when investigating articles published prior to 1991, it is important to take into account that only a low percentage of WoS records for articles published in 1990 have abstracts.

Abstract
International collaboration on research publications is increasingly evaluated as part of a raft of performance measures. Levels of international co-authorship have increased substantially over the last few decades and vary substantially by research field and publication type; however, these variations are not typically accounted for by international collaboration indicators. In this research-in-progress paper, we introduce a novel metric, the Normalised International Collaboration Score, which adjusts the number of countries appearing on publication records using baselines relevant to the subject, age and type of the publication. A pilot analysis shows that these baselines vary substantially and that the application of this metric yields very different results to a more common measure of international collaboration. The limitations of the metric are discussed, along planned extensions for the full version of the study, as well as the relationship between normalised collaboration and citation.

Conference Topic
Indicators

Background and Purpose

Measuring international co-authorship

The availability of author address metadata on publication indices such as Web of Science and Scopus allows the analysis of patterns in co-authorship, including the collaboration by authors from different countries on research outputs. This approach has been used in many studies for decades (such as Glänzel & De Lange, 1997; Narin, Stevens, & Whitlow, 1991; Nederhof & Moed, 1993) and metrics describing international collaboration now appear regularly in bibliometric handbooks (Colledge, 2014; Rehn, Kronman, & Wadskog, 2007) and in reporting tools such as Thomson Reuters' InCites, Elsevier's SciVal and SCImago's Journal & Country Ranking. Such publications tend to receive higher levels of citation, an effect that is not due to the increased propensity for self citation arising from additional authors (Van Raan, 1998), but likely rather shared experience, knowledge and equipment.

Analysis of international co-authorship metadata has highlighted other important aspects of collaboration. Firstly, levels of international collaboration have increased substantially over the last quarter century (Leydesdorff & Wagner, 2008); and secondly, levels of international collaboration vary by field of research (Frame & Carpenter, 1979). A report on Thomson Reuters' InCites (retrieved 7 January 2015) indicates that 2013 articles, reviews and proceedings papers in Tropical Medicine involved international collaboration 46.7% of the time, while for History, this was only 4.3% of the time. Even within Medicine, Emergency Medicine saw only 9.9% foreign collaboration, far lower than Tropical Medicine. Variation is significant over time, with Astronomy & Astrophysics international collaboration rising from 19.4% in 1993 to 45.0% in 2013. To these two aspects, we must add publication type; 2013

Astronomy & Astrophysics articles saw 51.4% international collaboration, but its Proceedings Papers only 0.2%. Such variations exist across the full gamut of subject, years and publication types but most metrics used to evaluate collaboration do not take account of them.

Existing metrics

Frequently, analyses use either the number or proportion of collaborative publications (see for example Boekholt et al., 2009; Colledge, 2014; Luukkonen et al., 1993). Glänzel and De Lange (2002) use a Multilateral Collaboration Index to measure the number of collaborative links compared to the number of collaborative papers, establishing the intensity of collaboration.

Beaudet, Campbell, Côté, Haustein, Lefebvre and Roberge (2014) use a regression model based on power law relationships to establish the expected level of collaboration for a country and an Affinity Index to identify key partners. Degelsegger et al. (2013) propose thematic assessment, normalized either by relating it to the output of the country in the subject, or by comparing it to co-authored output in the same subject but with a different partner. Ding, Yang and Liu (2013) propose using network metrics to evaluate collaboration impact, which is a sound approach within a subject and time frame. Pohl, Warnan and Baas (2014) go the greatest distance to normalizing for the three aforementioned influences, by adjusting the proportion of publications with international collaboration by the number of collaborating countries in each subject. This study only considered a single year, however, did not adjust for publication type and was based on adjusting the share of research with a binary attribute (either internationally collaborative or non-internationally collaborative). The properties and results of this alternative will be compared to our metric in the full version of our study.

The Normalised International Collaboration Score (NICS)

The Normalised International Collaboration Score uses fundamentally the same calculation as the "new" Crown Indicator by which it was inspired (Waltmann, van Eck, van Leeuwen, Visser, & van Raan, 2011). For each publication, a global baseline is constructed, representing the average number of countries contributing to publications of the same type, from the same year and appearing in the same subject area(s). The number of countries contributing to the publication in question is then divided by the relevant baseline to yield a ratio. This ratio is then averaged for all publications in a set (for an institution, country, journal, etc). Our exploratory analysis uses both the mean (as in the Crown Indicator) and the statistically preferable median (Bornmann, Mutz, Neuhaus, & Daniel, 2008), for the purposes of comparison. While the present study only includes a selection of publication types, years and subjects, our full study will include all subjects and publication types back to 1996.

Methodology

The Advanced Search function on Web of Science was used to isolate publications of the Article, Review and Proceedings Paper types with issue cover dates in 1993, 2003 and 2013, and allocated to the subject categories Dance, Engineering (Manufacturing), Evolutionary Biology, Gastroenterology & Hepatology, Political Science, Psychology (Educational), Soil Science and Tropical Medicine. These publication types were selected as those most likely to contain address data; these years as spaced such to demonstrate evolution in collaboration trends and aspects of the data; and those subjects as representing a broad spectrum across science, social science, and the arts and humanities. The selection of a single discipline of period would not have illustrated any variation over time or theme. Record metadata were downloaded, tagged with the relevant subject name and recombined into a single dataset. Individual addresses were broken out, the non-country information in each field deleted and duplicate country entries deleted. A count of unique country contributions per publication was

made. The baselines were constructed by averaging all unique country contribution counts for each combination of year, publication type and subject, using the arithmetic mean and the median. These represented the denominator of the metric's article-level ratio.

The institutional data came from a database of Australian publication records from 2001 to 2014. A query extracted the unique identifier, selected subject areas, year, type and Crown Indicator of each publication, along with the author addresses. The addresses were subjected to a unique contributing country count, yielding the numerator of the metric's article-level ratio. The subject, publication type and publication year data were used to look up the mean and median baseline data (our ratio's denominator). Dividing the latter by the former yielded the article-level NICS, which was then averaged for each Australian institution – using the arithmetic mean and then the median, as appropriate for the baseline.

This gives the following notation for the mean form of NICS:

$$\frac{1}{p}\sum_{i=1}^{p}\frac{n_i}{g_i}$$

And the following notation for the median form of NICS:

$$\widetilde{\left(\frac{n_i}{m_i}\right)}$$

Where p denotes the number of publication produced by a unit of analysis, n_i denotes the number of countries contributing to the unit's publication i, g_i denotes the global mean number of countries contributing to publications of the same type, year and subject(s) as publication i and m_i denotes the global median number of countries contributing to publications of the same type, year and subject(s) as publication i. A third, "hybrid", version of was calculated, finding the median of article level ratios based on a mean:

$$\widetilde{\left(\frac{n_i}{g_i}\right)}$$

Results & Discussion

Table 1 shows the mean baselines for each year in each subject, combining publication types into a single entry. Several points are clear. Some subjects see a substantial increase in average country contributions over time – such as the increase from 1.15 to 1.71 for Evolutionary Biology – indicating a need to normalise for this change if fair comparisons are to be made among publication sets from different year ranges. There are also significant disparities between subjects, with the Engineering subject baseline 1.09 in 2013, compared to 1.78 for Tropical Medicine. It is also notable that, unlike citation counts, there does not seem to be a pattern of lower country contributions for social sciences as opposed to sciences, at least in this very limited dataset; Political Science has one of the higher baseline sets and Engineering, Manufacturing one of the lower. Lastly, some subjects, most likely those in the Arts & Humanities, may be difficult to assess using this metric, due to a paucity of address and a low publication count; the baselines would be based on too low a sample size and very prone to skew from outliers. It is also worth noting that, while country contributions are strongly positively skewed, the variance of the natural log of country contribution counts is lower than that of citation counts for publications of the same year, type and subject, in a all of a selection of the below instances that were considered.

Table 2 shows the number of publications missing address data in each of the three years for each subject. Coverage is a problem in Dance for all years and is more of a problem in the social science subjects than the sciences, but is an issue for all subjects in 1993. In the full analysis, work will be conducted to establish the point at which coverage is sufficient for robust analysis, but the institutional analysis in this pilot study exclude the 1993 publications.

Table 1. Mean Subject Country Contribution Baselines by Year.

	1993		*2003*		*2013*	
Table	*# Pubs*	*# Countries*	*# Pubs*	*# Countries*	*# Pubs*	*# Countries*

Political Science	987	1.15	3172	1.26	5549	1.76
Psychology, Educ.	483	1.05	1167	1.10	2253	1.20
Soil Science	1724	1.09	3890	1.23	4721	1.36
Tropical Medicine	798	1.45	1381	1.68	3128	1.78

Table 2. Instances of Publication Entries Missing Address Data by Year.

	1993			*2003*			*2013*		
Table	*No Address*	*Total Pubs*	*%*	*No Address*	*Total Pubs*	*%*	*No Address*	*Total Pubs*	*%*
Dance	245	247	99.2%	386	411	93.9%	184	230	80.0%
Eng., Manufact.	936	2178	43.0%	587	8522	6.9%	219	14732	1.5%
Evolutionary Biology	698	1685	41.4%	15	3915	0.4%	10	5553	0.2%
Gastro. & Hepat.	2080	5647	36.8%	158	8753	1.8%	68	11368	0.6%
Political Science	3421	4408	77.6%	965	4137	23.3%	636	6185	10.3%
Psych., Education.	573	1056	54.3%	20	1187	1.7%	47	2300	2.0%
Soil Science	1702	3426	49.7%	132	4022	3.3%	16	4737	0.3%
Tropical Medicine	475	1273	37.3%	11	1392	0.8%	24	3152	0.8%

Table 3 shows the mean baselines for each publication type in each subject, combining years into a single entry. It is clear that publication type is also a major factor for the baselines, with the Proceedings Papers consistently seeing fewer country contributions than other types. However, there is further variation; Political Science, for example, sees higher country counts for Articles than Reviews, while the reverse is true for Soil Science.

Table 3. Mean Subject Country Contribution Baselines by Publication Type.

	Articles		*Proceedings*		*Reviews*	
Table	*# Pubs*	*# Countries*	*# Pubs*	*# Countries*	*# Pubs*	*# Countries*
Dance	73	1.10	-	-	-	-
Engineering, Manuf.	9192	1.20	14398	1.00	100	1.23
Evolutionary Biology	9665	1.54	101	1.00	664	1.59
Gastroent. & Hepat.	20482	1.21	811	1.00	2169	1.24
Political Science	8650	1.57	790	1.18	268	1.28
Psychology, Educ.	3542	1.16	263	1.00	98	1.09
Soil Science	8547	1.31	1641	1.01	147	1.69
Tropical Medicine	5113	1.71	23	1.00	171	1.73

Table 4 shows a comparison of institutional collaboration analysis using the proportion of publications with international collaboration and each of the three variants of the NICS metric. The Median calculation appears the least useful; every baseline in each year, subject and document was 1, so this version essentially reports the median country contribution per article and cannot strongly differentiate among institutions. The version using mean baselines are more useful for ranking but, like the Crown Indicator, remains sensitive to outliers (as in the example of Flinders University, where performance was inflated by a single article with 35 contributing countries). Even though the full study will involve far larger sample sizes, which should be less susceptible to such outliers, it appears that the "hybrid" (median of ratios based on mean baselines) is the strongest option. This would preclude statistical analysis based on parametric data, but it is impossible to tell from the pilot study whether the article level results of the mean calculation would be normally distributed on a global scale either.

Discussion

While only a few institutions see a large difference in ranking when applying NICS rather than proportion of international publications, the difference in results and the variations in baselines on which they are based suggest the metric has informational content. It is also worth noting that, at an article level, the Crown Indicator correlates positively and fairly strongly with NICS (Spearman's Rank r=0.384) and that at an institutional level, the two versions of NICS derived from mean baselines correlate more closely with NCI performance (r=0.289 and 0.148) than does share of publications with international collaboration (r=0.09).

There are clearly limitations to this approach. It does not account for collaboration intensity; eight co-authoring institutions in a specific foreign country count the same as one. The NICS

baselines could be rescaled to count not only contributing foreign countries but also the numbers of institutions in those countries, and even potentially types of institutions. As it would require a set of baselines for each country, this would be computationally intensive but will be explored in the full study. This approach would also normalise for the propensity of a country to collaborate, which many of the above-mentioned metrics are aimed at doing. Lower collaboration levels can arise from several causes, including a lower advantage yielded and having a large share of global output (therefore limiting the avenues available for external collaboration); normalising for national collaboration levels may obscure these differences and render accurate national comparisons challenging. In its present form, NICS serves best as a metric to compare the collaboration of countries and institutions, variations in which may then be considered in the context of national motivation and propensity to collaborate.

Other criticisms leveled at the Crown Indicator apply to NICS, most notably a limited representation of global output in some subjects and of some publication types, and the reliance on a subject taxonomy designed for information retrieval rather than bibliometric analysis. In the pilot study, moreover, many articles analysed here appeared in more than one subject area, and yet were normalised only with the baselines for one of those subject areas.

The full study will apply a wide range of statistical tests to the properties of the baselines, the country contribution counts and the resultant ratios; for now, however, and even with the aforementioned caveats, this metric shows potential for robust and meaningful analysis of institutional and national research collaboration abroad.

Bibliometric Indicators of Interdisciplinarity Exploring New Class of Diversity Measures

Alexis-Michel Mugabushaka[1], Anthi Kyriakou & Theo Papazoglou

[1] *Alexis-Michel.MUGABUSHAKA@ec.europa.eu*
European Research Council Executive Agency[1], Brussels, (Belgium)

Abstract
In bibliometrics, interdsicsiplinatity is often measured in terms of the "diversity" of research areas in the references that an article cites. The standard indicators used are borrowed mostly from other research areas, notably from ecology (biodiversity measures) and economics (concentration measures). This paper discusses a new class of measures, which are used in the study of biodiversity and especially the Leinster-Cobbold diversity measure (Leinster Cobbold 2010). We present a case study based on previously published dataset of 12 journal articles from a group of five researchers from the bio-nano science described and published by Rafols and Meyer (2010). We replicate the findings of this study to show that the various interdisciplinarity measures are in fact special cases of the Cobbold-Leinster diversity measure. The paper discusses some interesting properties of the Cobbold-Leinster diversity measure, which makes it appealing in the study of disciplinary diversity than the standards diversity indicators used as proxy for interdisciplinarity.

Conference Topic
Indicators

Introduction
Considerable efforts have been made to operationalize and measure the concept of interdisciplinarity in bibliometrics (Porter et al., 2007; Rafols & Meyer, 2010). The most commonly used indicators of interdisciplinarity are mostly borrowed from other research areas, notably from ecology (biodiversity measures) and economics (concentration measures).
The purpose of this paper is to bring to discussion a relatively new class of diversity indicators which are used in ecology but so far not been used to investigate disciplinary diversity. Drawing from the literature in ecology, the paper highlights important properties of those measures and discusses how they can help the bibliometric study of interdisciplinarity.
The paper is divided in three parts. The next section briefly presents indicators of interdisciplinarity in bibliometrics. The second section discusses the development of new class of diversity measures used in ecology and presents the Leinster-Cobbold diversity measure, highlighting its properties and why they are relevant for bibliometric usage. The third section presents a case study to illustrate the potential of Leinster-Cobbold diversity indicators as a measure of disciplinary diversity.

Currently used Bibliometric indicators of interdisciplinarity
Bibliometric analyses of interdisciplinarity take as unit of analysis a scientific paper and assume that the extent to which it integrates elements of different disciplines is reflected in the references it cites. References in scientific papers are expected to reflect various aspects of interdisciplinary because researchers will credit what they are indebted to other disciplines: conceptually (concepts, ideas and approaches from other disciplines); analytically (methods for defining, collecting and analyze data) and technically (tools developed in other fields).

[1] The views expressed in this paper are the authors'. They do not necessarily reflect the views or official positions of the European Commission, the European Research Council Executive Agency or the ERC Scientific Council.

Porter et al. (2007) developed the integration score as measure of interdisciplinary which takes into account not only the distribution of the cited references in different subject categories but also how closely related those subject categories are (see also Porter et al., 2006; Porter et al., 2008). In line with Porter's conceptualization, Rafols and Meyer (2006, 2010) introduced a new set of bibliometric indicators to quantify the disciplinary diversity of references as a proxy measure of interdisciplinarity. They are mostly based on the general framework for analyzing diversity developed by Stirling (2007). The most commonly used indicators are summarized in table 1. We note that there are also efforts to use network based measures (Rafols & Meyer, 2010; Karlovčec & Mladenić, 2015) but here we focus on diversity measures.

Table 1. Most common indicators of interdisciplinarity in bibliometric studies .

Indicators	Definition/description	
Variety	The number of different disciplines that a given paper cites**	N
Shannon entropy	As measure of diversity the Shannon Entropy quantifies how diverse the subject categories in the references are.	$H_{SH} = -\sum_{i=1}^{S} p_i \log p_i$ Where p_i is the proportion of elements in a system and S the number of elements in the system.
Simpson diversity	It measures how references are distributed (or concentrated) in subject categories.	$H_{GS} = 1 - \sum_{i=1}^{S} p_i^2$ Where p_i is the proportion of elements in a system and S the number of elements in the system
Rao-Stirling index	Can be understood as the Simpson diversity which takes into account distance/similarity (between disciplines).	$= \sum_{i,j} d_{i,j}\, p_i p_j$ Where di,j is the distance between the ith and jth element in the distance matrix and pi is the proportion of element i

Source: Rafols & Meyer 2010, p. 267 **Its variants includes normalization by the total numbers of subject categories or the shares of references outside a given subject category

New classes of diversity measures in ecology

Effective numbers

The diversity measures listed in table are also among the commonly used indicators of biodiversity in ecology. However, they have recently faced strong criticisms (Jost, 2006; Chao & Lou, 2012).

The main criticism is that those measures fail to satisfy the most basic property that ecologist would expect from a meaningful measure of diversity, namely the replication principle. In simple term, the "replication principle" states that if you have two completely distinct communities (i.e. without any overlap in the species) with each community having a diversity measure X, one would expect that combining those two communities would result in a community with a diversity measure 2X.

One category of diversity measures, which satisfy this replication principle is the so called "Hill-numbers" (also called "effective numbers of species"). They can be interpreted as the

"number of equally abundant specifies that are needed to give the same value of the diversity measure (Chao & Lou, 2012, p. 204).

The Hill numbers have some properties that other measures of diversity based on entropy lack:

- They satisfy the replication principles. i.e. two communities with each 4 effective numbers of species will – if pooled together – result in a community whose effective number equal 8. They therefore give logically consistent answers.
- Their linear scale makes it easier to interpret the magnitude of their change.
- In addition to this this advantage of intuitive consistency, they have another interesting property that we call "unifying framework status". Jost (2006) has shown that practically all traditional measures of diversity can be easily converted to "Hill numbers/ "effective numbers" and vice-versa.

Leinster-Cobbold Diversity Measure

Leinster and Cobbold (2012) developed a measure, which extends the Hill numbers to include the similarities/differences between species. Their measure – called here the Leinster-Cobbold Diversity Measure - can be used with any similarity coefficient between each pair of the species. This extends the scope of its usage to other contexts such disciplinary diversity in bibliometrics. In the following, we first provide its formal definition and discuss its properties as well as its relation to other diversity measures. In the next section we provide a case study of its use in the study of disciplinary diversity.

Consider a system with S elements with relative frequencies translating in estimated probabilities p = (p1, …, pS) so that $\sum_{i=1}^{S} p_i = 1$

The similarity between the elements is encoded in an S x S Matrix Z.

Z = (Z_(i,j)), with Z_(i,j) measuring the similarity between the ith and jth elements.

Whereby 0 ≤Z_(i,j) ≤1, with 0 indicating total dissimilarity and 1 indicating identical elements.

The Leinster-Cobbold diversity measure is defined as

$$ {}^{q}D^{Z}(\boldsymbol{p}) = \begin{cases} \left(\sum_{i:p_i>0} p_i (Z\boldsymbol{p})_i^{q-1} \right)^{\frac{1}{1-q}} & q \neq 1, \\ \prod_{i:p_i>0} (Z\boldsymbol{p})_i^{-p_i} & q = 1, \\ \min_{i:p_i>0} \frac{1}{(Z\boldsymbol{p})_i} & q = \infty. \end{cases} $$

where

$$ (Z_p)i = \sum_{j=1}^{S} Z_{i,j} p_i $$

q is in number in range 0 ≤ q ≤ Infinity. It is called a sensitivity parameter and control the relative emphasize that the user wishes to place on common and rare species.

Case Study: Using the Leinster-Cobbold Diversity as a measure of disciplinary diversity

In our view, there are three main advantages in adopting the Leinster and Cobbold diversity measure in the study of disciplinary diversity as well:

- First, Leinster and Cobbold (2012) have discussed the relation between this measure and other diversity measures and showed that they can be seen as its special cases. The advantage here would be to have a single formula which would replace the Shannon entropy, the Simpson Diversity and the Rao-Stirling Index used in bibliometrics.
- Second, because the Leinster and Cobbold measure quantifies diversity on a spectrum which depends on how much emphasis should be given to relatively rare elements (sensitivity parameter q), it provides potentially more information than measures which consider only one value of this sensitivity parameter.
- The third advantage is the intuitive consistency of the Leinster and Cobbold measure. Because it directly produces "effective numbers" which obey the replication principle, the values can be easily interpreted and compared. Consider two publications: one with references from 2 (unrelated) categories and the other with reference from 4 (unrelated) categories. With the Leinster and Cobbold measure, they can be compared to say that the second has a twice as large diversity in references as the first one.

In the following, we present a case study to illustrate the potential of Leinster-Cobbold diversity profiles in quantifying disciplinary diversity.

Disciplinary diversity of selected papers in bio-nanoscience (Rafols & Meyer 2010)

The case study is based on a dataset of 12 journal articles from a group of five researchers from the bio-nano science described and published by Rafols and Meyer (2010). For those 12 papers, Rafols and Meyers published the distribution of their references in Web of Science Categories (Rafols & Meyers, 2010; p. 276, Table 3) as well as the scores on various indicators of diversity (ibid. p. 277, Table 4). The similarity/distance measures between the Web of Science subject categories are taken from the supplementary materials to the paper[2] by Chavarro et al. (2014).

This case study illustrates that the various diversity measures are in fact special cases of the Leinster-Cobbold diversity profiles. We do this by replicating the diversity measures computed by Rafols and Meyer 2010 using the Leinster-Cobbold diversity profiles. We first compute the values of the Leinster Cobbold measure using different values for the sensitivity parameters (0, 1, 2, 3, 4 and infinity) and in two variants: without taking into account the

[2] http://www.interdisciplinaryscience.net/topics/interdisciplinarity-and-local-knowledge

distance/similarity between the subject categories (i.e. the matrix Z is an identity matrix) and by taking into account the distance/similarity between the subject categories (using the similarity data provided in supplementary materials of Chavarro et al. (2014). Using the conversion formulas in the first row of Table 3, we use those Leinster Cobbold values to derive the diversity measures provided in Rafols and Meyer 2010 (table 4 on page 277). The Table 3 below replicates the diversity values reported in Rafols and Meyer 2010. There are some differences, which are due to rounding but also to the fact that some indicators in Rafols and Meyer (2010) were given in normalized form.

Concluding remarks

In bibliometrics, the interdisciplinarity is operationalized in terms of the diversity of the references in a scholarly article. The most commonly used indicators are derived from the fields of ecology (biodiversity measures) and from the fields of economics (concentration measures). We discuss a new class of biodiversity measures – the "effective numbers" - which not only generalize most of other diversity measures but also have some proprieties which make their interpretation intuitively consistent with the concept of diversity Jost (2006). They were further developed by Leinster-Cobbold (2012) to take into account the similarity/distance of elements (species) in a system (community). We provide an example on how the bibliometric indicators of interdisciplinarity are in fact special cases of this more general Leinster Cobbold indicator.

Future work should not only take a closer look at their statistical properties (distribution, parameters etc.) but also test their reliability and validity. In particular, it would be of interest to analyze how sensitive the indicators are to various degree of granularity of different classifications of research disciplines and to assess extent to which they depend on measures of distances used.

Acknowledgments

We thank Ismael Rafols for helpful comments on an earlier draft of the paper and Diego Chavarro for making the similarity matrix freely available.

Abstract
Research funding organizations invest substantial resources to stay current with important research findings within their mission areas to identify and support promising new lines of inquiry. To that end, we continue to pursue the development of tools to identify research publications that have a strong likelihood of driving new avenues of research. This research-in- progress paper describes our work incorporating multiple time-dependent and -independent features of publications into a model that aims to identify candidate breakthrough papers as early as possible following publication. We used multiple Random Forest models to assess the ability of indicators to reliably distinguish a gold standard set of breakthrough publications as identified by subject matter experts from among a comparison group of similar *Thomson Reuters Web of Science*™ publications. These indicators will be selected for inclusion in a multi-variate model to test their predictive value. Prospective use of these indicators and models is planned to further establish their reliability.

Conference Topic
Indicators

Introduction
The National Cancer Institute (NCI) of the US National Institutes of Health (NIH) continues to show a commitment to encouraging transformative research, which the NIH recognizes on its Transformative Research Award website as "unconventional research projects that have the potential to create or overturn fundamental paradigms." Key requirements for identifying and nurturing these potential scientific breakthroughs are an enhanced understanding of the research landscape and awareness of novel approaches with great potential.

Defining Breakthrough Publications
The term "breakthroughs" has been used in prior work by Thomson Reuters (Ponomarev et al., 2014) and operationally, breakthrough publications have previously been defined as those that are highly cited and result in a change in research direction. The body of literature addressing breakthrough publications also uses the term "transformative research." Here, we define a breakthrough publication as an article that results from transformative research. In 2007, the National Science Board (NSB) defined transformative research as "research driven by ideas that have the potential to radically change our understanding of an important existing scientific or engineering concept or leading to the creation of a new paradigm or field of science or engineering. Such research also is characterized by its challenge to current understanding or its pathway to new frontiers" (NSB, 2007).

Prior Work Identifying Breakthrough Publications
Much of the research literature on breakthroughs focuses on retrospective identification of breakthroughs or pivotal points within a specific topic or field (Chen, 2006; Compañó & Hullmann, 2002; Fujita et al., 2012; Huang et al., 2013; Klavans et al., 2013; Ponomarev et

al., 2014). In addition, many of the current approaches require manual selection or curation of all data analysed (Chen, 2006; Klavans et al., 2012). Ponomarev et al. (2014) used variations of a single indicator, citation velocity, to predict highly cited papers while other groups made use of multiple indicators, full-text data and/or co-citation analysis to identify and characterize breakthrough publications in retrospective analyses (Chen, 2006, 2012; Klavans et al., 2012; Klavans et al., 2013). Other efforts focused on the development of analysis and visualization tools for quick visualization and assessment of potential turning points and breakthroughs (Boyack & Börner, 2003; Dunne et al., 2012).

Here, we aim to establish automated and semi-automated approaches to provide early indicators of published research with great potential. The goal is to provide program staff with a robust methodology that highlights pockets of breakthrough research, thereby enabling more informed program management. The methodology leverages an array of indicators to identify work that may contribute significantly to progress in its field. Here we describe work done to identify time-dependent and -independent publication indicators for differentiating breakthrough papers.

Data and Methods

Creating a Gold Standard Data Set

The first challenge in testing the importance of various publication features in predicting research breakthroughs is defining a core set of publications to be used as a gold standard. For our gold standard set of breakthroughs, we selected research articles from the following sources that highlight advances in cancer research:

1. The American Association of Cancer Research (AACR) publishes the AACR Cancer Progress Report annually (176 articles from the 2011-2014 reports).
2. The American Society of Clinical Oncology (ASCO) reports on key research in their annual Report, ASCO Clinical Cancer Advances. (58 articles from the 2009-2013 reports).
3. *Nature Medicine* 2011 special edition focused on advances in cancer research (74 articles spanning publication years 2008-2010).

Using these three sources we identified 287 distinct breakthrough publications that were indexed in the *Web of Science.* Table 1 shows the frequency by *Web of Science* Journal Subject Category. The inclusion of older publications (e.g., publication years of 2008 and 2009) enabled the curation of a dataset that included papers mature enough to have a range of breakthrough characteristics.

Table 1. Top 10 Web of Science Journal Subject Categories by Frequency for the Breakthrough Gold Standard Set (N=287).

Journal Subject Category	Count
Oncology	118
Medicine, General & Internal	109
Multidisciplinary Sciences	31
Cell Biology	17
Biochemistry & Molecular Biology	11
Public, Environmental & Occupational Health	7
Hematology	7
Genetics & Heredity	6
Immunology	6
Medicine, Research & Experimental	5

227 of the 287 breakthrough publications (81.7%) were published in journals in either the Oncology or Medicine, General & Internal *Web of Science* Journal Subject Categories.

Comparison Group Publication Set

We chose a comparison group of publications from a similar set of *Web of Science* Journal Subject Categories. We retrieved 647,879 publications from the 1) Oncology and 2) Medicine, General and Internal categories published between 2008 and 2014. We selected 2,500 publications at random from this dataset for use as the comparison group. We chose to select our control group by matching on the distribution of journal subject categories between the gold standard and comparison sets. However, we did not match the control group on publication year distribution due to the uneven publication year distribution resulting from the gold standard selection criteria.

Publication Indicators- bibliographic, citations, and altmetrics

We collected data from *Web of Science* to generate indicators for inclusion in our assessment. The majority of indicators were derived from the individual *Web of Science* citation records. These indicators were at the publication level (Table 2) and were collected in January 2015. While using a field-normalized Journal Impact Factor (JIF) would have been preferable, some publications in the gold standard set do not have JIFs determined for the publication journal, so we chose to use JIF best quartile as the best available alternative. Npayoffs reflects the inclusion of altmetrics gathered from *Web of Science* usage.

Table 2. Publication-level Indicators Considered For Inclusion in Random Forest Models.

Indicator level	Variable	Description
publication	TimesCitedTotal	total cites
	TimesNSCitedTotal	total cites (non-self)
	TimesCited2y	total cites in past 2 years
	TimeNSCited2y	total non-self cites in past 2 years
	NPages	total number of pages in an article
	NCitedRefs	number of references
	NAuthors	number of authors
	PubYear	publication year
	NCitedJSC	number of JSCs present in cited references
	NCountries	number of countries associated with publication authors
	NOrgs	number of institutions associated with publication authors
	CitVel6m	Citation velocity of specified time period (or maximum number of days since the article was published)
	CitVel1y	
	CitVel2y	
	CitVel5y	
	Bestquartile	Journal's best quartile from the 2013 Journal Citation Report
	DocumentTypeID	Describes publication type (article, review, etc.)
	Npayoffs	Total number of payoff events in Web of Science since January 2013 • A payoff event is when a WoS user downloaded the full-text article, added EndNote library, or saved for future use • Robot data filtered using multiple algorithms

Author-level indicators, person disambiguation

Some of the indicators in the study at the publication-level require a time lag after publication so we sought to increase the number of indicators that could identify potential breakthroughs immediately upon publication. Currently, these additional indicators are based on author publication history characteristics (Table 3). A critical aspect of author-based indicators is ensuring that each author's characteristics are correctly attributed. Therefore, we used a proprietary semi-automated algorithm to disambiguate authors and assign publications to each unique author.

Author-level indicators were assigned to each publication and computed in one of two ways: by averaging the indicator for all authors on a publication or by averaging the indicator for the top three authors on the paper as ranked by the indicator values.

Table 3. Author-level Indicators Considered for Inclusion in Random Forest Models.

Indicator level	Variable	Description
author	AvgNCoAuth	Number of distinct co-authors on all publications in the journal subject categories of oncology or general and internal medicine from 2008-2014
	AvgNCoAuth_Top3	
	AvgHindex	H-index based on all publications in the journal subject categories of oncology or general and internal medicine from 2008-2014
	AvgHindex_Top3	
	AvgPubHist	Total number of publications in the journal subject categories of oncology or general and internal medicine from 2008-2014 divided by six years
	AvgPubHist_Top3	
	NHighCitPubs	Highly cited publications defined by top 10% of publications in a particular year and journal subject category
	AvgNHighCitPubs	
	AvgNHighCitPubs_Top3	

Random Forest™ Model

We used the Random Forest™ machine learning algorithm (Brieman, 2001) as implemented by Liaw and Wiener (Liaw & Wiener, 2002) to assess the relative importance of each of the indicators listed above for differentiating breakthroughs from our comparison group. As Random Forest™ cannot handle null values; we were required to exclude all publications without citations and all publications where authors could not be disambiguated. This resulted in a final dataset of 223 breakthrough publications and 1,170 comparison publications.

The Random Forest™ algorithm is an example of a bagged decision tree algorithm (Breiman, 1996) that combines the classification results of some number N of individual decision trees. This set of N trees comprises the forest and is one of two input parameters that can be specified by the user. The other input parameter is an integer m which specifies the number of variables to consider when deciding how many variables to use for each node in the tree. Details on implementing this algorithm can be found in Liaw 2002 and references therein. As the random forest is built, a random subset of 2/3 of the data is used in the construction of each tree. The remaining 1/3 of the data is referred to as 'out-of-bag' (oob). For the analyses shown, the values $N = 500$ and $m = 4$ were found to minimize the out-of-bag error rate, which is a measure of the misclassification of the oob data by the random forest.

Results

We first examined the correlation among our publication indicators and removed the following indicators that were highly correlated: CitVel6m; CitVel2y; CitVel5y; TimesCitedTotal; TimesCited2y; AvgHindex_Top3; NHighCitedPubs_Top3. With the remaining set of indicators, we then ran the first Random Forest models using both the Mean

Decrease Accuracy (MDA) and Mean Decrease Gini (MDG) to determine the relative importance of the indicators, as shown in Figure 1. The indicators with the highest relative importance are time-dependent (left of the dotted line). However, in order to best inform program management, it would be preferable to predict breakthroughs soon after publication, requiring indicators that can be calculated at, or near, the time of publication.

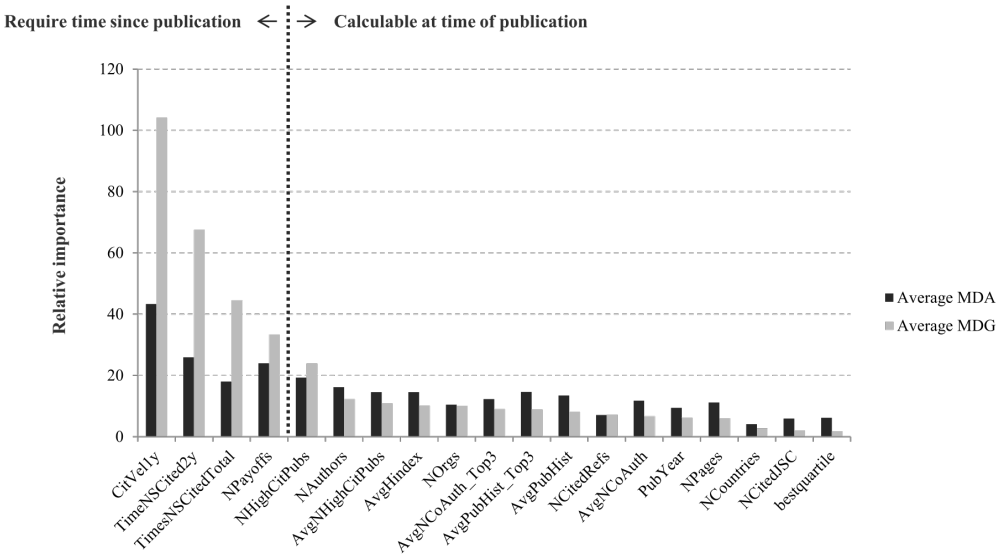

Figure 1. Relative Importance Ranking of Time-Independent and –Dependent Indicators based on Random Forest models (MDG and MDA). Out-of-bag error rate is 4.67%.

Because this work focuses on identification of publications with strong breakthrough potential near time of publication, we then considered only the time-independent indicators and produced new Random Forest models using these data. The relative importance ranking of the time-independent indicators are shown in Figure 2.

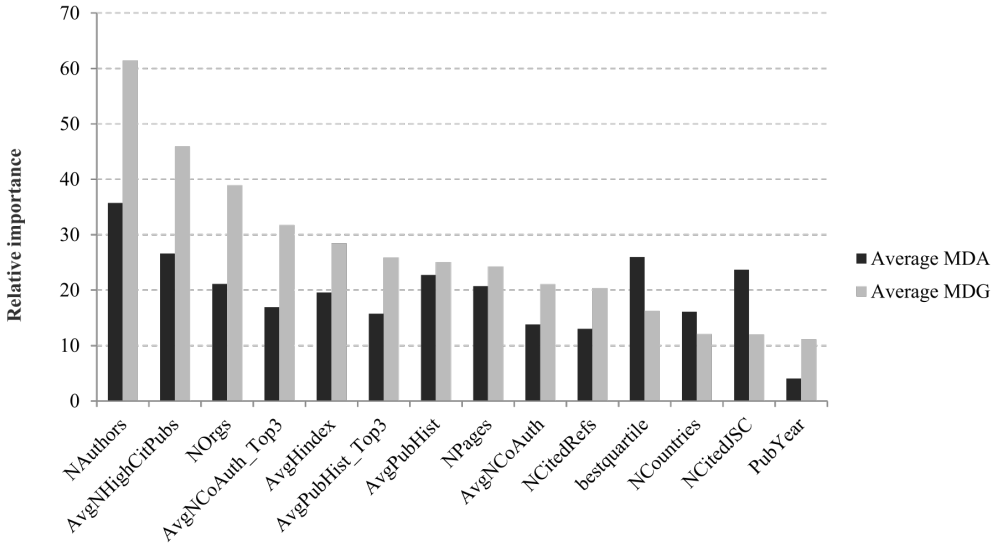

Figure 2. Relative Importance Ranking of Time-Independent Indicators based on Random Forest models (MDG and MDA). Out of bag error rate is 9.48%.

The highest ranked time-independent indicators, sorted by Average MDG, were: NAuthors, AvgNHighCitPubs, NOrgs, AvgNCoAuth_Top3, and AvgHindex. Sorting by Average MDA gives a slightly different set of top five variables: NAuthors, AvgNHighCitPubs, bestquartile,

NCited Journal Subject Category (JSC), and AvgPubHist. While the first two variables are the same for either type of ranking, it would be interesting to explore the divergence of the other variables between the two rankings. The relative importance of these time-independent indicators is consistent with breakthrough work being associated with teams and researchers with a history of strong performance.

Conclusions and Next Steps

We have identified and ranked a set of time-dependent and -independent indicators for their importance in differentiating a set of breakthrough publications from a comparison group. Our results are early steps in developing tools for potentially identify promising emerging research in a timely manner. Our next steps include using a subset of these indicators to establish a multivariate model where the outcome is the estimated probability of being a breakthrough paper based on the existing training set. Using this model, we will prospectively identify candidate breakthroughs and share the results with program officers within NCI to assess the practical value of the model. Future work could include efforts to determine which indicators gain or lose predictive value over time through iterative evaluation of the relative strength and importance of each indicator.

Introduction

It is well known that in some fields the average number of citations per publication is much higher than in others (Moed, 2005).

For decades, the number of publications and the number of citations have been the two accepted indicators in ranking authors. Recently, alternative indicators which consider both production and impact have been proposed (Dorta-González & Dorta-González, 2011; Egghe, 2013). However, these indicators based on the h-index do not solve the problem when comparing authors from different fields of science. Given the large differences in citation practices, the development of bibliometric indicators that allow for between-field comparisons is clearly a critical issue (Waltman & Van Eck, 2013).

Traditionally, normalization of field differences has usually been based on a field classification system. In said approach, each publication belongs to one or more categories and the citation impact of a publication is calculated relative to the other publications in the same field.

In our topic normalization we use the aggregate impact factor of three different sets of journals as a measure of the different dimensions in the citation potential of an author.

Dimensions of the author citation potential

Even within the same field, each researcher is working on one or several research lines that have specific characteristics, in most cases very distant from those of other researchers.

Generally, the citation potential in a field is determined within a predefined group of journals. This approach requires a classification scheme for assigning publications to fields. Given the fuzziness of disciplinary boundaries and the multidisciplinary character of many research topics, such a scheme will always involve some arbitrariness and will never be completely satisfactory. Therefore, we propose measuring the citation potential in the specific topic of each author and using this measure as an indicator of the probability of being cited in that topic.

The problem underlying the characterization of the author citation potential is as follows. Given a set of publications from an author in different journals and years, we will try to obtain a measure of the author topic defined by some dimensions of these publications so it can be compared with that of a different author (with publications in different journals and years).

Let us consider a 5-year time window Y. In this paper, we propose characterizing the topic of an author in period Y using three different dimensions (see Figure 1): the weighted average of the impacts in the journals containing the author's papers in Y (production dimension P), the weighted average of the impacts in the journals citing the author's papers in Y (impact dimension I), and the weighted average of the impacts in the journals included as references in the author's papers in Y (reference dimension R).

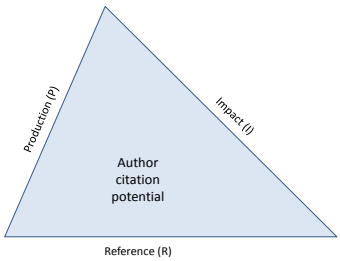

Figure 1. The three dimensions of the author citation potential.

In this characterization we propose the use of journal impact indicators instead of number of citations received by a particular paper. This is because it is necessary that several years pass after the publication of a document, so that the number of citations can be a consistent indicator in comparing similar documents of the same type published in the same year with that of other researchers in the same field. In some fields (e.g., Economics) more than 5 years are needed to obtain a consistent measure of impact (Dorta-González & Dorta-González, 2013). In many fields of the Humanities it is necessary to wait even longer (Dorta-González & Ramírez-Sánchez, 2014).

Materials and Methods

The bibliometric data was obtained from the online version of the Scopus database. Only journal papers in the period 2009-2013 were included, considering for each journal the Scimago Journal Ranking –SJR–. Four subject areas were considered: Chemistry, Computer Science, Medicine, and Physics & Astronomy. This was motivated in order to obtain authors with systematic differences in publication and citation behavior. We designed a random sample with a total of 120 authors (30 in each subject area). They were selected from the highly productive authors of the Consejo Superior de Investigaciones Científicas –CSIC– (Spain).

Results and discussion

The subject areas considered are very different in relation to the citation behavior. For this reason, in the sample there are important differences among the dimensions of the citation potential from one author to another. However, the proportion between production and impact dimensions is very close in all the subject areas considered (Figure 2).

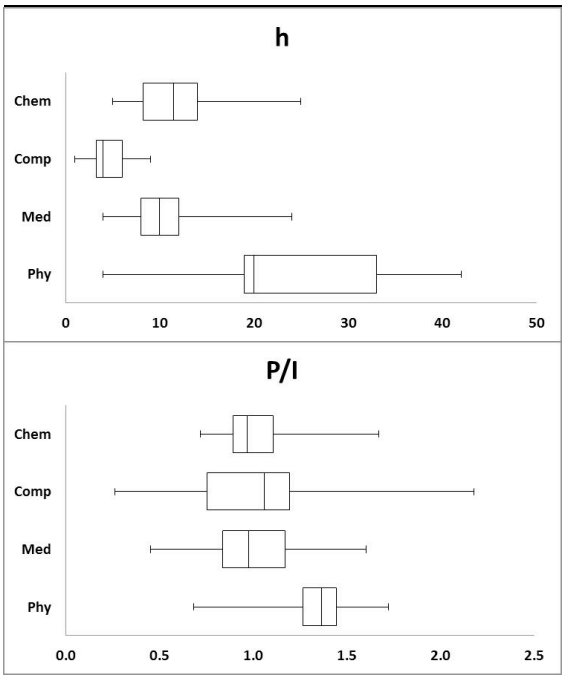

Figure 2. Box-plots comparing the subject areas.

Within- and between-group variability are both components of the total variability in the combined distributions. So: within variability + between variability = total variability.

Note in Table 1 that the proportion between production and impact dimensions produces the greatest percentage reduction of the variance. A more detailed analysis of the results can be found in Dorta-González et al. (2015).

Table 1. Central-tendency and variability.

	P	I	R	P/I
Median	1.521	1.526	2.564	1.065
Mean	1.719	1.546	2.759	1.093
Range of variation	3.692	3.776	7.527	1.915
Within-group variance	46.360	25.089	192.557	9.972
Between-group variance	39.434	17.325	54.463	2.358
Reduction in the variance	14.9%	30.9%	71.7%	76.3%

Conclusions

We have developed a measure of scientific performance whose distributional characteristics are invariant across scientific fields. Such a measure could be employed in the normalization of the impact at the author level in order to allow direct comparisons of scientists in different fields and permit a ranking of researchers that is not affected by differential publication and citation practices across fields.

Scholarly Book Publishers in Spain: Relationship between Size, Price, Specialization and Prestige

Jorge Mañana-Rodríguez[1] and Elea Giménez Toledo[2]

[2] *jorge.mannana@cchs.csic.es*
Centre for Human and Social Sciences, Spanish National Research Council. C/ Albazanz, 26-28. Madrid. Spain.

Introduction

The prestige of book publishers is an important element for the assessment of SSH scholars in Spain. Until 2012, that 'prestige' remained based upon subjective, individual judgements from assessment committees' members. In order to provide a more objective reference for the prestige of book publishers, ÍLIA research group developed a ranking of book publishers (so called SPI) based on the opinion of almost three thousand experts from all SSH fields (Gimenez et al., 2013). Nevertheless, the factors underlying the perceived prestige are unknown. Some authors worked on the influence of marketing on the perception of books. Squires (2007) point out that 'we should not underestimate the value or efficiency that the association with a specific publisher provides to its contents'. It is hypothesized that three factors (among others) might be related to the perceived prestige: size of the book publisher (number of titles published), specialization (share of titles in each discipline) and price of the books. This research present the results of a correlational study on prestige, size, specialization and price of SSH book publishers in Spain.

The perception of 'prestige' strongly differs among different subjects to which the term can be applied. When the object is a product or a brand (with book publisher names as equivalent) the quantifiable variables related to the perception by different subjects of the different levels of prestige is relevant for explaining or defining the construct. The overall number of titles published by a book publisher could act as a reinforcement of the perception of prestige since the frequency with which the reader or consumer will be exposed to the brand is statistically more probable and this could lead to a perception of the publisher as able to publish more and better than others. In many goods, the perception of the prestige of competitors, in a similar way to how multi-branding strategies operate (Rahnamaee, A., & Berger, 2013). A brand prestige might also affected by the price (Yeoh & Paladino, 2013), and so the price of book might partially contribute, in a linear fashion, to the perceived prestige of book publishers.

Finally, specialization, as a factor, which might create a link between a specialized scholar with an specialized publisher, might contribute to influence the perception of the publisher as more prestigious in absolute terms. Since Scholarly Publishers Indicators (SPI) is being currently used as a source of information for assessment procedures in Spain (in some SSH fields), it is important to know whether the perceived prestige can be attributed to factors unrelated to the essential issues in research evaluation or if, by the opposite, the perceived prestige is not strongly (linearly) associated to these external factors.

Objectives

The objective of this research is to test the hypothesis stating that there is a linear relationship between prestige, size, specialization and price of books of book publishers in the case of Spain.

The information sources are the following:

-Prestige values: Scholarly Publishers Indicators (SPI, 2012).

-Size, price and specialization: DILVE (DILVE, 2013).

Variable definition:

-Prestige: ICEE (Prestige measure based on extensive survey to researchers and lecturers)

-Size: Raw number of different titles in DILVE for each discipline

-Mean price: the average price of all the titles published by the book publisher in the period analyzed.

-Max. Price: the maximum price of a single title in the whole set of titles published by each publisher.

-Specialization: Share of titles of publisher according to DILVE.

Methodology

For a total number of 119 book publishers (this number was fixed so that the number of lost cases is minimized), their ICEE was retrieved from SPI (2014, and the size, mean price and specialization degree obtained from the extensive database DILVE, for the years 2004 onwards up to 2012. The reason for including data from 2004 onwards is the fact that prestige, as other consumer perceptions, are developed over time so a smaller time span would not provide suitable. Data prior to 2004 is not fully consistent in DILVE database when compared with the publishers resulting from the questionnaire on publishers prestige due to the several changes (splits and merges) which took

place sin that date among book publishers, often involving the disappearance of book publishers names as they were and therefore requiring a much more complex codification of the previous names in order to keep the reliability of the data set. After a verification of the non-normality of the distribution of all the variables, using Kolmogorov-Smirnov nonparametric tests, Spearmans' Rho was selected as the appropriate technique contrasting the linear association hypothesis. The correlation matrix for all the variables was calculated using IBM SPSS (v. 19).

Results

Only significant results (p-value = .05) have been considered, since there is no reason for supposing any bias effect of *n* on the significance of the results (119, in all cases). The following table resumes these statistically significant correlations.

Table 1. Statistically significant correlations (Spearman's Rho).

ρ Publisher Prestige, Raw Size	.269; p < .05
ρ Publisher Prestige, Max Price	.217; p < .05
ρ Raw Size, Max Price	.198; p=.019
ρ Raw Size, Average price	-.232; p < .05
ρ Raw Size, Max Share	.433; p < .05
ρ Max Price, Average price	.593 p < .05

Conclusions

The main conclusion which can be drawn from the results is the seemingly (at least linear) independence of the construct 'prestige' from all the variables hypothesized as potentially influential in the values given to book publishers by the experts. The correlations of publishers' prestige with Raw Size (Number of Titles) and Max. Price, although statistically significant, are small enough as to suppose that the influence of these two variables in the perception of a publisher's prestige is not strong enough as to make necessary normalization measures. These results also suggest (at least from the perspective of a linear relationship) that the rankings in use are not biased by the possible influence of the great number of books, multiple branding and specialization or prices which sometimes can be displayed by some of the publishers belonging to big publishing houses which occupy the highest positions in the rankings.

Discussion

The fact that none of the variables analyzed is linearly related to the perceived prestige of book publishers is consistent with the multi-component structure generally involved in the composition of a concept such as 'prestige'. Also, since it is hardly possible to quantify the 'quality' (an also multi-faceted concept, particularly in the framework of research evaluation) of the contents of the books which, escalated to book publisher level of aggregation could contribute to the perceived prestige, the plausible influence of this factor remains unknown, although further research might offer new insight into this particular relationship. The existence of such relationship between the intrinsic quality of the contents and the prestige of a publisher is also plausible given that the use of books by those who have provided the prestige values presumably use the books as a source of information and as a form of scholarly communication where the quality of the contents might be the core of the perceived prestige, leaving behind other subjectively perceived variables. Also, given the relevance of peer review for assessment processes (Verleysen & Engels, 2013) as well as for the quality of the contents, the use of these filters might be related to the perceived prestige of book publishers.

Introduction

Bibliometric indicators ranking aggregate units have a long tradition, including criticisms of methodology, interpretation and application. Despite the criticism, there is a demand for these indicators, and recent developments have led to improvements of methodology and interpretation. An essential element of these interpretations is to provide estimates of the accuracy, robustness, stability and confidence of bibliometric indicators, thereby providing the reader with data required to interpret results. This has, for example, been demonstrated for the set of indicators in the Leiden ranking (Waltman et al., 2012), the Journal Impact Factor (Chen, Jen, & Wu, 2014) and other journal indicators (Andersen, Christensen, & Schneider, 2012) as well as author metrics (Lehmann, Jackson, & Lautrup, 2008). The present study applies the same type of bootstrapping technique to estimate stability, as is used in the Leiden ranking (Waltman et al., 2012), on an array of citation-based journal indicators. The purpose of this analysis is to compare recent methodological advances, as well as traditional approaches. The study is based on clinical medicine journals in the Web of Science (WoS).

Methods

Data acquisition

The dataset contains all articles and reviews in the WoS, published in 2012 in journals classified as clinical medicine according to the National Science Foundation (NSF) classification system. This amounts to 362,556 papers and 2,699 journals from 34 different specialties within the discipline of clinical medicine. Each journal and paper is assigned to exactly one specialty. Citations are observed for a two-year window. In order to account for field differences in citation patterns, relative citations, $\hat{c}$, are computed by normalising observed against expected citations per specialty and year.

Journal indicators

The journal citation indicators selected for this study represent both traditional (means and medians of observed and relative) and novel (percentile) approaches. For a given journal *j*, we calculate the mean citations, μ_c, median citations, M_c, mean relative citations, $\mu_{\hat{c}}$, median relative citations, $M_{\hat{c}}$, top decile ratio of citations, N_{D10}, and relative citations. The top decile ratio for a journal is the percentage of papers present in the overall set of papers with citations in the highest decile range.

Indicator evaluation

Each indicator is evaluated for every journal by performing bootstrapping (Efron & Tibshirani, 1993). The technique involves resampling with replacement, i.e. for a given sample, all observed values are resampled so that a new sample of the same size is drawn randomly, but with the possibility that the same observation can be drawn multiple times. When repeating this resampling numerous times, we can calculate stability intervals to estimate how accurately the observed indicator value describes the underlying observations or whether it is influenced by outliers and thus less robust. To make our results comparable to those reported in the Leiden ranking, we have chosen to iterate each bootstrap 1,000 times and calculate 95% confidence intervals. In addition to this confidence interval we also calculate the standard deviation for each distribution. As the values of the different indicators are observed in very different ranges, we provide an additional mean-standardized version of every indicator. All calculations are performed using the *boot* package (Canty & Ripley, 2015) for *R* version 3.0.3 x64 (R Development Core Team, 2010).

Results and Discussion

We find that bootstrapping can identify outlying indicator scores within a specialty, by showing stability intervals (95% confidence intervals) for every indicator. As exemplified in Figure 1 for the subset of dentistry journals, the stability intervals demonstrate the robustness of rankings based on particular indicators. While, for example, the

stability intervals indicate that the citation impact of the 1st journal in Figure 1 is higher than that of the 5th, the first four journals cannot be clearly distinguished in terms of mean citation impact. Their mean citation rates are heavily influenced by a few highly cited papers.

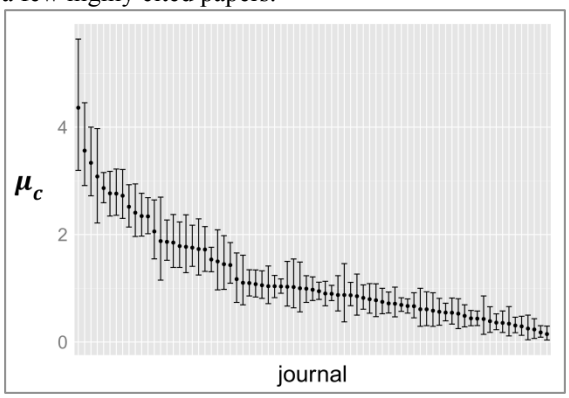

Figure 1. μ_c with stability intervals for all journals in the dentistry specialty.

The study also shows that the percentile-based indicators perform considerably better regarding stability than both mean- and median-based indicators (Figure 2 and Table 1). It is particularly interesting that the medians indicators do not seem to be more stable than the means.

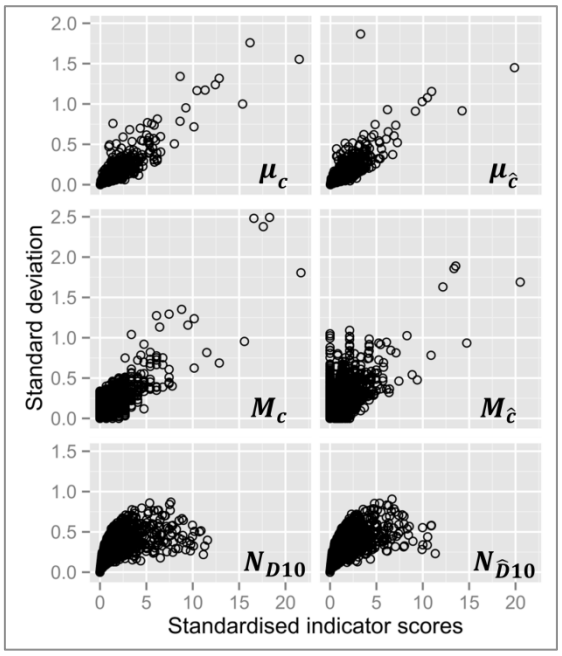

Figure 2. Standard deviation of bootstrapped scores as a function of standardised indicator scores, limited to journals with at least 50 papers.

Finally, we show that indicators are extremely sensitive to sample sizes. Journals with less than 50 papers published in the observation period show significantly larger variance than those publishing at least 50 papers (Table 1). Our results reiterate the importance of testing indicators and providing stability intervals to improve their interpretability. This would identify the limitations of rankings and avoid cases like the 24-fold increase of *Acta Crystallographica A*'s impact factor in 2009 (Haustein, 2012).

Table 1. Mean indicator values and standard deviations for all journals ("All") and journals publishing 50 or more papers ("≥50").

	All				≥50	
	Raw		Standardised			
Indicator	*mean*	*SD*	*mean*	*SD*	*mean*	*SD*
μ_c	2.321	3.897	1.000	1.679	1.052	1.261
M_c	1.477	2.278	1.000	1.543	1.079	1.471
$\mu_{\hat{c}}$	0.835	1.107	1.000	1.326	1.053	1.076
$M_{\hat{c}}$	0.520	0.717	1.000	1.381	1.075	1.297
N_{D10}	0.081	0.131	1.000	1.625	1.107	1.640
$N_{\hat{D}10}$	0.078	0.119	1.000	1.536	1.090	1.513

Further research will include in-depth analyses of multiple indicators and differences of stability intervals across specialties.

Introduction

Although the 2-year Thomson-Reuters Impact Factor (IF) has become a usual tool for measuring the scientific productivity of all fields of the natural sciences (see Aleixandre-Benavent, Valderrama Zurián, & González Alcaide, 2007), its behavior in the particular case of the journals of pure mathematics (the area MATHEMATICS in the thematic directory of Thomson-Reuters) is far from being stable when its values in consecutive years are considered. If we consider the changes of the values of the IF of a given journal in the last decade, it can be easily seen that the variation of the values is surprisingly high if we compare with other disciplines. Mathematical journals seem to have the worst behavior regarding the time stability both of the IF and the position in the IF list.

A series analysis of a set of journals uniformly distributed in the IF list shows that the variations of the values of the IFs are very big when compared with other scientific disciplines, e.g., APPLIED PHYSICS and MICROBIOLOGY. The reader can see a representation of this behavior for three mathematical journals together with three journals of physics that have been chosen as representatives of these groups in the following graph (Fig. 1).

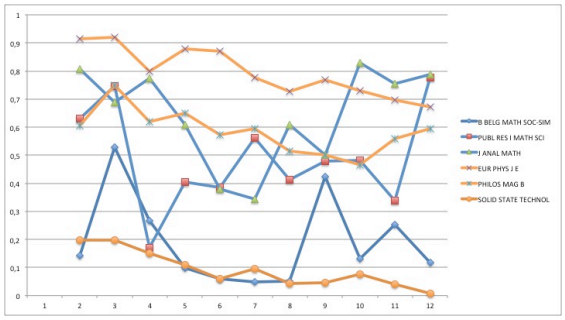

Figure 1. Variations of three journals of mathematics and three journals of physics.

In our study, we analyze the possible reasons for this fact, explaining some typical characteristics of the mathematical journals and of the research in mathematics, that make this science to have unusual properties from the point of view of the bibliometrics.

The research in pure mathematics

In general, mathematicians work in small groups of researchers from different parts of the world that are specialized in some topics, which have a long development period. For instance, it is usual that a group of mathematicians continue with some problems that appeared 50 years ago, or even before (see Behrens & Luksch, 2011). Although some of these topics were intensively studied some years ago, sometimes the research was left at that moment without having complete answers for some central questions, due to the fragility and the small size of the specialized group of researchers working on it. In this context, it is natural that after some years, a new group can recover the research and fruitfully continue with the investigation. The group of interested mathematicians is, almost in all cases, small. Even in new open topics, the size of the interested community of mathematicians is sparse and small. This of course changes when some particular theory becomes important due to the applications. But in these cases, the publication of the mathematical contents is redirected to more applied journals, or to journals of the fields where the theory finds applications.

This research dynamics is not usual at all, if we compare it with the pattern that can be observed in other fields. The main consequence is that the obsolescence of the scientific documents is faster in other sciences than in mathematics.

Mathematical journals

Classical journals that publish papers on pure mathematics follow also a different pattern that the

usual one in other scientific fields that are in some sense similar with respect to some descriptive parameters, as physics or other natural sciences. Although there are a lot of journals that are supported by big publishers—for example, Elsevier and Springer—, some of them preserve the editorial policy and the publication format that they used to have before. Another important group of journals is still published by national societies, universities and research institutes. Very often, these publications are small—in the sense that they publish a small number of papers per year—, but they are prestigious and serious papers are published in them.

This implies that the impact factor of these journals has a strong statistical variability, depending on the number of citations that a small number of papers can receive.

On the other hand, the publication of the papers is slow when compared with journals in other disciplines. Sometimes it takes more than two years for a paper from submission to publication. In general, this does not produce any problem for the dissemination and exchange of information, since the contents are often previously published by the authors in popular open access repositories as arXiv. Moreover, again the small size of the group of specialists interested in the topic reduces the pressure on the authors for a fast publication.

Conclusions: IF-based evaluation of the scientific productivity

The main direct consequence of the properties of the journals of mathematics together with the slow long-term activity in the research of the topics is the small rate of papers that are cited two years after their publication, when compared with other fields. This causes that the value of the IF of the journals is small even if they are prestigious and well-known in the field. For example, an IF of 0.5 is a reasonable impact factor for a journal, and enough to let it to be considered as a serious publication. This value is very small if we compare with other areas (see Bensman, Smolinsky & Pudovkin, 2010; Smolinsky & Lercher, 2012).

However, the 2-year IF is still the main tool in many countries—for example, Spain—to measure the production of a single mathematician or a research institute. This produces some fails in the evaluation systems, and lead the researchers to publish in journals that are considered by the community as less prestigious than others, as a consequence for example of the fact that these journals publish much more papers, and then have a better IF. Therefore, pure mathematics provides an example of a group of disciplines for which the IF-based evaluation clearly distorts the image of the scientific production.

Introduction

Traditionally, biomedical research is measured by bibliometric indicators of scientific production and impact (such as number of publications and h-index) and indicators linked to clinical trial activities (Pozen & Kline, 2011). However, there has been an increasing demand in the last few years to measure the impact of medical research in terms of how it improves patients' well-being and public health (Wells & Whitworth, 2007; Ovseiko, Oancea, & Buchan, 2012). Measuring the final impact of research on patients' outcomes is difficult because of attribution problems and time lag between research and outcomes (Ovseiko, Oancea & Buchan, 2012). The aim of our research project is to select and test indicators measuring the impact of cancer research on health service and patient care

First step: indicators selection

See Figure 1 below for details of this process.

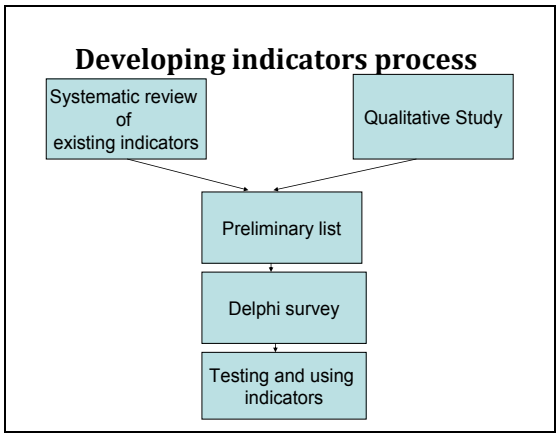

Figure 1: Indicators development process.

Systematic review of indicators

We firstly undertook a systematic review of existing indicators measuring the output and outcome of medical research in order to (1) enlist all the indicators that could potentially be used and (2) to describe their methodology, use, advantages and disadvantages. We took care of designing a study as comprehensive as possible, in order to include indicators ranging from those measuring research activity to those measuring the long-term impact of research. As a result we drew a detailed list of 57 indicators (Thonon et al., 2015).

Qualitative study of researchers

We wanted to develop indicators that would be accepted by those concerned by this evaluation system. Therefore, we undertook a qualitative study to explore the views of actors in translational research on the definitions, issues and evaluation modes of translational research. This study was done to complete the results of the systematic review with an input from the stakeholders directly involved. We interviewed 23 researchers, engineers, administrators and clinicians from diverse backgrounds and engaged in diverse fields of oncological translational research.

Delphi survey

Those two exploratory studies led us to the drawing of an initial list of 61 indicators. We submitted this list to all members of the platform for a modified Delphi survey (N=267). Participants were presented indicators, as well as their methodologies, advantages and disadvantages, and were asked to rate their feasibility and validity on a scale from 1 to 9, and to comment on them. Comments from participants were particularly useful to adjust the methodology of the indicators. In addition, a physical meeting was held where 26 participants discussed the inclusion and methodology of some indicators.

Results

As a result we were able to draw a list of 12 indicators, including 4 indicators that focused on measuring the impact of research on health service and patient care but not used in evaluation systems very often:

- Citation of research in clinical guidelines;
- Citation of research in public health guidelines;
- Number of clinical guidelines authored; and
- Number of validated biomarkers identified in publications.

Second step: indicators testing

We constructed the following methodology to measure those indicators: 17 European cancer centres have been selected in this study. We used

the Scopus database to extract all original articles published between 2000 and 2014 and analysed the data.

Citation of research in clinical guidelines

We selected clinical oncology guidelines published by the European Society of Medical Oncology (ESMO), the American Society for Clinical Oncology (ASCO), and the National Comprehensive Cancer Network. Those guidelines are published in, respectively, *Annals of Oncology, Journal of Clinical Oncology* and the *Journal of the National Comprehensive Cancer Network.* We analysed the number of publications cited in the 'clinical practice guidelines' issues of those journals. We searched the literature for data on the AGREE score of those guidelines to measure the validity of this indicator.

Authorship of clinical guidelines

We extracted and analysed data relative to the clinical oncology guidelines mentioned above.

Citation of research in public health guidelines

From the database of European publications (https://bookshop.europa.eu/en/home/) we searched for public health guidelines related to cancer. Then we extracted the references of the selected guidelines in Scopus and carried out a citation analysis.

Number of validated biomarkers identified in publications

We firstly performed a literature review to identify and list all validated biomarkers used in clinical practice for oncology patients. We then performed a search for all publications related to those biomarkers in the corpus of original articles.

Discussion

This study is still ongoing and the results will be available shortly. We believe those four indicators can provide an additional tool to measure the impact of cancer research on health service and patient care. Citation of research in clinical guidelines is the most investigated indicator (Lewison, 2003; Mostert et al., 2010). There is little literature on indicators linked to the citation of research in public health guidelines (Lewison, 2003) but none linked to indicators measuring the identification of biomarkers, despite the importance of their use for cancer patients' outcomes.

A New Scale for Rating Scientific Publications

Răzvan Valentin Florian[1]

Introduction

Citation-based bibliometric indicators are increasingly being used for evaluating research. This reflects the need of decision-makers to increase the efficiency of allocating resources to research institutions and scientists, while also keeping manageable and cost-effective the evaluation process that grounds the allocation of resources. There often is much room of improvement in how bibliometric indicators are being used in practice. But even state-of-the art bibliometric indicators suffer of a fundamental problem when used for evaluating research: the citations they are based upon are influenced by many factors beyond the quality of cited publications (Bornmann & Daniel, 2008) and these indicators need to be tested and validated against what it is that they purport to measure and predict, which is expert evaluation by peers (Harnad, 2008).

A solution to this problem is aggregating online ratings provided post-publication by the scientists who read the rated papers anyhow, for the purpose of their own research. Online-aggregated ratings are now a major factor in the decisions taken by consumers when choosing hotels, restaurants, movies and many other types of services or products. It is paradoxical that in science, a field for which peer review is a cornerstone, rating publications on dedicated online platforms is not yet a common behavior. For example, if each scientist would provide one rating weekly, it can be estimated that 52% of publications would get 10 ratings or more (Florian, 2012). This would be a significant enhancement for the evaluative information needed by decision makers that allocate resources to scientists and by other users of scientific publications.

For collecting this kind of ratings, a rating scale should be defined. Here I present the choices made during the development of the scale used at Epistemio, an online platform for aggregating ratings and reviews of scientific publications (www.epistemio.com).

Purpose

The expected usage of these ratings is: first, in steering of science by decision-makers, i.e. choosing to whom to allocate resources (typically contributed publicly), such as institutional funding, grants, jobs, positions, tenure, among the institutions, scientists, fields of science, etc. that compete for them; and second, in helping scientists to prioritize and filter the publications that they choose to read or use. For the first purpose, it is important to be possible to aggregate ratings across the set of publications of an individual, of a group of scientists or of an institution; and to be able to use the individual or aggregated ratings to rank the assessed entities. This implies that ratings should be unidimensional. While publications may be assessed across a number of characteristics, such as quality of research, quality of presentation, novelty, and interest, collecting individual ratings across all these dimensions reduces the response rates, and it is not clear how these multidimensional ratings may be aggregated into a scalar one. Therefore, it is desirable that an overall rating that reflects the overall properties of a publication is collected independently of ratings regarding individual characteristics of the publication. Collecting the latter may be left optional. This paper focuses on the overall rating.

What should be rated, exactly?

When experts are asked to rate a publication, the property that should be rated must be named. What is exactly this property? A proper discussion of this issue should analyze the foundations of scientific research, being outside the scope of the present paper. A different way of posing the problem is starting with the needs of expected users of the ratings, which were mentioned above. Typical desired properties of publications (and, therefore, of the results presented in these publications) that are mentioned in the context of steering of science is quality, importance, relevance, and impact. For usability purposes, the text of the question to raters should be kept brief; therefore, a choice must be made among the various wordings that may be used. Importance, long-term societal and scientific relevance, and long-term societal and scholarly impact seem to have similar semantics. Quality seems to be a complementary property: a publication may present potentially important results, but methodology and/or presentation may lack quality, therefore raising uncertainties about the real value of the publication; and a publication may be of high quality while the potential importance is low. We have thus chosen to use the wording “scientific quality and importance” for defining the variable that the ratings are supposed to estimate.

Scale type and range

Online ratings typically take the form of a five-star or ten-star discrete scale: this standard has been adopted by major players such as Amazon, Yelp, TripAdvisor and IMDb. However, these types of scales are likely not being able to measure well the quality and importance of scientific publications, because of the likely high skewness of the distribution of values of this target variable.

Let us consider the number of citations of scientific publications as a relevant proxy for the quality and importance of publications. About 44% of publications in Web of Science have zero citations, and the median number of citations is about 1, yet there is one paper having more than 305,000 citations and 148 papers having more than 10,000 citations (Van Noorden, Maher, & Nuzzo, 2014). In the case of patents, where the monetary value is defined by markets, the top 0.8% were valued at more than 1,000 times the median (Giuri et al., 2007). Let us assume that the main properties of these distributions generalize to the variable we want to measure, i.e. the maximum value can be of about 3 to 5 orders of magnitude larger than the median value. Therefore, a scale of 5, 10 or even 100 discrete categories cannot represent well this variability if the values that the scale represents vary linearly across categories. A logarithmic scale would be suitable, but it is psychologically difficult for most people to estimate values across so many orders of magnitude and to place them on a logarithmic scale.

A solution to this conundrum is asking experts to assess not the absolute value of the target variable, but its percentile rank. Then, the maximum value (100%) is represented by a number just 2 times larger than the median (50%), rather than several orders of magnitude larger. For usability and computational reasons, we limited the precision of the scale to 1%. Theoretically, this limits the capacity of indicating differences between top papers; in the case of the number of citations, in the top 1% the value varies from several hundreds to hundreds of thousands. In practice, test-retest reliability tends to decrease for scales with more than 10 response categories; users consider that a scale with 101 response categories allow them to best express their feelings adequately, but its ease and speed of use is slightly lower than of scales with 11 categories or less (Preston & Colman, 2000).

Because of the skewness of the distribution of absolute values, it is likely that experts are able to discriminate the percentile ranking of high quality papers better than the one of low quality papers. The confidence in rating papers also depends on how close the topic of the publication overlaps the expertise of the rater. For these reasons, raters should be able to express their uncertainty. Therefore, we allowed experts to give the rating as an interval of percentile rankings, rather than a single value. The rating is collected through a graphical interface representing the interval with sliding ends (Fig. 1). For ease of use on mobile devices, the interval can also be expressed using numerical selectors. A review may be associated to the rating, for explaining and supporting the rating.

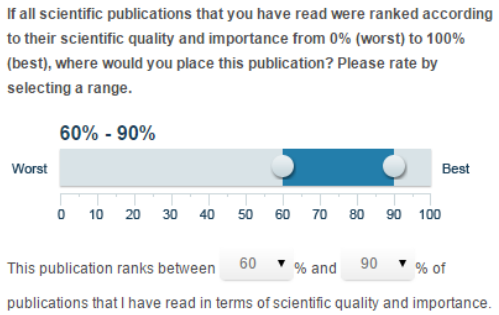

Figure 1. The Epistemio® rating scale for scientific publications.

Introduction

In recent years, there has been a growing recognition of the necessity for interdisciplinary research that crosses disciplinary boundaries to deal with increasingly complex social issues (Rafols & Meyer, 2010). The relationship between the changes in interdisciplinarity of research over the years and researchers' attributions has rarely been investigated. Understanding the relationship between them will make it possible to gain useful information to foster interdisciplinary research, career-development of researchers, and development of research institutions. Thus, considering different periods, this study examines interdisciplinarity of research and the transdisciplinarity of researchers (targeted researchers themselves and their co-authors).

Methodology

This study targeted full-time faculty members of 2 iSchools, University of Pittsburgh (Pitt) and Syracuse University (SU), as of August 2014. The following data were employed: (1) information about targeted researchers and their co-authors, such as academic degrees or biographies, extracted from web pages; (2) bibliographic data of articles published by targeted researchers, which were extracted from Web of Science (WoS); (3) the title lists of WoS by subject categories acquired from the web site of Thomson Reuters; and (4) a matrix of the distance between categories of WoS, which was computed by Leydesdorff using Stirling's distance (http://www.leydesdorff.net/overlaytoolkit/stirling.htm). The procedure of this study was as follows: First, we examined transdisciplinarity of targeted researchers on the basis of the numbers of different disciplines where they had been engaged. We estimated their disciplines by several points of view such as belonging departments and academic degrees. As for their co-authors, though disciplines were estimated in the same way, we counted only disciplines that were different from those of the targeted researchers who had published the co-authored articles. Next, for each article of (2), by relating its reference list to (3) and (4), we computed indexes regarding interdisciplinarity that were used in later studies. This study applied the following indexes to the distribution of WoS categories assigned to the articles and their citing literature:

a. Total number of categories;
b. Simpson's Index (I);
c. Shannon's Index (entropy, H);
d. Distance between categories; and
e. The proportion of literature cited from different disciplines.

Indexes b and c evaluate the degree of diversity, taking into account both variety and equality in the frequency distribution. Index d indicates the distance between the categories of the articles and their citing literature. It ranges from −1 to 0, multiplying Stirling's distance by −1. As interdisciplinarity grows, their values become higher. Index e indicates the ratio of literature cited from different disciplines. Here, a different discipline is defined as a category with a distance over −0.7. Then, we performed a principal component analysis using these indexes and observed the correlation between the transdisciplinarity of targeted researchers or their co-authors and the interdisciplinarity of their articles along with its time-series variation. We discussed factors affecting the interdisciplinarity of research.

Results

Tendencies of indexes

Table 1 shows the basic statistics regarding transdisciplinarity of researchers and interdisciplinarity of their articles. We targeted 57 researchers, out of 73 faculty members, whose disciplines could be identified on the basis of information from university web sites and WoS.

The result of a principal component analysis for 5 indexes (C to G) revealed that the cumulative contribution rate of the first 2 principal components (PC1 and PC2) is 0.873. The characteristics of the 5 indexes can largely be explained by the first and second principal components. In Table 2, the principal component loading of PC1 suggests strong relationships between all 5 indexes. On the other hand, PC2 is characterized by large negative values of indexes F and G. Figure 1 is a plot of the first and second principal components and indicates that the 5 indexes can be divided into two groups (C, D, and E) and (F and G). It also implies that

highly interdisciplinary articles are remarkably diverse and rarely have common tendencies. In addition, we separated articles into two groups that were roughly equal in size (from 1981 to 2005 and from 2006 to 2014) to investigate the time-series variation related to the transdisciplinarity of researchers and the interdisciplinarity of research. The values of indexes concerning the interdisciplinarity of research (C to G) increased, while there were almost no changes in indexes concerning the transdisciplinarity of targeted researchers and their co-authors (A and B).

Table 1. Basic statistics regarding interdisciplinarity and transdisciplinarity.

		Pitt	SU	ALL
Targeted researchers/all faculties		23 / 30	34 / 43	57 / 73
Number of articles		267	259	526
Number of articles/targeted researchers	median	8	5	6
	range	1-33	1-31	1-33
A: Transdisciplinarity of targeted researchers	median	2	1	2
	range	1-2	1-3	1-3
B: Transdisciplinarity of co-authors	median	1	1	1
	range	0-6	0-4	0-6
C: Total number of categories	median	13	15	14
	range	1-79	1-59	1-79
D: Simpson's Index	median	0.781	0.767	0.777
	range	0-0.949	0-0.934	0-0.949
E: Shannon's Index	median	2.383	2.383	2.383
	range	0-4.385	0-4.061	0-4.385
F: Distance between categories	median	−0.438	−0.413	−0.424
	range	−1–−0.005	−1–−0.013	−1–−0.005
G: Proportion of literature cited from different disciplines	median	79%	79%	79%
	range	0%-100%	0%-100%	0%-100%

Table 2. Principal component loading for 5 indexes.

	PC1	PC2	PC3	PC4	PC5
C	−0.648	0.536	−0.540	0.002	−0.032
D	−0.876	0.301	0.345	0.037	−0.148
E	−0.898	0.350	0.202	−0.051	0.168
F	−0.717	−0.652	−0.089	−0.229	−0.031
G	−0.750	−0.610	−0.093	0.236	0.029

The relationship between transdisciplinarity of researchers and interdisciplinarity of their research

We computed Spearman's rank correlation coefficient for indexes A to G to survey the relationship between transdisciplinarity of researchers (A and B) and interdisciplinarity of their research (C to G) (Table 3). No strong correlation was found between them. However, comparing index A with B, we observed stronger and significant correlation between index B and the indexes concerning interdisciplinarity of research (C to G). In addition, we compared the articles before 2005 with those after 2006 to examine the time-series variation of correlation between indexes. Although there was no distinguished distinction between them, the degree of correlation tended to become stronger and the number of significant coefficients was increased for indexes A and B.

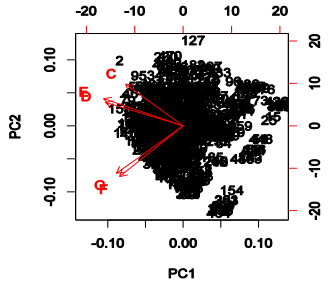

Figure 1. Plot of the first and second principal components.

Table 3. Rank correlation ρ among 7 indexes for all articles.

	A	B	C	D	E	F	G
A	1	0.23*	0.12*	0.17*	0.18*	0.05	0.06
B		1	0.21*	0.20*	0.21*	0.07	0.14*
C			1	0.69*	0.76*	0.17*	0.16*
D				1	0.99*	0.37*	0.30*
E					1	0.37*	0.30*
F						1	0.88*
G							1

*Significant ($p < 0.05$)

Discussion and Conclusions

This study computed indexes for interdisciplinarity of research in library and information science and performed principal component analysis to clarify the relationship among the indexes. The results indicate that the indexes considering the distance between subject categories of WoS have characteristics very different from the indexes considering only the number of categories and their frequency distributions. This suggests that we should consider a more multidimensional approach. Furthermore, we investigated changes over time in the indexes of interdisciplinarity, and observed the progress for interdisciplinarity of research in library and information science. As the results of the correlation analysis between interdisciplinarity of research and transdisciplinarity of researchers, stronger and significant correlations were seen with the transdisciplinarity of co-authors than with that of the targeted researchers themselves. This suggests that interdisciplinarity of research might be more affected by the transdisciplinarity of co-authors than by that of the researchers themselves. We will conduct further investigations with more samples.

Introduction

In Serbia, like in other countries all over the world, career opportunities in computing are growing faster than most of the other professions. This trend should be in accordance with the growth of the number of study programs and consequently the number of teaching staff. The most important researchers' and university teaching staff's promotion criteria, according to the regulations in Serbia, are the papers published in journals from the JCR list, which is, for the area of computing, reduced to the SCIe list. The number of such papers is also relevant for projects financed by the Ministry of Education, Science and Technological Deve- lopment of the Republic of Serbia.

In this paper, we present an analysis of the references of Serbian researchers retrieved from the Web of Science. Using the bibliometric indicators from the Web of Science, we also examine the distribution of such references across WoS categories that belong to the broader area of computing. We show the distribution of such publications over the years, cities and universities and identify the relations with global trends in Serbian science.

Data Set

Data used in this paper were taken from Thompson Reuters Web of Science on 29 September 2014, selecting Science Citation Index Expanded (SCIe) journal articles. A basic search was conducted using the keyword ‘‘Serbia’’ in the field address and the retrieved results were limited to articles published during the period 2006–2013. All document information, including names of authors, titles, years of publications, source journals, contact addresses, and number of citations for each article, for every year, were downloaded into Microsoft Excel worksheets. The custom program in C# programming language was developed in order to perform data analysis.

The same data extraction was performed for WoS categories, that we considered the subcategories of the broader scientific area of Computer Science. The distribution of the number of papers from the year 2006 till 2013 (since results for 2014 were incomplete) is presented on Figure 1, and the number of papers over years and WoS categories is presented on Figure 2.

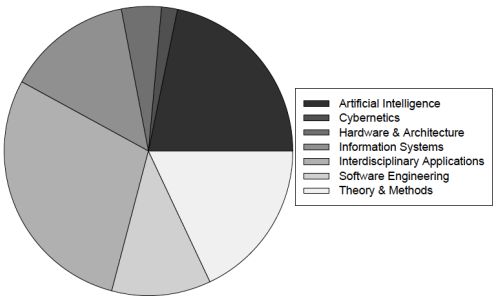

Figure 1. The number of papers in subcategories.

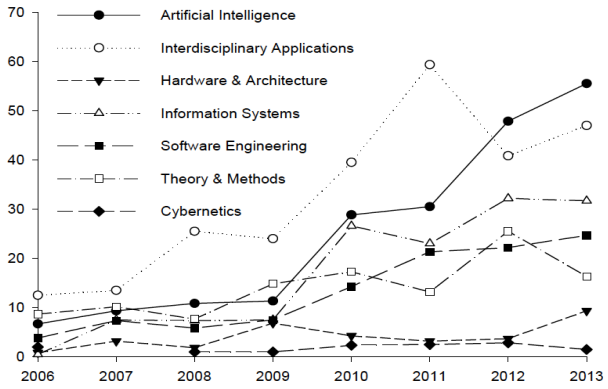

Figure 2. The number of papers in subcategories for each year.

To get numbers presented in Figure 2, disciplinary affiliation is computed fractionally, by assigning 1/N to each category, for a journal paper published in a journal indexed in N different categories.

The name of the country was not always correct for papers submitted before 2006, since our country changed its name to Serbia in 2006, and some papers had the former name Serbia and Montenegro, or even Yugoslavia in their affiliation. Therefore, the additional search was performed using only the names of significant Serbian cities and university centres. It was noticed that our dataset did not hold absolutely correct

information, because of unintentional mistakes in the authors' signatures or other elements of the affiliation. Incorrectly entered data propagate errors to later identification and grouping, as stated in Mitrovic (2014). This issue can be solved partially using text similarity matching algorithms. Our program uses Jaro-Winkler algorithm as proposed in Winkler (1995), also known as JWSF, "Jarod-Winkler similarity function" to overcome this problem.

Distribution of papers over major cities and institutions show interesting results. For the Serbian capital city of Belgrade, only 65.4% of all papers have affiliation of the state University of Belgrade, the biggest and oldest Serbian university, ranked between positions 300 and 400 on the ARWU list. For other university centres in Serbia, the share of publications of state universities is: 93.3% for Novi Sad, 87.4% for Niš and 97.9% for Kragujevac. We conclude that bigger cities have greater potential for scientific productivity outside the university, but this ratio also reflects some problems identified in the past, that institutes belonging to the University of Belgrade did not include the name of the University in affiliation before the initiative to do so, started during the procedure and efforts to qualify for ARWU ranking. The significant growth in the number of papers started in 2008, probably as the result of accreditation procedure regulated by national accreditation body CAQA (www.kapk.org).

Table 1. Journals with more than 20 papers published in the period from 2006 till 2013.

Journal Name	No.	5 years IF
MATCH-communications in mathematical and in computer chemistry	101	1.829
ComSIS - Computer science and information systems	67	0.575
Mathematical and computer modelling	47	2.020
Expert systems with applications	42	1.965
Advances in electrical and computer engineering	28	0.642
Fuzzy sets and systems	27	1.880
International journal of computers communications & control	23	0.694
Information sciences	21	3.893
Journal of multiple-valued logic and soft computing	21	0.667

The list of journals with more than 20 papers in the Table 1 shows that journals in multiple WoS categories are predominant. The journal MATCH publishes the mathematical results and applications in solving chemical problems, without significant content in computing research. The second journal on the list, ComSIS (Computer Science and Information Systems), is an international journal published in Serbia, dedicated to computing, that appeared for the first time on the SCIe list in 2010. In fractional counting, it has been shown that some other disciplines are represented in the comparable quantity to the basic computer science disciplines: Engineering, Electrical & Electronic (71.65), Mathematics, Applied (62.75) and Chemistry, Multidisciplinary (41.67) are in-between Computer Science, Theory & Methods (76.98) and Computer Science, Hardware and Architecture (22.83). Since the leading category is Computer Science, Interdisciplinary Applications (153.00), it is obvious that computer science in Serbia can be viewed predominantly as applied science, blended with electrical engineering, applied mathematics and multidisciplinary chemistry. The leading scientists are I. Gutman with 74 papers in total and 26 in fractional counting, and M. Ivanovic with 23 papers in total and 6.33 in fractional counting.

Conclusions

Considerable growth of publications from Serbia since 2006 was identified in Ivanovic (2014). Serbian national system that transfers data from WoS on weekly bases kobson.nb.rs shows that there were 1746 publications of Serbian authors during 2006 and the yearly production tripled in 2013. At the same time, the number of all publications in Computer Science categories in WoS core collection increased from 123 to 286, while articles only increased from 60 to 204, which was about 3.9% of total Serbian production and 0.47% of the world production in aforementioned categories in the year 2013. The ratio of total world production and total Serbian production is 0.39%, so the results of computer science disciplines are better than average, mostly due to the interdisciplinary approach.

Acknowledgments

We are grateful to Ms. Biljana Kosanović and Ms. Darija Dašić for their assistance in data retrieval, and for valuable advice.

Abstract

The increasing number of researchers and the limited financial resources has caused a tight competition among scientists to secure research funding. On the other side, it has become even harder for funding allocation organizations to evaluate the performance of researchers and select the best candidates. However, it seems that the current evaluation methods are highly correlated with subjective criteria. In addition, the subjective nature of peer-review as one the most common methods in scientific evaluation calls itself for an accurate complementary quantitative method to help the decision makers. This paper proposes an automatic computer system, which is based on machine learning techniques for predicting the performance of researchers. The proposed system uses various features of different types as the input to a complex machine learning module to predict the performance of a researcher in a given year. The method provides the decision makers with fair comparative results regardless of any subjective criteria. Our results show the high accuracy of the proposed system in predicting the performance of researchers.

Methods and techniques, Science policy and research assessment

Introduction

Research grants is known as one of the crucial drivers of scientific activities that can influence the size and efficiency of R&D sector and its productivity (Jacob & Lefgren, 2011). It can also affect the performance of researchers through providing them with a better access to the research resources (Lee & Bozeman, 2005). In the meantime, policies on R&D activities have evolved over the past fifty years (Elzinga & Jamison, 1995; Sanz-Menendez & Borras, 2000). Funding agencies put a lot of efforts on selecting the best candidates for allocating grants as well as on evaluating the performance of researchers in regards to the amount of funding that they have been receiving. On the other hand, the growing number of researchers worldwide has made the competition for securing the limited financial resources even harder. For example, according to Polster (2007) the contest for receiving research funding is on the rise in Canada especially among the academic researchers mainly due to the changes in federal funding policies, lack of university operating budgets, and increasing research costs. The researchers' demand for funding cannot be fully satisfied by the finite financial capacity of the funding agencies. However, the case could be even worse for the young researchers since the senior researchers are more known within their scientific community that might help them in getting money for research.

Peer review is the oldest measure that has been being used for evaluating researchers' performance and their proposals. Most of the funding agencies use a committee of independent researchers to review the researchers' proposals for funding and select the most appropriate researcher(s) through a competitive process. However, the peer review process has been widely criticized in the literature due to the potential biases since the accuracy of the procedure is highly dependent on the selected experts. For example, preferences of peers can affect the final decision or it can act as a gatekeeper for new research interests since peers may not come into an integrated conclusion (King, 1987). Despite the aforesaid drawbacks, the great advantage of peer review process is that the impact of the proposed research could

be assessed quite easily and accurately (Allen et al., 2009). For this important reason it has still remained as one of the most popular techniques in scientific evaluation. Though, the current trend is to combine the expert review with quantitative performance indicators (Butler, 2005; Hicks et al., 2004) in order to achieve a more balanced evaluation since it cannot be reliable enough as a single indicator. For this purpose, citation and publication counts based indicators are commonly used as the quantitative indicators of researchers' performance.

One of the reasons that scientists publish their work in the form of scientific papers is that in this way they can secure their priority in discoveries (De Bellis, 2009). According to the review of literature done by Tan (1986), performance evaluation of individual researchers and research departments are in most cases based on publication counts measures (at least partially). For the quality of publications, citation counts based indicators, first introduced by Gross and Gross in 1927, are commonly accepted as a proxy for the impact of a scientific publication (Gingras, 1996). In general, they count the number of citations received by an article after the date it is published; hence, papers with higher number of citations are assumed to have higher impact.

Invention of the Internet and availability of the digital data have made it feasible to extract and collect data in a very large scale. In addition, the rapid advancement in the field of computer science has made new ideas and algorithms available to the data scientists. Therefore, large scale digital data and complex algorithms provide researchers with novel opportunities to explore new directions of the information science as well as scientific evaluation. This paper presents an integrated highly accurate automatic productivity prediction system that can assist decision makers (and peers) to detect the most appropriate researchers for funding allocation. The remainder of the paper proceeds as follows: *Data and Methodology* section describes the data gathering procedure in detail while explaining the methods and methodologies that were used; the *Results* section presents the performance evaluation results and interpretations for the proposed system; the paper concludes in *Discussion* section; and limitations and future research directions are stated in the last section of the paper.

Data and Methodology

Data

We decided to focus on performance of the researchers who have been funded by the Natural Sciences and Engineering Research Council (NSERC)[1] of Canada. The main reasons for choosing NSERC was its role as the main federal funding organization in Canada, and the fact that almost all the Canadian researchers in natural sciences and engineering receive at least a basic research grant from NSERC (Godin, 2003). Therefore, as the first stage information about the funded researchers was collected from NSERC[2]. In the next phase, Elsevier's Scopus[3] was used to gather all the information about the funded researchers. The data spans from information about the authors themselves (*e.g.* Scopus ID, their affiliation, number of publications in a given year, *etc.*) to their articles (*e.g.* year of publication, authors of the paper, keywords, *etc.*).

The time interval of the research was set to the period of 1996 to 2010 since the data coverage of Scopus was better after 1996. Moreover, to have a proxy of the quality of the papers we

[1] For more information, see: http://www.nserc-crsng.gc.ca/index_eng.asp

[2] Students were excluded from the data as the goal of the paper is evaluating the performance of researchers.

[3] Scopus is a commercial database of scientific articles that has been launched by Elsevier in 2004. It is now one of the main competitors of Thomson Reuter's Web of Science.

used SCImago[4] to collect the impact factor information of the journals in which the articles were published. SCImago was chosen for two main reasons. Firstly, it provides annual data of the journal impact factors that enables us to perform a more accurate analysis since we are considering the impact factor of the journal in the year that an article was published not its impact in the current year. Secondly, SCImago is powered by Scopus that makes it more compatible with our publications database.

In the next phase of data preparation, we calculated several bibliometric features such as amount of funding received by a researcher in a given year, his/her career age, average number of co-authors, average number of publications, average number of citations, *etc.* In addition, using Pajek[5] software social network analysis techniques were employed to construct the collaboration networks of the researchers within the examined time interval. The created networks were used to calculate various network structure properties (*e.g.* betweenness centrality, eigenvector centrality, and clustering coefficient) of the researchers at the individual level. All the calculated features were integrated in a MySQL[6] dataset. The final database contains 117,942 records of researchers. In the next section, methodologies are discussed in more detail.

Methodology

Several features of various types and from different sources were selected for this study. Funding is acknowledged in the literature as one of the main drivers of scientific activities where a three-year (*e.g.* Payne & Siow, 2003) or a five-year (*e.g.* Jacob & Lefgren, 2007) time window is mostly considered for the funding to take effect. In this paper a three-year time window was considered for all the bibliometric variables, *e.g.* for assessing the productivity of a given researcher in year 1999 his/her amount of funding was summed up for the period of 1996 to 1998 (*sumFund3*). Intuitively, productive researchers are expected to at least maintain their performance level. Various past productivity features were hence included in the model reflecting the quality and quantity of the publications. As a proxy for the rate of publications, number of publications in a three-year time window (*noArt3*) was considered. Two indicators were used as proxies for the quality of publications, *i.e.* average number of citations in a three year time window (*avgCit3*) and the average impact factor of the journals in which the articles were published in a three year time interval (*avgIf3*). Both of the mentioned features can serve as a proxy for quality, but with a slightly different meaning. Impact factor indicates the respectability of the journal, *i.e.* the quality and the level of contribution perceived by the authors and the reviewers of the paper, whereas citation counts show the impact of the article on the scientific community and on the subsequent research.

A multi-level feature representing the scientific field of the researcher (*discip*) was also used in the model since publication and citation habits can be different in various scientific fields. For example, citing habits and the rate of citations may vary across different scientific fields in a way that in some scientific fields authors publish articles more frequently or the published papers contain more references (MacRoberts & MacRoberts, 1996; Phelan, 1999). It is argued in the literature that older researchers in general can be more productive (Merton, 1973; Kyvik & Olsen, 2008) due to several reasons (*e.g.* better access to the funding and expertise sources, more established collaboration network, better access to modern equipments). Hence, the career age of the researcher (*careerAge*) was included in the model representing the time difference between the date of his/her first article in the database and the given year. As a common indicator of the scientific collaboration, the average number of co-authors per paper was also included in the prediction model (*teamSize*). It is expected that

[4] For more information, see: http://www.scimagojr.com

[6] Open source relational database management system, for more information see: http://www.mysql.com/

researchers who have on average higher number of co-authors have more connections that might result in relatively higher number of projects or future publications, hence this feature was also considered as one of the influencing factors.

As discussed in the previous section, social network analysis was used to construct the collaboration networks and to measure the structural network properties of researchers. In particular, four network structure indicators were calculated namely betweenness centrality (*bc*), clustering coefficient (*cc*), eigenvector centrality (*ec*), and degree centrality (*dc*). Betweenness Centrality (*bc*) is an indicator of the important players (researchers) in a network who have a control over the flow of knowledge and resources. These players, who are also called as *gatekeepers*, are able to bridge different communities. Theoretically, betweenness centrality of the node *k* is measured based on the share of times that a node *i* reaches a node *j* via the shortest path passing from node *k* (Borgatti, 2005) and is calculated as follows (σ_{ij} is the total number of shortest paths from node *i* to j and $\sigma_{ij}(k)$ is the number of shortest paths from node *i* to node *j* that contains node *k*):

$$bc_k = \sum_{i \neq k \neq j} \frac{\sigma_{ij}(k)}{\sigma_{ij}} \qquad (1)$$

Clustering Coefficient (*cc*), also called *cliquishness*, indicates the tendency of researchers to cluster with other researchers in the network. Hence, researchers with high clustering coefficient may have a relatively high number of connections with the other team members who are collaborating in a tightly knit group. Therefore, this indicator was selected to represent the tight collaboration impact on the overall performance of the team. Theoretically, clustering coefficient of node *i* (cc_i) is defined based on the number of triangles (inter-connected sub-network of three nodes) that contains the node *i* (t_i) normalized by the maximum number of triangles in the given network (Watts & Strogatz, 1998). Let n_i denotes number of neighbors of the node *i*, hence:

$$cc_i = \frac{2t_i}{n_i(n_i - 1)} \qquad (2)$$

Degree Centrality (*dc*) that was also considered as one of the network variables is defined based on the number of ties that a node has (degree) in an undirected graph. Hence, researchers with high degree centrality should be more active since they have higher number of ties (links) to other researchers (Wasserman, 1994). Moreover, in co-authorship networks it can be regarded as the number of direct partners or team members of a given researcher. Hence, it is expected to have an influence on the scientific activities. Degree centrality for node *i* (dc_i) is thus defined based on the node's degree (deg_i) and then the values are normalized between 0 and 1 (dividing by the highest degree in the network) to be able to compare the centralities:

$$dc_i = \frac{deg_i}{deg_{high}} \qquad (3)$$

Eigenvector Centrality (*ec*) takes the importance of a node and its connections into the account. Hence, a researcher has high eigenvector centrality if he/she is connected with other important actors who are themselves occupying central positions in the network. These researchers can be identified as *leaders* in the scientific networks since they are connected

with too many other influential and highly central researchers, and it is hence expected that they shape the collaborations and play an important role in setting priorities in scientific projects that might affect the performance of researchers. A complete list of the selected features is shown in Table 1.

Table 1. List of attributes for the prediction models.[7]

No	*Attribute*
1	Scientific area in which the researcher is working (*discip*)
2	Total amount of funding received by each researcher in a 3 year time window (*sumFund3*)
3	Total number of publications of each researcher in a 3 year time window (*noArt3*)
4	Average number of citations received by researcher's articles in a 3 year time window (*avgCit3*)
5	Average impact factor of the journals in which researcher's articles were published in a 3 year time window (*avgIf3*)
6	Average betweenness centrality of each researcher in a 3 year time window (*btwn3*)
7	Average degree centrality for each researcher in a 3 year time window (*deg3*)
8	Average clustering coefficient of each researcher in a 3 year time window (*clust3*)
9	Average eigenvector centrality of each researcher in a 3 year time window (*eigen3*)
10	Average number of authors per paper for each researcher (*teamSize*)
11	Career age of the researcher (*careerAge*)

The mentioned features were used as an input to the prediction model. Figure 1 shows the whole process of the researchers' performance prediction. Number of publications was considered as the target variable for the performance prediction task. As it can be seen, data is first preprocessed and cleaned. For this purpose, several JAVA programs were coded to check the data for redundancy, out of range values, impossible combinations, errors, and missing values and then data was filtered based on the records that contained all the required data. The resulted data containing all the mentioned features was fed into the data preparation block where at first all the features were normalized to a value between 0 and 1. This was a crucial step since the features were of different units and scales. Local Outlier Factor (LOF) algorithm was then implemented to detect the outliers. LOF that was proposed by Breunig et al. (2000) is based on the local density concept in which the local deviation of a given data is measured with respect to its k nearest neighbors. A given data is outlier if it has a substantial different density from its k neighbors. The final step of the data preparation step was optimizing the attributes' weights. For this purpose we used an evolutionary attributes weights optimizer that employed genetic algorithm to calculate the weights of the attributes. The weighting procedure improved the accuracy of the system by giving more value to the most influential attributes. The resulted data was integrated into a single data repository named as the target data.

[7] The initial list of the selected features was prepared as a result of an intensive statistical analyses performed on the target data. The list was then refined and weighted within the proposed system.

After making the data ready for the analysis, a stratified 10-fold cross validation design was used for the model validation. Cross validation is an analytics tool that is used to design and develop fine tune models. In other words, the data is split into two disjoint sets where one part is used for training and fitting a model (training set) while the other part is employed for estimating the error of the model (test set) (Weiss & Kulikowski, 1991). We used a nested 10-fold cross validation in which the data is split into 10 disjoint subsets in a way that union of the 10 folds results the original data. The method runs 10 times and in each time one fold is considered as the test data while the rest are regarded as the training data.

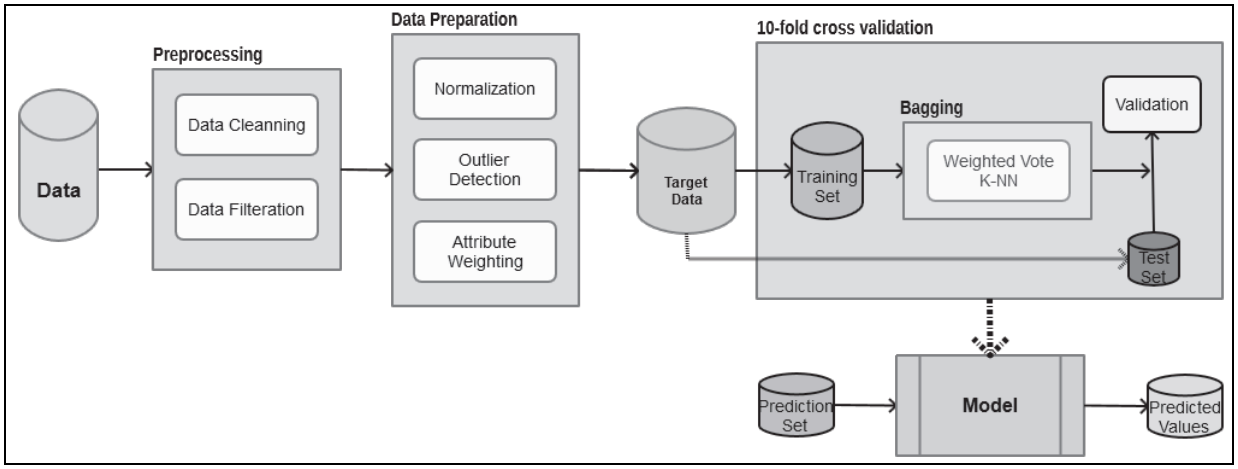

Figure 1. Proposed model for automatic evaluation of researchers' performance.

As mentioned earlier, number of publications was considered as the target variable. To further improve the accuracy of the prediction the ensemble meta-algorithm was employed. For this purpose, bootstrap aggregating (bagging) approach was used. Bagging is an ensemble method that makes random subsets of the data and trains them separately where the final result is obtained by averaging over the results of the separated models (Breiman, 1996). Bagging is a nested module in which we used weighted vote 10-Nearest Neighbor (10-NN) algorithm to train the data and to create the model. In weighted vote 10-NN the distance of the neighbors to the given data is considered as a weight in the prediction in a way that neighbors that are closer to the given data get higher weights. This particularly helped to increase the accuracy of the prediction. Data in the range of 1996 to 2009 was used to train and build the model while a separate disjoint data for 2010 (prediction set) was used for testing the accuracy of the prediction model. The final output of the proposed automatic computer system was the predicted number of publications for the researchers in the prediction set.

Results

In this section the results of the performance evaluation of the proposed automatic computer system (PACS) is presented. As discussed earlier, the model was trained on the data from 1996 to 2009 and a disjoint dataset for 2010 was used for the prediction and the accuracy tests. The accuracy of the proposed model was compared with several well-known machine learning algorithms, however, in this paper the results are presented and compared for the PACS model as well as two other algorithms that showed the highest accuracy in predicting the target variable.

Figure 2 shows the prediction errors of PACS, linear regression, and polynomial regression of degree three[8]. We considered three error measures for comparing the performance of the

[8] Other algorithms (*e.g.* decision trees) were also tested but these listed algorithms were the top two ones with the highest accuracy.

mentioned algorithms. Root mean squared error is one of the main measures for comparing the accuracy of the prediction models and is defined as the square root of the average of the squares of errors. According to Figure 2, PACS is predicating the number of publications of researchers with 1.451 average deviation between the predicted value and the real number of publications. Normalized absolute error is the absolute error (difference between the predicted value and the real value) divided by the error made if the average would have been predicted. The root relative squared error takes the average of the actual values as a simple predictor to calculate the total squared error. The result is then normalized by dividing it by the total squared error of the simple predictor and square root is taken to transform it to the same dimension as the predicted value. As it can be seen PACS is performing better in all the three measures where the degree 3 polynomial fit is the worst.

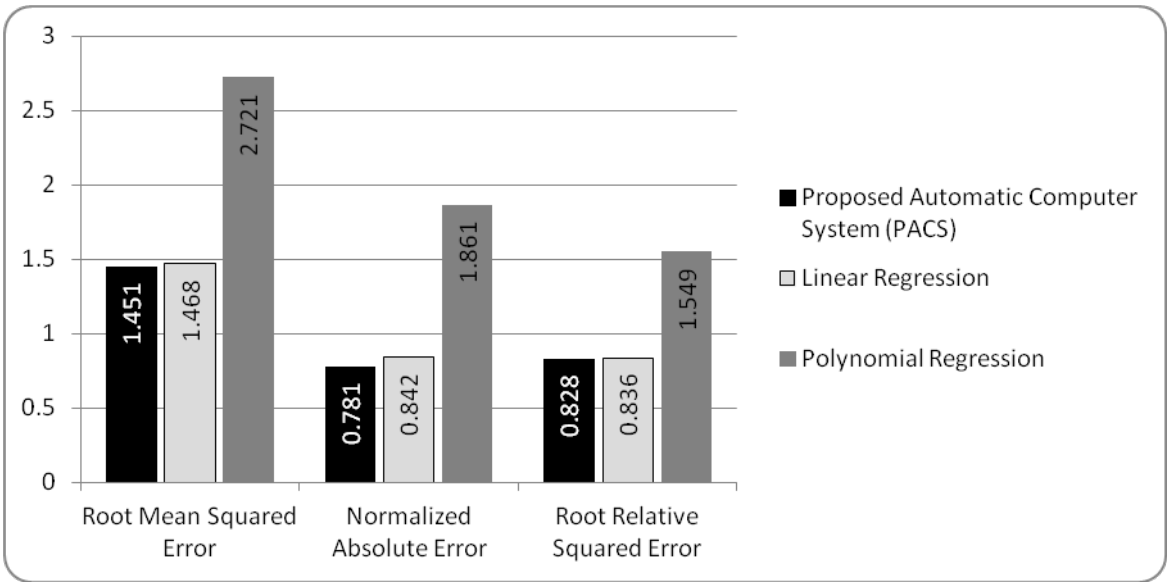

Figure 2. Accuracy test, PACS vs. other two top performing algorithms.

A randomly selected sample of the predictions is presented in Table 2. Each row represents a distinct researcher's profile in 2010 for whom several indicators have been calculated and used in the PACS model as the input features. The real number of articles is shown in *noArt* column that was not fed into the prediction model. Based on the other attributes the proposed system automatically predicted the number of publications of a researcher in 2010, *i.e.* column named *Predicted no of articles* in Table 2 and is highlighted in dark grey. As it can be seen using several features of different types and employing various techniques for data gathering (*e.g.* bibliometrics, social network analysis) and preparation provides the system with highly accurate high-dimensional input data that led to a low error rate and good predictions. Interestingly, it seems that the system successfully considered the differences between various scientific fields in performing scientific activities. According to the results, although the profile of the researchers numbered 1 and 9 in Table 2 are relatively similar, the predicted performance differs as they do not belong to the same scientific field. Hence, the results confirm the importance of the scientific disciplines in predicting the performance of researchers. In addition, comparison of the researchers numbered 6 and 7 highlights the importance of the past productivity as well as the quality of publications in predicting the number of publications.

Discussion

In this paper we used various bibliometric as well as network structural property features to build a model to predict the performance of researchers. Machine learning techniques and availability of the digital data has made it possible to use complex algorithms on high dimensional large scale data. This provides scientometrists with an opportunity to go beyond the current border of using common indicators or simple statistical analyses. Although some researchers recently worked on citation prediction using machine learning algorithms (*e.g.* Fu & Aliferis, 2010; Lokker et al., 2008) to our knowledge this is the first study that focused on the prediction of researchers' productivity using input features of different types and at the individual level of the researchers.

The attribute weighting method to rank features based on their importance that was implemented in the proposed model as well as the outlier detection module for data filtration increased the accuracy of the predictions significantly. Results of the attribute weighting module can also shed light on the most influential attributes in predicting the scientific activities of the target researchers. Another unique approach that was employed in designing the proposed system was using several features of similar nature in building the model that reinforced the prediction power of the system. For example, average number of citations and average impact factor of the journals were used to represent the quality of the paper. Another example is the degree centrality and scientific team size as the former represents the number of direct connections of a researcher while the latter indicates the average number of his/her co-authors. These attributes of similar nature surely empowered the accuracy of the model by providing it with more dimension and flexibility.

To conclude, as it was observed complex computer algorithms can be used to design automatic evaluation systems and prediction tools to evaluate different aspects of scientific activities of researchers. It is obvious that peer reviewing cannot be completely replaced by such tools. However, such systems can help decision makers in setting both long-run and short-term strategies in regard to the funding allocation and/or analyzing researchers' productivity. In addition, the availability of high-dimensional large scale data (in our case, a large dataset spanning from 1996 to 2010) that is intensively cleaned and preprocessed for learning the model will surely contribute to highly accurate predictions that are not based on a limited criteria or a limited feature set. Therefore, this can also help to establish a fairer funding allocation or scientific evaluation system.

Limitations and Future Work

We were exposed to some limitations in this paper. Firstly, Scopus was selected for gathering information about the funded researchers' articles. Since Scopus and other similar databases are English biased, hence, non-English articles are underrepresented (Okubo, 1997). Secondly, due to the better coverage of Scopus before 1996, the time interval of 1996 to 2010 was selected for the analysis. Although Scopus is confirmed in the literature to have a good coverage of articles, as a future work it would be recommended to focus on other similar databases to compare the results.

Furthermore, we were exposed to some limitations in measuring scientific collaboration among the researchers where we used the network structure properties. In particular, we were unable to capture other links that might exist among the researchers like informal relationships since these types of connections are never recorded and thus cannot be quantified. In addition, there are also some drawbacks in using co-authorship as an indicator of scientific collaboration since collaboration does not necessarily result in a joint article (Tijssen, 2004). An example could be the case when two scientists cooperate together on a research project and then decide to publish their results separately (Katz & Martin, 1997). For assessing the quality of the papers based on citation counts we did not account for self citations, negative citations, or special inter-citation patterns among a number of researchers. Although we also used another proxy (average impact factor of journals) to overcome this limitation, it can be addressed in the future works.

Abstract

Several approaches exist related to categorizing academic journals/institutions/countries into different levels. Most existing grading methods use either a weighted sum of quantitative indicators (including the case of one properly defined quantitative indicator) or quantified peer review results. An important issue of concern for science and technology management is the efficiency of resource utilization. In this paper we deal with this issue and use multi-level frontiers of data envelopment analysis (DEA) models to grade countries/territories. Research funding and numbers of researchers as used as inputs, while papers and citations are output variables. The research results show that using DEA frontiers we can grade countries/territories on six levels. These levels reflect the corresponding countries' level of efficiency in S&T resource utilization. Furthermore, we use papers and citations as single outputs (with research funding and researchers as inputs) to show changes in country/territory level.

Conference Topic

Science Policy and Research Assessment

Introduction

The efficiency of science and technology (S&T) resource utilization is one of the important issues for S&T management (Yang et al., 2013a; Yang et al., 2014a). Johnes and Johnes (1992) evaluated the efficiency of S&T organizations using data envelopment analysis (DEA) as a performance analysis tool. Rousseau and Rousseau (1997, 1998) assessed the efficiency of countries using gross domestic product, active population and research and development (R&D) expenditure as inputs, and publications and patents as outputs. They showed that DEA can be used in scientometrics as a tool to measure the efficiency of decision making units (DMUs, e.g., countries) by gauging closeness to the efficiency frontier. Similar techniques have been used by other researchers (Kao & Lin, 1999; Roy & Nagpaul, 2001; Shim & Kantor, 1998). Yang and Chang (2009) used DEA under constant and variable returns to scale (RTS) to measure firms' efficiency. Worthington (2001) conducted an empirical survey of frontier efficiency measurement techniques in education. Other researchers have analyzed the efficiency or productivity in the education sector, (e.g., Abbott & Doucouliagos, 2003, Avkiran, 2001, Carrington et al., 2005, Worthington & Lee, 2008, Flegg et al., 2004, Johnes & Johnes, 1995, Johnes, 2006a,b, Kempkes & Pohl, 2010, Wolszczak-Derlacz & Parteka, 2011, and Aristovnik, 2012). When studying the standard university model, Brandt and Schubert (2013) observed that universities are large agglomerations of many (often loosely

affiliated) small research groups. They explained this observation by typical features of the scientific production process. In particular, they argued that there are decreasing RTS on the level of the individual research groups. RTS is a concept with strong relation to scale efficiency. Somewhat similar observations (decreasing RTS) were published earlier by Bonaccorsi and Daraio (2005). Schubert (2014) used non-parametric techniques of multidimensional efficiency measurement, such as DEA, to analyse the RTS in scientific production based on survey data for German research groups from three scientific fields. Based on DEA models, Yang et al. (2013a, 2014a) analyzed the directional RTS of a couple of biological institutes in the Chinese Academy of Sciences (CAS).

Some fairly recent studies have examined the efficiency of countries or regions in utilizing R&D expenditures or other resources. Lee and Park (2005) evaluated R&D efficiency across nations using patents, technology balance of receipts and journal articles as outputs. Wang and Huang (2007) analyzed R&D efficiency of nations by considering patents and papers as outputs. Lee et al. (2009) used DEA to measure and compare the performance of national R&D programs in South Korea. Sharma and Thomas (2008) investigated the R&D efficiency of developing countries in relation to developed countries, taking into account time lags. Other, and similar, studies include Chen et al. (2011), Sueyoshi and Goto (2013), and Zhong et al. (2011).

The literature referred to hitherto focuses on the quantitative measurement of efficiency of resource utilization. In this context, DEA is one of the most popular mathematical tools for estimating the relative efficiency of DMUs. However, Banker (1993) pointed out that DEA efficiency scores usually overestimate efficiency and are biased. Smith (1997) argued that the extent of the overestimation is highly dependent on sample size and the complexity of the production process (as indicated by the numbers of inputs and outputs). However, in many cases we only need to know the general level (grade) of DMUs in terms of efficiency instead of their exact scores or complete ranking.

Several efforts have been made regarding categorization of academic journals, institutions and countries into different levels of standing or quality. Since 2007, the Association of Business School (ABS) has issued the Academic Journal Quality Guide, which classifies journals in business and management into four categories (grade 1 to 4) recognizing the quality of those journals based on a survey of hundreds of experts in the field (Harvey et al., 2007a,b; 2008). From 2010, a new category, termed 4*, was added to the four existing categories to recognize the quality of the top journals (Harvey et al., 2010). Bandyopadhyay (2013) categorized business and management journals into four categories (Excellent, Very Good, Standard, Satisfactory) based on multiple inputs, including Thomson Reuters' Social Science Citation lists of ranked journals and WoS impact factor analyses. In 2005, CAS evaluated its dependent institutes and classified them into three grades (Excellent, Good, and Satisfactory) (CAS, 2006). Glänzel (2011) used characteristic scores and scales as parameter-free tools to identify top journals. Yang et al. (2013b) analyzed the overall development and the balance of the disciplinary structure of China's science based on papers covered by Science Citation Index and with the use of bibliometric methods. These authors further categorized selected countries to reflect their developmental status.

The grading methods in the research reported above use either a weighted sum of quantitative indicators (including the case of one properly defined quantitative indicator) or quantified peer review results. In general, the weighted sum approach normally needs indicator weights and corresponding threshold values as a priori information, while the peer review process usually costs a lot of time and expenditures (Smith, 1996). In the light of these downsides, this paper presents an alternative approach, involving multiple DEA frontiers, to divide various countries/territories into different levels with respect to the efficiency of their S&T resource utilization.

The rest of the paper is organized as follows. The next section introduces the input and output indicators, and the corresponding dataset used in the analysis. The used methods are described in the third section, in which we treat multi-level efficient frontiers and show how to divide the countries/territories into grades using these frontiers. In the fourth section, the results of the study are given, whereas conclusions appear in the final section.

Indicators and data

In this work, research funding and researchers are used as input indicators. Research funding here means Gross Domestic Expenditure on R&D (million current PPP$). The total number of researchers (full time equivalents, FTEs) in one country is used as indicator for researchers. For the output indicators, we used the number of papers covered by the Science Citation Index (SCI) and Social Science Citation Index (SSCI) from the Web of Science (WoS), and the number of citations to these papers in the year 2011. We use OECD statistics and Thomson Reuters' research evaluation tool InCites as sources for input and output data, respectively. All 34 OECD member countries and seven non-OECD member countries/territories were selected for the study. The other non-OECD member countries, covered by OECD statistics, were excluded due to lack of input data. This also holds for the two OECD members Australia and Switzerland (the Gross Domestic Expenditure in 2011 on R&D of these two countries is missing), and thereby the number of OECD member countries included in the study is 32. See Table 1 for details.

Methods

DEA models and their frontiers

DEA is an approach based on linear programming for analyzing performance of organizations and operational processes. This approach was first proposed by Charnes et al. (1978). All DEA models use input and output data to evaluate the relative efficiency of DMUs without prior knowledge of input/output functions and the weights for indicators. Nowadays, numerous theoretical and empirical works on this method have been published, extending the original approach in different ways, and applying them to many areas, including the private and the public sector (e.g., Cooper et al., 2007).

Let $X = (x_1, x_2, \dots, x_m)$ and $Y = (y_1, y_2, \dots, y_s)$ be input and output vectors of n DMUs, respectively of m and s dimensions. Then the Production Possibility Set (*PPS*) is defined by

$$PPS = \{(X, Y): X \; can \; produce \; Y\} \quad (1)$$

There can be different forms of PPS based on different assumptions. Banker (1984) defined the PPS under the assumption of variable RTS to obtain the BCC-DEA model:

$$PPS(X,Y) = \left\{(X,Y) | X \geq \sum_{j=1}^{n} \lambda_j X_j \, , Y \leq \sum_{j=1}^{n} \lambda_j Y_j \, , \sum_{j=1}^{n} \lambda_j = 1 \, , \lambda_j \geq 0, j = 1, \dots, n\right\} \quad (2)$$

where λ_j is a coefficient.

The *PPS* implied in the CCR-DEA model, which was proposed by Charnes et al. (1978) under the assumption of constant RTS, is defined as follows:

$$PPS(X,Y) = \left\{(X,Y) | X \geq \sum_{j=1}^{n} \lambda_j X_j \, , Y \leq \sum_{j=1}^{n} \lambda_j Y_j \, , \lambda_j \geq 0, j = 1, \dots, n\right\} \quad (3)$$

The boundary of the *PPS* is referred to as the production technology or production frontier.

Definition 1: The efficient frontier of *PPS* is defined as follows:

$$EF = \{(X,Y) \in PPS | there\ is\ no\ (\bar{X},\bar{Y}) \in PPS\ such\ that\ (-\bar{X},\bar{Y}) > (-X,Y)\} \quad (4)$$

Note: This unobservable production frontier is called the true efficient frontier hereinafter. When there is only a single output, the production frontier is known in the economic literature as the production function. DMUs, which are technically efficient, operate on the frontier, while technically inefficient DMUs operate at points in the interior of the *PPS*. Thus it is rational to rank DMUs according to their distance to the true frontier.

The core idea of classic DEA is to identify first the production frontier. DMUs on the frontier are regarded as efficient. DMUs not situated on the frontier are compared with their peers or projections on the frontier to measure their relative efficiency. All DMUs on the frontier are considered to represent the best practices and have the same level of performance.

Let $\{(x_j, y_j)|j = 1, \dots, n\}$ be a group of observed input and output data. Based on such observations, DEA models construct a piecewise linear production frontier, a non-parametric estimate of the unobservable true frontier. Then DEA models measure the efficiency of a DMU via its distance to the estimated frontier. Using radial measurement and input orientation, we have the following input-based CCR-DEA model (Charnes et al., 1978):

$$\theta_c^* = min\,\theta$$
$$s.t.\begin{cases} \sum_{j=1}^{n} x_{ij}\lambda_j \le \theta x_{i0}, i = 1, \dots, m, \\ \sum_{j=1}^{n} y_{rj}\lambda_j \ge y_{r0}, r = 1, \dots, s, \\ \lambda_j \ge 0, j = 1, \dots, n. \end{cases} \quad (5)$$

where $\lambda_j \ge 0$ are the multipliers of inputs and outputs. Here θ_c^* measures the degree of efficiency by radial measurement under the assumption of constant RTS.

If we assume that the production technology satisfies the variable returns to scale assumption, we have the following input-based BCC-DEA model (Banker et al., 1984):

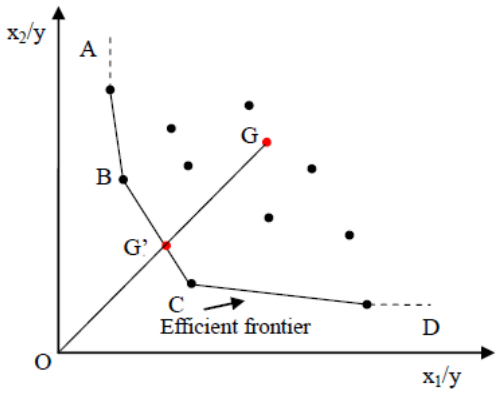
$$\theta_b^* = min\,\theta$$
$$s.t.\begin{cases} \sum_{j=1}^{n} x_{ij}\lambda_j \le \theta x_{i0}, i = 1, \dots, m, \\ \sum_{j=1}^{n} y_{rj}\lambda_j \ge y_{r0}, r = 1, \dots, s, \\ \sum_{j=1}^{n} \lambda_j = 1, \\ \lambda_j \ge 0, j = 1, \dots, n. \end{cases} \quad (6)$$

where θ_b^* measures the degree of efficiency by radial measurement under the assumption of variable returns to scale. It should be noted that Model (6) differs from Model (5) only regarding the constraint $\sum_{j=1}^{n} \lambda_j = 1$, which yields that the variable RTS assumption is satisfied.

Obviously, if $\theta_c^* = 1$ in model (5) or $\theta_b^* = 1$ in Model (6), then the DMU is situated on the efficient frontier in CCR-DEA or BCC-DEA, respectively.

We visualize the frontier of a DEA model in Figure 1, using two inputs (x_1 and x_2) and one output (y). The piecewise linear line ABCD defines the efficient frontier of the existing observations. For example, for point G, representing a DMU, its efficiency score can be calculated as the ratio of distance OG' to distance OG.

We now give an example to illustrate the detection of the efficient frontier and the evaluation of DMUs using a DEA model. We suppose there are six DMUs with two inputs and a single output. In Table 2, hypothetical data is given.



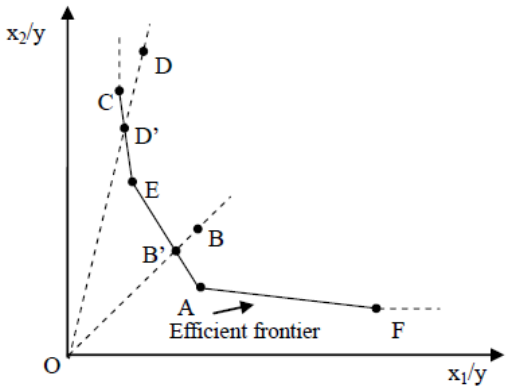


Figure 1. Efficient Frontier of a DEA model. Figure 2. Efficient Frontier and DMUs.

First, for comparison, we expand the inputs and output of each DMU proportionally and let the output of each DMU be 120 (Table 3).

Table 2. 6 DMUs with 2 inputs and a single output.

DMUs	DMU_1	DMU_2	DMU_3	DMU_4	DMU_5	DMU_6
Output (y)	120	8	24	40	120	24
Input 1 (x_1)	19	1	1	2	10	8
Input 2 (x_2)	10	1	6	15	17	1

We show these six DMUs in Figure 2 (which gives projections in input space) using points A-F to denote DMU_1-DMU_6.

Table 3. Expanded DMUs with 2 inputs and single output.

DMUs	DMU_1	DMU_2	DMU_3	DMU_4	DMU_5	DMU_6
Output(y)	120	120	120	120	120	120
Input 1(x_1)	19	15	5	6	10	40
Input 2(x_2)	10	15	30	45	17	5

We use a piecewise linear curve to link points C, E, A, F and merge it with the horizontal and vertical lines from point F and C, respectively, to obtain the piecewise linear convex hull, which is the efficient frontier produced from this DEA model. Points C, E, A, F are on the efficient frontier and their efficiencies are all unity. On the contrary, points B and D are inside the convex hull, so these two DMUs are inefficient compared with their peers or projections (points B' and D') on the efficient frontier. Taking point B as example, the DEA model uses the ratio of distance OB' to the distance OB to measure point Bs relative efficiency.

Decomposition of countries/territories based on multi-level frontiers in DEA

In the preceding section, we showed how the effective frontier can be detected. If we remove the efficient DMUs on the frontier, we can use the DEA model again to obtain a new frontier. We do this repeatedly in order to decompose DMUs into different levels. This process is illustrated in Figure 3. In this figure, the first tier of the efficient frontier is the piecewise line ABCD (Efficient frontier – tier1), on which the DMUs with the best level of efficiency are located. After we remove the DMUs on the Efficient frontier – tier1, we rerun the DEA model, obtaining the DMUs on the efficient frontier – tier2 as the second group, and so on.

This process is iterated until there is no DMU left, and the grading of the DMUs ends. The efficient frontier in Figure 1 is the same as the efficient frontier– tier1 in Figure 3.

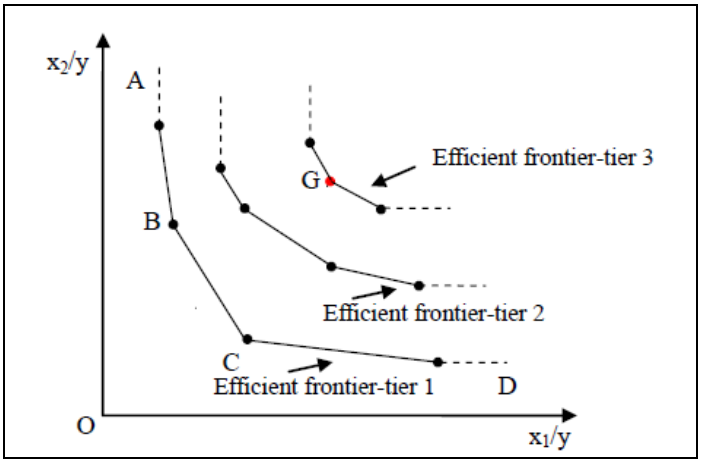

Figure 3. Multi-level efficient frontiers of a DEA model.

In earlier works, DEA frontiers have been used either to measure the relative efficiency of the DMUs (e.g., Charnes et al., 1978; Cook and Seiford, 2009) by comparing them with their peers or projections on the frontier, or to estimate the RTS by the frontier's shape (Banker et al., 2004). To the best of our knowledge, no research similar to the research reported in this paper has used multi-level frontiers in DEA models to decompose DMUs into different grades to reflect different levels of performance.

In the process of decomposing the DMUs into different grades, we need to ensure that a given DMU can only be assigned to one level to avoid conflicts. An efficient frontier is a convex hull. This implies that if a point belongs to F_k it cannot belong to any other F_{k+l} (if it exists, where l is a positive integer). Indeed a point on the frontier is a convex linear combination of efficient points on the frontier. If point P would belong to F_k and F_{k+l} this would mean that P is a convex linear combination of points that do not belong to F_k, which is not possible. Thus, one country/territory can only be assigned to one level.

Results

The BCC-DEA model was applied to produce multi-level efficient frontiers, and these were used to decompose the countries/territories of the study into different grades. Table 4 reports the levels of the countries/territories for the three experiments: two inputs & two outputs, two inputs & the first output (papers), and two inputs & the second output (citations).

We first consider the case of two inputs and two outputs. The results show that Chile, Greece, Iceland, Italy, Netherlands, UK and USA are the first level countries in the sense of efficiency of S&T resource utilization (Table 4). Mexico is the least efficient unit among the 39 countries/territories and belongs to the last level (Tier 6).

We reused the multi-level efficient frontiers in the BCC-DEA model on the 39 countries/territories with two inputs and the first output (papers) to decompose the countries/territories into different grades. We can see that now Chile, Greece, Iceland, Italy, Netherlands, UK and USA are the most efficient countries/territories (Table 4). Mexico, Finland, Israel and Singapore have with the lowest efficiencies.

We also used the multi-level efficient frontiers in the BCC-DEA model on the 39 countries/territories with two inputs and the second output (Citations), which is shown in table 4. Also in this case Chile, Greece, Iceland, Netherlands, UK and USA are first level countries, and Italy has moved into Tier 2. The latter means that Italy performs better for papers than for citations. Mexico and Turkey are in the last tier, Tier 7. It is interesting to see

that Turkey is in Tier 3 in the case of two inputs and two outputs while in Tier 7 in the case of two inputs and the second output, which means that the citation performance of Turkey is considerably worse than its performance for papers.

Table 4. Levels of the countries/territories.

36	Argentina	5	5	6
37	Russia	5	5	6
38	Finland	5	7	6
39	Mexico	6	8	7

Figure 4 corresponds to Table 4 and visualizes the levels of the countries/territories when using two inputs and two outputs, two inputs and the first output (paper), and two inputs and the second output (citation). From this figure, it is clear that some countries/territories (e.g.,

Argentina, Belgium, Czech Republic, Turkey) belong to a lower level in the case of two inputs & the second output (citations) compared to the case of two inputs & the first output (papers), which indicates that these countries perform more efficient for papers than for citations. Inversely, some countries (e.g., Austria, Denmark, Finland) perform more efficient for citations than for papers.

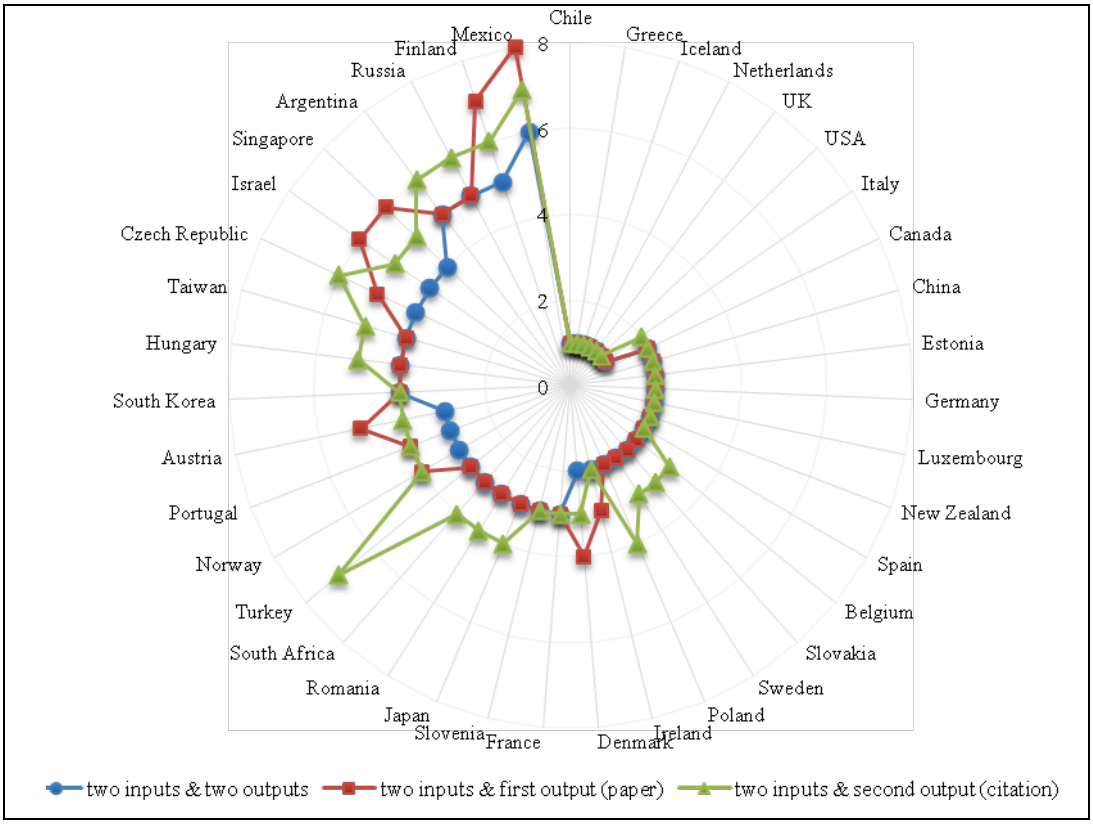

Figure 4. Visualisation of the levels of the countries/territories.

It is surprising that Greece and Chile are rated first level countries together with S&T-developed countries like USA and UK. For papers as output, we can verify this result using the ratios Papers to Researcher and Papers to Research Funding. From Table 5, we can see that Greece and Chile perform very well for these two ratios. On the contrary, we can see China, Japan and South Korea have low performance compared to other countries. We believe that a reason for this is that researchers from these countries publish relatively frequently in domestic journals that are not covered by WoS. We do not tabulate the values of the corresponding two ratios for citations, but it turned out that Chile and Greece perform well also with respect to these ratios.

Discussion and conclusions

In this paper we have shown that multi-level frontiers of DEA can be used to decompose countries/territories into different levels, reflecting the efficiency of S&T resource utilization of the countries/territories. The approach put forward is not restricted to the grading of countries/territories. It can also be used to grade, for instance, journals and research institutions based on properly selected indicators. In case of no explicit inputs, e.g., when journals should be graded, we can assume that there is single constant input, which is equal to unity for all observations (e.g., Yang et al. 2014b).

There are two main advantages of the grading approach proposed in this paper. First, it is a nonparametric and recursive approach, which needs no a priori information such as indicator

weights and threshold values for different grading levels. Second, the observations within the same level are indifferent in the sense of efficiency of resource utilization. The main disadvantage of the approach is that in some cases there are too few indicators (single input and single output). Under such circumstances, it might be the case that each level includes exactly one observation (in our case, exactly one DMU). Thus, the approach is more suitable for grading observations with multiple input and output indicators.

For future research, we would like to investigate the multiple DEA frontiers regarding weight restrictions in DEA models. There are at least four types of restrictions on the weights of input and output variables (e.g., Allen et al., 1997), and the efficient frontiers will vary accordingly and show different properties. Furthermore, this grading approach can be easily extended to the classification of scientific journals, research institutions, etc.

Table 5. Ratios of Papers to Researcher and Research Funding.

Abstract

Current research assessment is built on the basis of core-journals-selection system. Journal evaluation is not equal to article evaluation, evaluating scientists, institutions and countries based on article-level evaluation is more reasonable than the current journal-based evaluation. Different from the current research evaluation tools and databases, e.g., ESI and Nature Index, in this study, we propose the idea of continuous, dynamic and comprehensive article-level-evaluation based on article-level-metrics data. Different kinds and sources of metrics are integrated into a comprehensive indicator, to quantify both the long-term academic and short term societal impact of the article. At different phases after the publication, the weights of different metrics are dynamically adjusted to mediate the long term and short-term impact of the paper. Using the sample data, we collect the metrics data over two years for each sample article, and make empirical study of the article-level-evaluation method. The original data and interactive visualization of this research is available at http://xianwenwang.com/research/ale/.

Conference Topic

Altmetrics; Indicators; Science policy and research assessment

Introduction

For decades, citation has been regarded as the sole indicator to evaluate the impact of a paper, a paper that is cited more frequently means the research results gained more recognition. However, citations need a long time (often over two years) to accumulate. In many situations, e.g., funding decisions, hiring tenure and promotion, people need to make evaluations for newly published papers. Alternatively, some people begin to use journal based metrics, e.g., Journal Impact Factor, as an alternative way to quantify the qualities of individual research articles (Alberts, 2013). There are many debates about the abuse of Impact Factor (Bordons, Fernández, & Gomez, 2002; Garfield, 2006; Opthof, 1997; PLoS_Medicine_Editors, 2006; Seglen, 1997), applying Journal Impact Factor to assess the research excellence is not the most appropriate way. In addition, only tracking citation metrics could not tell the whole story about the influence of a paper. Besides citation, the impact of scientific papers could be reflected with article usage (browser views and pdf downloads), captures (bookmarks and readership), online mentions (blog posts, social media discussions and news reports) (Priem, Taraborelli, Groth, & Neylon, 2010). Therein, the idea of altmetrics comes into being. Different from citation, which puts particular emphasis on describing the academic impact of articles, altmetrics is based on data gathered from social media platforms and focuses on the societal impact (Kwok, 2013; Sud & Thelwall, 2014; Zahedi, Costas, & Wouters, 2014). Compared with the long time for papers to reach their citation peaks, it takes a short period for newly published articles to peak for altmetric scores. In summary, citation is an indicator to measure the long-term academic impact, when the indicator of altmetrics reflects short term societal impact. Neither citations nor altmetrics individually could fully indicate the complete impact of a paper, we cannot accurately conjecture the results of one metric by the results of another.

It is necessary to find a way to quantify both the academic and societal impact together, and mediate the long term and short-term impact of the paper. Some publishers have already listed

the different types of metrics for an individual article, e.g., PLOS, when some altmetrics tools and services are also available, e.g., Impact Story, Altmetric.com, Plum Analytics, etc. Although altmetric score from altmetric.com is a weighted count that integrates different online mentions of the paper. If we go further on this way, taking all available metrics (e.g., citation, usage, online attention, etc.) into consideration to design a comprehensive metric, which could be used to evaluate the complete impacts of articles.

Based on the calculated total impacts, the comprehensive metric makes it possible to rank articles on a unified dimension, which solo academic or societal impact indicator could not.

The absence of evaluating data source

According to the official statement of Web of Science, it is designed for researchers to "find high-impact article". Nowadays, with the absence of specialized evaluating data source, Web of Science has been adopted by many scientometrics researchers and institutions as the primary data source of article evaluation. In some countries, e.g., China, articles indexed in Science Citation Index/Social Science Citation Index or not is a very important criterion to judge the quality of the research.

However, applying Web of Science to assess the research performance and research excellence is not a good choice. Web of Science is designed and created on the basis of journal selection, it collectively index journals cover-to-cover. However, articles published in the same journal, the same issue, have totally different impacts. Even for those high impact factor journals, there are many articles have few citations.

We check the articles published in 2000 and indexed in Science Citation Index Expanded, as Table 1 shows. For example, 2901 of the total 13660 articles in Chemical Engineering have never been cited. For the area of Condensed Matter Physics, the zero-citation percentage is 10.91%, for the area of Biochemistry, Molecular Biology, the zero-citation percentage is 3.23%.

Table 1. Number of Zero-citation articles in 2000 indexed in Science Citation Index Expanded.

	Total	*Zero-citation*	*Percentage*
Engineering, Chemical	13660	2901	21.24
Physics, Condensed Matter	21974	2397	10.91
Biochemistry, Molecular Biology	42710	1380	3.23

There are also some publishers regard Web of Science as a profit-making tool. For example, *Academic Journals* charges a US$550-$750 manuscript handling fee from the author for each accepted article (http://www.harzing.com/esi_highcite.htm). Among which, several ISI-listed journals publish more than 1,000 articles per year, e.g., in 2007, *African Journal of Business Management* only published 28 articles, in 2010, it published 446, when in 2011, as many as 1350 articles were published by this single journal. Thomson Reuters has the mechanism to review the exiting journal coverage constantly, some journals that have become less useful would be deleted. However, this kind of mechanism does not apply to the articles, even some journals are deleted from the coverage, numerous low-quality papers published by these journals are still indexed in Web of Science.

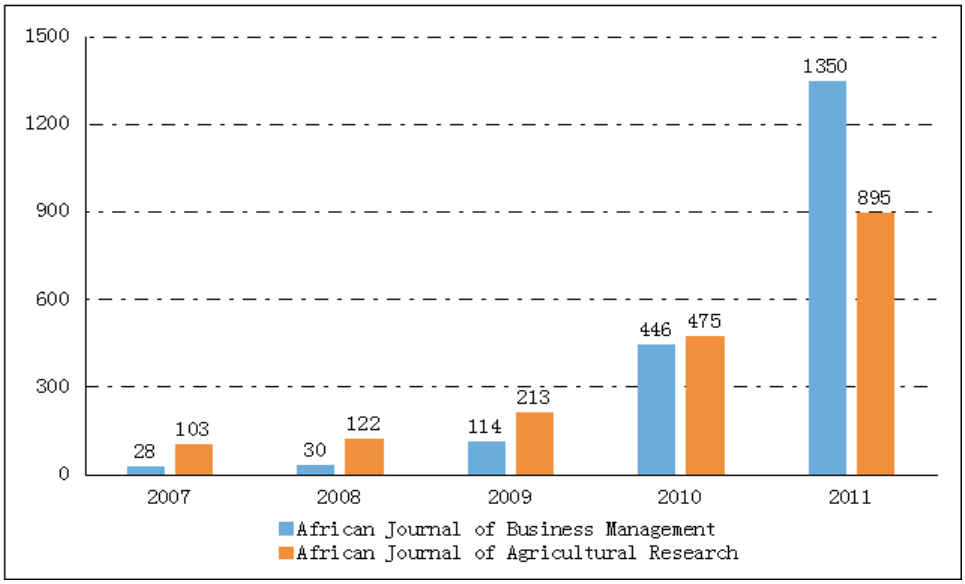

Figure 1. Rapid growth of yearly indexed articles of two journals.

With the same idea of Web of Science, Nature Publishing Group (NPG) introduced the Nature Index in November 2014, which is "a database of author affiliation information collated from research articles published in an independently selected group of 68 high-quality science journals" (Nature, 2014). The 68 journals are selected by a group of professors and validated by 2,800 responses to a large-scale survey, when these 68 journals account for approximate 30% of total citations to natural science journals (http://www.nature.com/press_releases/nature-index.html).

Based on journal article publication counts and citation data from Thomson Scientific databases (mainly from Web of Science), ISI/Thomson (now Thomson Reuters) proposed Essential Science Indicators (ESI), which is an in-depth analytical tool and also a database where citations are analyzed, so that scientists, journals, institutions, and countries can be ranked and compared, for example, most cited scientists rankings, institutions rankings and countries rankings. Ranking in ESI is made by the citations, it has nothing to do with the Impact Factors of journals, which means that whichever journal the paper is published in, citations is the only factor to be taken into account. Although ESI set a relatively low selection criterion for newly published papers (http://www.in-cites.com/thresholds-highly-cited.html), using cited times to evaluate is not a good choice.

Compared to 8670 journals covered by Science Citation Index Expanded, the journals selected by Nature Index is so much less, which makes Nature Index become an elite database. The aim of Nature Index is "intended to be one of a number of metrics to assess research excellence and institutional performance" (http://www.natureindex.com/faq). However, we think journal-based database is not appropriate for research evaluation, including research excellence and institutional performance, which should be on the basis of article-level metrics. Because of the great influence of Nature Publishing Group, the Nature Index will definitely make great changes to the academia and research evaluation system.

It is necessary to make changes to the current evaluating way of scientific literature. In this research, our purpose is to design a new method, through which the continuous, dynamic and comprehensive evaluation of scientific literature could be made. This new method will be valuable to the research community. With this evaluating method and system, we could make a better evaluation of articles, scientists, journals, institutions, and even countries.

Design a new evaluation way

Considering both academic and societal impact of a paper

As mentioned above, the impact of a paper could be measured by citation, article usage and online mentions, etc., as Table 2 shows.

Table 2. Types and metrics of the impact of a paper.

Type	*Metric*
Article usage	browser views (abstract, full-text), pdf downloads
Captures	bookmarks (CiteUlike), readers (Mendeley)
Online mentions	blog posts, news reports, likes (Facebook), shares (Facebook), Tweets, +1 (Google plus)
Citations	citations

The Issue 6, Volume 8 of PLOS Computational Biology is selected as our research object. It was published in June 2012, and includes 46 research articles.

In November 2012, PLOS began to provide a regular report covering a wide range of article-level-metrics covering all of its journals via the platform http://article-level-metrics.plos.org/. In this research, the cumulative article-level-metrics data for the entire PLOS corpus are harvested from the PLOS ALM platform. From October 2012 to October 2014, PLOS has provided the ALM reports for 8 times, when the provided date are Oct. 10, 2012, Dec. 12, 2012, Jan. 8, 2013, Apr. 11, 2013, May. 20, 2013, Aug. 27, 2013, Mar. 10, 2014 and Oct. 1, 2014. Factor analysis is employed to study the metrics data of the 46 articles, Table 3 shows the results of the data extracted from the ALM report of Oct. 2014.

Table 3. Rotated Component Matrix.

	Factor 1: Academic impact	*Factor 2: Societal impact*
CiteUlike	0.775	
Mendeley	0.856	
HTML views	0.692	0.672
PDF downloads	0.917	
Scopus	0.751	
Facebook		0.745
Twitter		0.709

Note. Factor loadings < .5 are suppressed

7 metrics data of Oct. 10, 2012 are factor analyzed by using principal component analysis with Varimax (orthogonal) rotation. The analysis yields two factors explaining a total of 73.709% of the variance for the entire set of variables. Factor 1 is labeled academic impact to the high loadings by the following items: CiteUlike bookmarks, Mendeley readership, PDF downloads and Scopus citations. This first factor explained 48.691% of the variance. The second factor derived is labeled societal impact. This factor is labeled as such due to the high loadings by the two indicators of Facebook and Twitter. The variance explained by this factor is 25.018%. For the indicator of HTML views, the both factor loadings are greater than 0.65, which means that browser HTML views has both academic and societal impact.

The Altmetric score is a quantitative measure of the attention that a scholarly article has received. It is a weighted count of the different online platform sources (newspaper stories, tweets, blog posts, comments) that mention the paper. Downloads, citations and reader counts

from Mendeley or CiteULike are not used in the score calculation. So, Altmetric score could be regarded as a comprehensive indicator that measures the societal impact of paper partially.

Dual function of societal impact

The value of societal metrics is not only reflected by the social effects of the diffusing of the knowledge embodied in the literature, but also reflected by the possible additional academic impact caused by social online attention.

Social media make the research achievements and scientific discoveries spread to the general public, which is just the goal of scientific researches. From the other hand, wide spreading of scientific literature could lead to more scholarly citations. The mechanism from online attention to citation is very complicated, but social attention do have the potentiality to contribute some extra citations to a paper (Wang, Liu, Fang, & Mao, 2014; Wang, Mao, Zhang, & Liu, 2013).

Dynamic patterns of article-level metrics

For the 46 selected articles published in June 2012, we sum the metrics data at the 8 time periods separately, as Figure 2 shows. Different metrics show different dynamic evolution patterns. In October 2012, when the articles had been published for about 4 months, there is few citations. The curve of citations begins a sharp rise at the phase of May 2013, one year after the publication. However, for the Facebook and Twitter data, the two curves have almost reached their summits at the very first phase. During the next periods, there is little increase for the Facebook and Twitter data. And for the views data, which is placed on the secondary Y axis in Figure 2, the situation is somehow between the citations and Facebook/Twitter. At the first phase, there is considerable data. During the following 7 periods, there is a steady growth trend for the curve of views.

Dynamic patterns for the different metrics are distinct. Social attention comes to go, citation takes a long time to know, when article view also comes fast but keeps a steady growth.

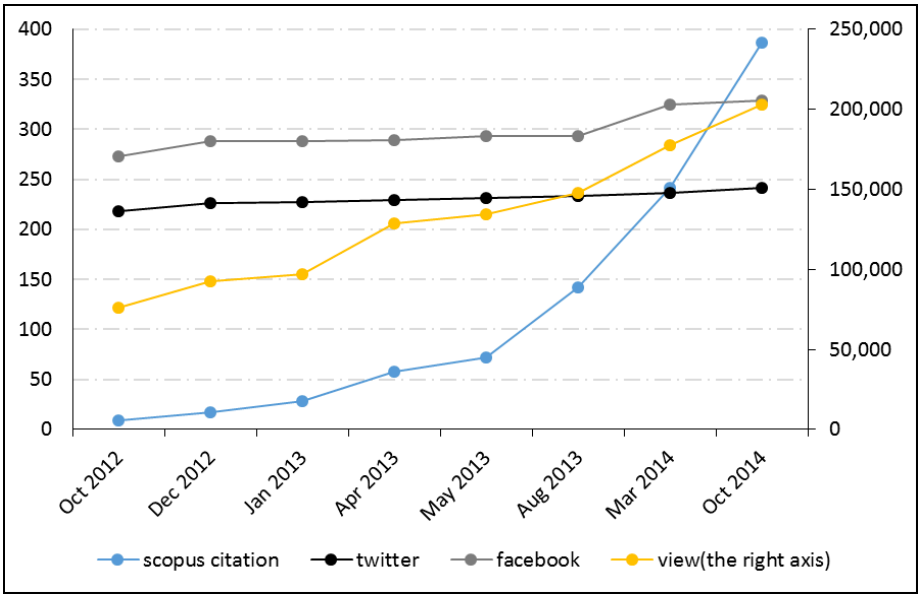

Figure 2. Temporal trend of different metrics of 46 articles published in June 2012.

Article-level evaluation based on Article-level-metrics

In the era of print, the article could not be separated from the whole issue. For example, libraries could provide the borrowing statistical data, however, it's difficult to know which

single article or articles readers are interested in. In the digital era, the situation has been changed greatly. Metrics data for each article are easy to know, including the views, downloads, altmetric score and citations. Of course, some data are easy for publishers to know but not released to public. As early in March 2009, PLOS inaugurated a program to provide "article-level metrics" on an article across all PLOS journals. The metrics data include five main categories, which are Viewed, Cited, Saved, Discussed and Recommended. Following PLOS, more and more publishers began to provide detailed article-level metrics data for readers and researchers. For example, in October 2012, Nature began to provide a real-time online count of article-level metrics for its published research papers, including citation data, news mentions, blog posts and details of sharing through social networks, such as Facebook and Twitter (http://www.nature.com/news/nature-metrics-1.11681). In 2014, the article-level metrics data are also available for PNAS and Science. The growing article-level metrics dataset provides us with the possibility to design a new evaluating way to make article-level evaluation.

Problems need to be solved

The first problem is there are too many indicators need to be considered. Citation has been regarded as the single indicator for the past tens of years, nowadays there are much more indicators which are worth being considered, including article views, bookmarks and readership, online discussion, news reports and citations, etc. So many indicators mean a lot of dimensions of the impact, different papers may have different values for the indicators, for example, paper A has been downloaded many times but retweeted few times, when paper B may has opposite situation, so it is very difficult to compare the impact of these two articles, especially when these articles are newly published.

Could these so many indicators be synthesized to one single comprehensive indicator, which could reflect the most of information of the original data and make the papers in diverse situations comparable?

The second problem is the dynamic adjustment of the results. At different phases after publication, the same indicator may have different effects on the impact of the paper. For the newly published articles, because the citations are generally low, it is difficult to judge the qualities and compare the new articles. At the early phase, it is a better choice to use article usage data, online mention data to make evaluation of the newly published articles. As time goes by, the evaluation is gradually dominated by citation metrics, which means that citation would play the most important role in the evaluation when the article has been published for a relatively long time. To solve these two problems, we propose the idea of designing a comprehensive indicator to reflect all the impacts of an article. The weights of the indicators at different phases should be adjusted dynamically due to the change of relative importance of metrics, just like Table 4 shows.

To integrate different metrics into a comprehensive indicator, the first problem needs to be solved is weighting. Here we use Analytic hierarchy process (AHP) to calculate the weights of different metrics. The AHP methodology was developed by Thomas L. Saaty in the 1970s (Saaty, 1980). It allows users to assess the relative weight of multiple criteria in an intuitive manner, so it has both advantages of quantitative criteria and qualitative judgment provided by the users. Using pairwise comparisons (X is more important than Y), the relative importance (priority) of one criterion over another can be expressed. To calculate the weights for the different criteria, a pairwise comparison matrix needs to be created. The matrix is a matrix A, where m is the number of evaluation criteria considered, denotes the entry in the *i*th row and the *j*th column of matrix. Each entry of the matrix represents the importance of the *i*th criterion relative to the *j*th criterion. If the cell value in the entry is greater than 1, then the *i*th criterion is more important than the *j*th criterion, and vice versa. If two criteria have the

same importance, then the cell value in the entry is 1. The relative importance between two criteria is measured according to a numerical scale from 1 to 9 or 1/9 to 1.

Table 4. Relative importance of metrics at different phases.

Phase	*Relative importance*	*Selection standard*
1 (0-6 months)	PDF downloads > HTML views > Twitter > Facebook > Mendeley > CiteUlike > Citation	Top 80% of all articles of same month and subject
2 (6 months-2 years)	PDF downloads > HTML views > Mendeley > CiteUlike > Citation > Twitter > Facebook	Top 70% of all articles of same month and subject
3 (2 -5 years)	Citation > Mendeley > CiteUlike > PDF downloads > HTML views > Twitter > Facebook	Top 50% of all articles of same year and subject
4 (5 years-)	Citation > Mendeley > CiteUlike > PDF downloads > HTML views > Twitter > Facebook	Top 30% of all articles of same year and subject

According to the definition of relative importance of different metrics, we need to construct different pairwise comparison matrixes at different phases. The pairwise comparison matrix at phase 1 is shown in Table 5. The higher the weight is, the more important the corresponding criterion becomes, which is represented by the cell value in the matrix. For example, the values in the cells where the row of CiteUlike, the column of HTML views and PDF downloads intersect are less than 1, moreover, the ratio of CiteUlike and PDF downloads is less than the ratio of CiteUlike and HTML views, it means that at phase 1, CiteUlike is less important than HTML views, and much less important than PDF downloads.

Table 5. Pairwise Comparison Matrix at phase 1.

	CiteUlike	*Mendeley*	*HTML views*	*PDF downloads*	*Citation*	*Facebook*	*Twitter*
CiteUlike	1	1	1/4	1/6	4	1/4	1/6
Mendeley		1	1/4	1/6	4	1/4	1/6
HTML views			1	1/4	6	3	2
PDF downloads				1	9	4	3
Citation					1	1/4	1/7
Facebook						1	1/2
Twitter							1

At phase 4, there is much change in the relative importance of the metrics, as Table 6 shows. CiteUlike and Mendeley become more important than HTML views, so the cell values get greater than 1. At this phase, citation is the most important criterion.

In this study, the weights and CI values of AHP models are calculated by a CGI system (http://www.isc.senshu-u.ac.jp/~thc0456/EAHP/AHPweb.html). The results are shown in Table 7.

In Figure 3, we show the change of the weights of metrics. At Phase 1 and 2, the metric of PDF downloads has the greatest weight. From Phase 1 to 4, the curve of PDF downloads shows a downward trend, when the weight of citation is upward.

Empirical Study

The weights in Table 7 are applied to calculate the comprehensive scores of the metrics data of the 46 articles. Metrics data of Oct. 10, 2012 is calculated with the weights of phase 1,

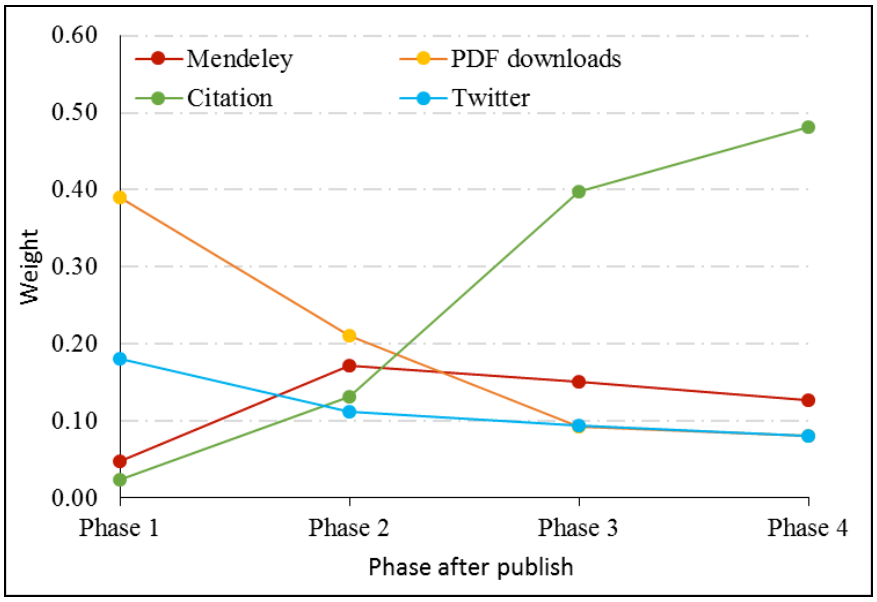

Figure 3. The change of the weights of different metrics.

when weights of phase 2 and 3 are used for metrics data of Aug. 27, 2013 and Oct. 1, 2014 separately. All the original metrics data are normalized to the range of 0-1. The normalized value of e_i for variable E in the ith row is calculated as:

$$Normalized\ (e_i) = \frac{e_i - E_{min}}{E_{max} - E_{min}}$$

Where $E_{\min}$ and $E_{\max}$ are the minimum and maximum value for variable E correspondingly.

In Table 8, the values of 7 metrics are original data, when the scores are calculated with the normalized data instead of the original metrics data.

	11	1002562	7	58	2840	529	10	0	0	0.1476

Note: (1) Because of the limited layout space, the first half of the doi is omitted. For example, for the doi 10.1371/journal.pcbi.1002358, we only keep 1002358 in Table 8.

(2) Detailed information of Table 8 is available at http://xianwenwang.com/research/ale

Table 8 lists the top 11 (top 25% of 46) articles of each phase. At phase 1, when the 46 articles had been published for 4 months, article 10.1371/journal.pcbi.1002358 has 16

CiteUlike bookmarks, 81 Mendeley readers, 5060 HTML views, 1733 PDF downloads and 3 Scopus citations, etc., when the comprehensive score of this article is 0.7906, ranks top 1. At phase 2, the values of the metrics of Mendeley, HTML views, PDF downloads and Scopus citations have risen sharply, but not for the metrics of Facebook and Twitter, when the score is 0.8579 and still ranks top 1. From phase 1 to 2 and 3, there is much change for the top 11 articles. The ranks of some articles rise, when others may fall. For example, article 10.1371/journal.pcbi.1002538 ranks 6th at phase 1, downs to 9 at phase 3, and is disappeared from the top 11 at phase 3; article 10.1371/journal.pcbi.1002531 ranks 11 at phase 1, and rises to top 4 at phase 3.

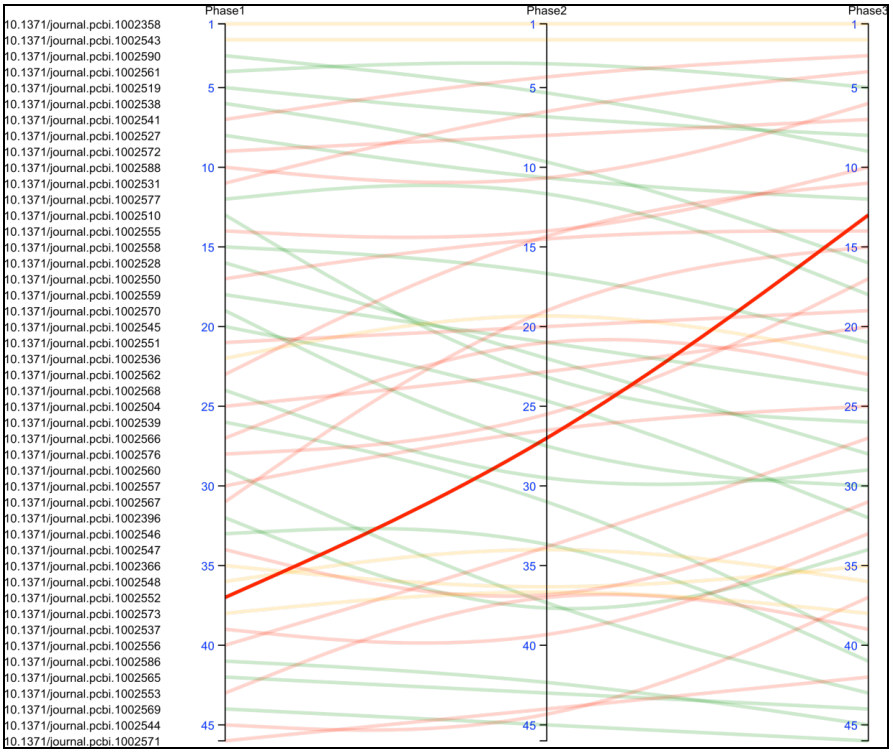

Figure 4. Dynamic changes according to the ranking at different phases.[1]

The dynamic changes of the scores and rankings of the 46 articles from phase 1 to 3 are shown in Figure 4. The DOIs of 46 articles are listed on the leftmost column, and ranked according to the scores at phase 1. The position of article at the certain phase is decided by the ranking of score at that phase. 46 articles could be only compared at the same phase. Articles at different phases, and even the same article at different phases are not comparable. As shown in Figure 4, if the rank of an article from phase 1 to 3 shows an upward trend, it is displayed with a red curve, there are 20 papers with red curves. We use green curve to represent the downward trend, there are also 20 papers with green curves. Otherwise, if the rank of the article has not changed, the color of the curve is yellow, there are 6 yellow curves. In Figure 4, one red curve with dramatic upward trend is highlighted, indicating that the performance of this paper is rising. The doi of this article is 10.1371/journal.pcbi.1002552, it only ranks 37 at phase 1, rises to 28 at phase 2 and continue to rise to 13 at phase 3.

According to the rankings calculated by the comprehensive metric, articles with the highest impact are selected into the database. There are different selection standards at different phases, as Table 4 shows. As time goes on, the data of the original indicators become

[1] An interactive version of Figure 4 is available at http://xianwenwang.com/research/ale/dynamic.html

increasingly sufficient, the accuracy of the results becomes higher. Due to the dynamic changes of the rankings of articles, the database is also dynamic, it ensures the articles included are always has the highest impact at each phase. It would be much easier for researchers to index the high quality articles through the dynamic database.

Discussion

In the 1950s, people read papers from printed journals. A group of articles are bundled together to form an issue of journal, it is difficult to separate single article from the whole issue, which is the carrier of articles. For example, if we want to know which paper the readers are interested in when they borrow the journal from the library, which seems to be an extremely difficult task. At that time, journal evaluation is the most important and basic issue. SCI is designed on the basis of core journals selection, specialized indicators and tools are proposed to evaluate journals, e.g., Impact Factor and Journal Citation Reports.

Compared to fifty years ago, scholarly communicating ways have changed a lot. With the advent and fast development of computers, internet and digital libraries, the transformation from print to electronic publishing is accelerating, just as the digital music revolution set music free from the carriers of cassette tape and CD, the concept of printed journals or even journals in the conventional sense is not important any more. Actually, for some new journals, articles are not organized and published by issues and volumes, e.g., PLOS ONE, Scientific Reports, eLIFE and Peer J, etc.

It is necessary to make changes to the current research evaluation way rooted in the journal selection system. We should be aware of that journal evaluation is not equal to article evaluation, evaluating scientists, institutions and countries based on article-level evaluation is more reasonable than the current journal-based evaluation. It would "be better to measure the performance of countries and institutions on the basis of individual papers, rather than on the journals in which they are published" (Haunschild & Bornmann, 2015). In order to make better assessment of research performance and research excellence, we propose the idea of article level evaluation system and database. Using metrics data at different time periods of 46 articles in one issue, we make empirical test of the article level evaluation method.

Firstly, the basic function of this evaluation system is to assess the qualities of articles. Based on article level evaluation, it is also available to assess the research excellence of scientists, journals, institutions and countries. For example, how many articles tracked in phase 3 and 4 are published by one specific institution? What are the top institutions in one specific field? Secondly, both scholarly and societal impact of articles are taken into account. Thirdly, using the article usage data and online mention data, we can make evaluation of newly published papers. At different phases after publication, the comprehensive score of the paper is calculated with different weights of metrics, so the score and rank of a paper in different phases change.

To accomplish this, the biggest problem needs to be solved is the availability of metrics data. The citation data could be obtained from Web of Science, Scopus, Google Scholar, etc. The online attention data, e.g., social media, news reports, Mendeley readership is also available from various but certain data sources. However, for the article usage data, only part of academic publishers and journals provide usage data to public, including Nature Publishing Group, Science, PLOS, Taylor & Francis, ACM Digital Library, IEEE Xplore Digital Library, etc. (Wang, Mao, Xu, & Zhang, 2013). For many others, e.g., Elsevier, Sage and Wiley, they may provide the metrics data of each article to some specific users and subscribers, but not free to public. If we want to evaluate all the papers whatever the publishers are, metrics data from publishers is indispensable.

With the movement from print to electronic publishing and the diversification of article-level-metrics, it is time to make change to the current research evaluation system. To better assess

scientists' research and satisfy the evaluation needs in many situations, ranging from funding decisions to hiring tenure and promotion, we need to build an article-level-evaluation system.

Limitation

In this study, we interpret the idea of building such a kind of system and make empirical study using a relative small size dataset, and we only track the metrics data of the sample articles in the last two years. To build the article-level-evaluation system is not an easy job, of course there are lots of problems need to be solved, including a bigger dataset, longer time period, more detailed metrics and maybe more scientific weighting methods, but we think it is the right way to make assessment of research, we are moving on the right direction.

Interdisciplinarity and Impact: Distinct Effects of Variety, Balance, and Disparity

Jian Wang[1], Bart Thijs[1] and Wolfgang Glänzel[1]

{Jian.Wang, Bart.Thijs, Wolfgang.Glanzel}@kuleuven.be
[1] KU Leuven (Belgium)

Abstract

Interdisciplinary research is increasingly recognized as the solution to today's challenging scientific and societal problems, but the relationship between interdisciplinary research and scientific impact is still unclear. This paper studies the relationship between interdisciplinarity and citations at the paper level. Different from previous literature compositing various aspects of interdisciplinarity into a single indicator, this paper uses factor analysis to uncover distinct aspects of interdisciplinarity and investigates their independent dynamics with scientific impact. Three uncovered factors correspond to variety, balance, and disparity. Subsequently, we estimate Poisson models with journal fixed effects and robust standard errors to investigate the relationship between these three factor and citations. We find that the number of citations (1) increase at an increasing rate with variety, (2) decrease with balance, and (3) increase at a decreasing rate with disparity. These findings have important implications for interdisciplinarity research and science policy.

Conference Topic

Science policy and research assessment

Introduction

Interdisciplinary research has been increasingly viewed as the remedy for the challenging contemporary scientific and societal problems. As important ideas often transcend the scope of a single discipline, interdisciplinary research is the key to accelerate scientific discoveries and solve societal problems. Given the normative interest in and the policy push for interdisciplinary research, it's important to empirically investigate the consequences of interdisciplinary research. Bibliometric studies have explored the relationship between interdisciplinary research and citation impact, but findings are mixed. For example, Steele and Stier (2000) found a positive effect of interdisciplinarity on citation impact for environmental sciences papers, where interdisciplinarity was measured as the disciplinary diversity of the cited references. Rinia, van Leeuwen, van Vuren, and van Raan (2001) studied physics programs in the Netherlands and operationalized interdisciplinarity as the ratio of non-physics publications. They found significantly negative correlations between interdisciplinarity and non-normalized citation-based metrics, but correlations became insignificant when field-normalization took place. Levitt and Thelwall (2008) found that interdisciplinary papers received fewer citations in life and physical sciences but not in social sciences, and interdisciplinary papers were defined as papers published in journals assigned to multiple subject categories. Larivière and Gingras (2010) analyzed all Web of Science (WoS) articles published in 2000, measured interdisciplinarity as the percentage of its cited references to other disciplines, and found an inverted *U*-shaped relationship between interdisciplinarity and citations.

One possible explanation for these conflicting results pertains to their different choices of the interdisciplinarity measure. On the one hand, a number of interdisciplinarity indicators have been proposed, at various levels (e.g., paper, journal, institution, and fields) and using various bilometric information (e.g., disciplinary memberships of authors, published journals, or cited references). On the other hand, the concept of interdisciplinarity remains an abstract and complex one (Wagner et al., 2011). One useful conceptualization is to view interdisciplinarity

as the diversity of disciplines invoked in the research (Porter & Rafols, 2009; Stirling, 1998, 2007). Furthermore, diversity has three distinct components (Stirling, 2007, p. 709):

> *Variety is the number of categories into which system elements are apportioned. It is the answer to the question: 'how many types of thing do we have?'*
>
> *Balance is a function of the pattern of apportionment of elements across categories. It is the answer to the question: 'how much of each type of thing do we have?'*
>
> *Disparity refers to the manner and degree in which the elements may be distinguished. It is the answer to the question: 'how different from each other are the types of thing that we have?'*

Many studies have devoted to compositing all aspects of interdisciplinarity into one single indicator. However, this paper adopts an opposite approach: we decompose different aspects of interdisciplinarity and explore their unique relationships with citation impact, at the individual paper level. Given that interdisciplinarity is an abstract and multidimensional concept, there might not be a straightforward answer to the question of whether interdisciplinary research draws higher impact. Instead, we should ask the question in another way: what kinds of interdisciplinarity have positive/negative relationships with citation impact? In addition, nuanced understanding of the divergent dynamics underlying different aspects of interdisciplinarity is also important for informing interdisciplinary research and science policy.

Data and methods

We analyzed all the journal articles published in 2001 indexed in the Thomson Reuters Web of Science Core Collection (WoS). Only articles were analyzed, while all other document types such as reviews and letters were excluded. The year 2001 was chosen so that studied papers could have a sufficiently long period to accumulate their citations (Wang, 2013).

Interdisciplinarity measures

Following previous literature, we constructed interdisciplinarity measures for each individual articles based on the disciplinary profile of its cited references, since referencing to prior literature in various disciplines indicates drawing and integrating knowledge pieces from these disciplines. Specifically, we constructed interdisciplinarity measures based on the WoS subject categories (SCs) referenced by each article. Interdisciplinarity measures constructed in this paper are listed in Table 1, which have been commonly used in the literature (Leydesdorff & Rafols, 2011; Rafols et al., 2012; Stirling, 2007). Because the last two interdisciplinarity measures cannot be constructed if the focal article references fewer than two subject categories, we excluded these articles from the analysis. Nevertheless, regressions using the whole dataset for the other measures yielded consistent results. In total, our data have 646,669 papers.

Factor analysis

We used factor analysis to uncover components underlying these interdisciplinarity measures. The first step was to determine the number of factors to retain. A classic approach is Kaiser's eigenvalue greater than one rule (Kaiser, 1960). The idea is that the retained factor should explain more variance than the original standardized variables. Horn's parallel analysis

Table 1. Interdisciplinarity measures.

Measure	*Description*
Ratio of references to other subject categories	
Number of referenced subject categories	n
1 – Gini	$1 - \frac{\sum(2i - n - 1)x_i}{n \sum x_i}$ where i is the index, x_i is the number of references to the i-th subject category, and subject categories are sorted by x_i in non-decreasing order.
Simpson index	$1 - \sum {p_i}^2$ where $p_i = x_i/X$, and $X = \sum x_i$
Shannon entropy	$-\sum p_i log\ (p_i)$
Average dissimilarity between referenced subject categories	$\frac{1}{n(n-1)} \sum_{i \neq j} d_{ij}$ where d_{ij} is the dissimilarity between subject category i and j. Specifically, $d_{ij} = 1 - s_{ij}$, where s_{ij} is the cosine similarity between subject category i and j based on their co-citation matrix.
Rao-Stirling diversity	$\sum_{i \neq j} p_i p_j d_{ij}$

modified Kaiser's rule, where the criterion for each eigenvalue is different and also superior to one, and these criteria are obtained from a Monte-Carlo simulation (Horn, 1965). Cattell's scree test provided a graphical strategy: plotting the eigenvalues against the component numbers and searching for the elbow point (Cattell, 1966). However it does not yield a definitive number of factors to retain, which still relies on subjective judgments of the researcher. Recently, Raiche, Walls, Magis, Riopel, and Blais (2013) developed numerical solutions for Cattell's scree test: (1) the optimal coordinate solution for the location of the scree and (2) the acceleration factor solution for the location of the elbow. We implemented all these methods to determine the number of factors. After determining the number of factors to retain, we extracted these factors using the varimax rotated principal components method. In addition, the number of referenced subject categories is highly skewed, so its nature logarithm was used in the factor analysis.

Regression analysis

To study the relationship between interdisciplinarity and citation impact at the article level, we ran regressions, using the number of long-term citations (in a 13-year time window from 2001 to the end of 2013) as the dependent variable and the interdisciplinarity measures and extracted factors as explanatory variables.

For all our regressions, we incorporated journal fixed effects to control for (1) unobserved topic/subfield heterogeneities at a very refined level and (2) journal reputation effects (Judge et al., 2007). Therefore, we estimated the within-journal effects, in other words, we were evaluating the association between interdisciplinarity and citations among papers published in the same journal. In addition, the following variables were incorporated as controls: the number of authors, the number of countries, the number of pages, and the number of references. The numbers of authors, pages, and references are skewed so that their natural

logarithms were used in regression analyses. The number of countries is still highly skewed after logarithm transformation, so we created a dummy variable, international: 1 if the paper has authors from more than one country, and 0 otherwise. In our sample, about 19% of the papers are internationally coauthored.

Because citation counts are over-dispersed count variables, we used Poisson regression with robust standard errors, following previous literature (Hall & Ziedonis, 2001; Hottenrott & Lopes-Bento, In Press; Somaya, Williamson, & Zhang, 2007). An alternative is the negative binomial model. However, because the Poisson model is in the linear exponential class, Gourieroux, Monfort, and Trognon (1984) have shown that the Poisson estimator and the robust standard errors are consistent so long as the mean is correctly specified even under misspecification of the distribution, but the negative binomial estimator is inconsistent if the true underlying distribution is not negative binomial. Therefore, we adopted the Poisson model with robust standard errors in our empirical analysis. Furthermore, we incorporated journal fixed effects. Such fixed effects Poisson models can be fitted by conditioning out the individual fixed effects (Hausman, Hall, & Griliches, 1984).

Results

Decomposing interdisciplinarity

We used the following variables in the factor analysis: log number of referenced subject categories, ratio of references to other subject categories, 1 – Gini, Simpson index, Shannon entropy, average dissimilarity between referenced subject categories, and Rao-Stirling diversity. The first three eigenvalues are greater than 1, so 3 factors should be retained according to Kaiser's rule. Horn's parallel analysis also suggests 3 factors. Raiche's nongraphic solutions for Cattell's scree test lead to conflicting conclusions: the optimal coordinate approach suggests 3 factors, while the acceleration factor approach suggests 1 factor to retain. Considering (1) the consensus between the classic Kaiser's rule and Horn's parallel analysis, (2) the divergence in this recent nongraphic solution for Cattell's scree test, and (3) that the optimal coordinate solution actually agrees with the more conventional approaches. We decided to retain 3 factors. Subsequently, we extracted 3 factors using the varimax rotated principal components method, and the cumulative proportion variance explained is 0.89. Factor loadings are reported in Table 2. Simpson index and Shannon entropy have the highest loading on the first factor, which reflects the variety aspect of disciplinary diversity. 1 – Gini has the highest loading on the second factor, which reflects balance, and the average dissimilarity between referenced subject categories has the highest loading on the third factor, which reflects disparity. The results are also in line with Harrison and Klein (2007) that Simpson index and Shannon entropy reflect more on variety, while Gini reflects more on unbalance.

Table 2. Factor loading.

	Factor 1	*Factor 2*	*Factor 3*

Interdisciplinarity and impact

We first estimated the fixed effects Poisson models using the citation counts as the dependent variable and original interdisciplinarity measures as the independent variables (Fig. 1A, regression table not reported). The divergent results suggest that the low consensus in previous literature regarding the relationship between interdisciplinarity and citation impact may be partially explained by their different choice of the interdisciplinarity measures.

Table 3 reports fixed effects Poisson models using the extracted interdisciplinarity factors as independent variables. Variety, balance, and disparity are the three extracted factors, and they follow the standard normal distribution with mean equals to 0 and standard deviation equals to 1. Holding that the papers are published in the same journal, with the same number of authors, pages and references, and have the same status in terms of whether being internationally coauthored, the expected number of citations increases by 1.48% as variety increases by 1 standard deviation (column 1), decreases by 2.45% as balance increases by 1 standard deviation (column 3), and increases by 5.77% as disparity increases by 1 standard deviation. Squared terms are subsequently added to test the non-linearity in these relationships. On the one hand, the square terms of variety and disparity are significant, suggesting nonlinear relationships. On the other hand, the squared term of balance is insignificant, suggesting a simply linear relationship. Fig. 1B plots the estimated number of citations with variety, balance, and disparity, based on column 2, 4, and 6 in Table 3, respectively. Again, for these estimations, we fix journal fixed effect at 0, international at 0, and all other variables at their mean.

We observe that long-term citations increase at an increasing rate with variety, which is in line with the information processing perspective that cognitive variety is very important for creative and innovative work (Lee, Walsh, & Wang, In Press; Page, 2007; Simonton, 2003). For interdisciplinary research, integrating knowledge from more disciplines contributes to potentially more broadly useful outcomes.

We also observe a negative relationship between balance and citation impact, which is also in line with Uzzi, Mukherjee, Stringer, and Jones (2013) that a paper with both higher novelty and conventionality are more likely to be a top cited paper. In other words, a paper is more likely to be top cited if it is embedded at the core of a discipline (drawing most of its prior knowledge/references from one discipline) while at the same time borrows some knowledge from some remote disciplines. However, the reason for this negative association between long-term citations and balance is still unclear. On the one hand, it could be that interdisciplinary research driving evenly by different disciplinary logics is more likely to fail in integrating these logics into something useful. Therefore, having one disciplinary core and simultaneously borrowing knowledge from other disciplines is a more effective research strategy, compared with drawing knowledge evenly from multiple disciplines. On the other hand, it could be that the current science system is biases against balanced interdisciplinary research. There are anecdotes that balanced interdisciplinary research which truly transcend disciplinary boundaries is difficult to evaluate and more likely to be unnoticed, simply because most scientists are trained within a discipline and unable to realize its value, although such balanced interdisciplinary research is very novel and broadly useful.

In addition, we observe that the number of citations increases with disparity but at a decreasing rate. This is in line with the combinatorial novelty literature that combining more remote disciplines is more novel than combining neighboring disciplines (Lee et al., In Press; Uzzi et al., 2013). Furthermore, there is a rather complex dynamics between novelty and impact. On the one hand, novelty is important for generating impact. On the other hand, a highly novel paper might not be useful or helpful for other scientists to further build on it, and therefore would fail to generate high impact (Latour & Woolgar, 1986; Merton, 1973; Whitley, 2000). We do observe that that the marginal return from disparity is decreasing. It's

possible that the effect of disparity on long-term citations might turn into a negative one after certain point, but this threshold is about six standard deviations above the mean, which is beyond the maximum disparity value in our data.

Conclusions

This paper studies three different aspects of interdisciplinarity and investigates their distinct relationships with citation impact. The factor analysis extracts three main factors underlying various interdisciplinarity measures, and these three factors correspond to variety, balance, and disparity. Regression analysis further uncovers their different relationships with long-term citation impact: citations (1) increase at an increasing rate with variety, (2) decrease with balance, and (3) increase at a decreasing rate with disparity.

This paper contributes to future interdisciplinarity research and science policy. First, we advocate the idea of using different interdisciplinarity measures in different contexts. This paper demonstrates that various interdisciplinarity measures bear non-identical relationships with citation impact. Interdisciplinarity is an abstract and multidimensional concept, and different aspects of interdisciplinarity may (1) respond to certain individual, team, or institutional factors in completely different ways, and (2) have unique consequences in terms of usefulness or impact. Furthermore, various theories which might shed light on interdisciplinarity research have their own unique focuses. For example, the information processing perspective focuses on cognitive variety, while the combinatorial novelty literature emphasizes disparity. Therefore, it's important to choose a suitable interdisciplinarity measure consistent with the invoked theory and focal research question.

Second, this paper suggests a more refined policy agenda for encouraging interdisciplinary research. This paper pushes forward the research on the relationship between interdisciplinarity and scientific impact: from a dichotomous question of whether interdisciplinary research draws higher impact towards a more complicated question about differentiated dynamics underlying different aspects of interdisciplinarity. Answers to this more complicated question is also important for more effective science policies. As science increasingly deals with boundary-spanning problems, various policy and funding initiatives have been developed to encourage interdisciplinary research, such as the US National Science Foundation (NSF) solicited interdisciplinary programs, the US National Institutes of Health (NIH) common fund's interdisciplinary research program, European Research Council (ERC) synergy grants, and UK Research Councils' cross-council funding agreement. However, interdisciplinarity is an abstract and multidimensional concept, and nuanced understanding of these different dimensions and their consequences are important for effective policies. Specifically, the positive relationship between variety and citation impact demonstrates the benefits of cognitive variety for creative work. Therefore, policy and funding initiatives can encourage research across more disciplinary boundaries and integrating knowledge from more disciplines. Furthermore, the positive relationship between disparity and citation impact also suggests potential improvements from encouraging interdisciplinary research across more remotely connected disciplines. However, since the positive marginal effect is decreasing, the policy might not want to push too far. It's possible that disparity effect on citations might turn into a negative one when the disparity is too high, that is, integrating disciplines too far apart may fail to find a common ground to produce something useful. In addition, the negative relationship between balance and citation impact may suggest that the most effective interdisciplinary research strategy in terms of generating impact is to have one disciplinary core and simultaneously borrow knowledge from some other disciplines, instead of drawing knowledge evenly from multiple disciplines without a disciplinary core. It's possible that research driving evenly by different disciplinary logics fails to integrate these logics into something useful. On the other hand, this might also suggest that balanced interdisciplinary research is biased against in the current discipline-based science system, in which scientists are mostly trained within a single discipline and therefore fail to realize the value of balanced interdisciplinary work which truly transcends interdisciplinary bounties. However, further research is required to better understand this problem. Specifically, to claim the bias against balanced interdisciplinary research, we need to estimate the unbiased should-be scientific impact first and then compare it with the observed citations. To recommend policies encouraging unbalanced instead of balanced interdisciplinary research, we would also need to test the usefulness or value of the papers directly, instead of only examining citation counts.

Abstract

The relevance and value of books in scholarly communication from both sides, the scholars who chose this format as a communication channel and the instances assessing the scholarly and scientific output is undisputed. Nevertheless, the absence of worldwide comprehensive databases covering the items and information needed for the assessment of this type of publication has urged several European countries to develop custom-built information systems for the registration of books, weighting procedures and funding allocation practices enabling a proper assessment of books and book-type publications. For the first time, these systems make the assessment of books as a research output feasible. This paper resumes the main features of the assessment systems developed in five European countries / regions (Spain, Denmark, Flanders, Finland and Norway), focusing on the processes involved in the collection and processing of data on books, weighting, as well as their application in the context of research funding assessment.

Conference Topic

Science policy and research assessment and/or University policy and institutional rankings

Introduction

Scholarly books are key for the communication of research outputs in Social Sciences and Humanities (Hicks, D., 2004; Thompson, 2002; Engels, Ossenbklok & Spruyt, 2012). At the same time, performance-based assessment and funding allocation systems, as well as evaluation exercises at an individual level are widespread throughout Europe, affecting all instances of universities and research institutions (Hicks, D., 2012; Frølich, N., 2011). Despite developments such as Book Citation Index (Adams & Testa, 2011) there still exist a clear need for comprehensive databases collecting 'quality' indicators for books and book publishers. Quality in books is a multi-faceted concept and translating it into indicators is a

difficult task, in many occasions closely oriented to the specific research and assessment policies of each country. This diversity at the policy level is matched by an intrinsic heterogeneity of scholarly books themselves (e.g. disciplines, languages, formats, peer review and other editorial standards, etc.). In the past, the vast variety of books has made their reliable and comprehensive registration notoriously difficult and, consequently, their inclusion in research assessments unrewarding. By introducing the information systems presented in this paper, five European countries/regions have sought to redress the balance.

Objectives

The aim of this paper is to compare different approaches for assessing books across Europe. To do so, the context of each assessment exercise -where books evaluation occurs- is presented. The existence of valid peer review processes, the prestige of book publishers or the division in tiers according to the quality of the communication channel and the specific features of each discipline are some of the elements on which Spain, Denmark, Flanders, Finland and Norway have developed assessment systems for books. These developments are the result of applied research and also the object of a research-in-progress. This paper summarizes the main features of the current registration and assessment systems developed in the five countries in their present state. After a detailed discussion of each system, preliminary conclusions are presented, as well as a perspective on possible future developments.

Results

Scholarly Book's evaluation practices at the micro level

Spain

Scholarly books are taken into account in various assessment processes on the research outputs of scholars. As an example, both ANECA and CNEAI (Spanish assessment agencies) include various aspects of books and book publishers among their assessment criteria at the individual level. One of them is the prestige of the publisher (the latest, being CNEAI Resolution of November 26, 2014, but included as quality criteria various years backwards). Given the lack of specific data on the prestige of book publishers, the Research Group on Scholarly Books (ÍLIA) at CSIC developed Scholarly Publishers Indicators (SPI) on the grounds of the research conducted in previous years (Giménez-Toledo & Román Román, 2009). SPI ranks the perceived prestige of book publishers in the social sciences and humanities (SSH), both Spanish and non-Spanish, according to the scores resulting from an extensive survey to Spanish lecturers, researchers and scholars specializing in all fields of SSH. The system is based on more than 3,000 usable responses in 2012 and almost 3,000 in 2013. The responses are given to the question of which are the first, second or third (and from first to tenth in the 2013 edition) most prestigious book publishers in the responder's field; only specialists with positive assessment of their research are susceptible of being included among the respondents. Once collected, the responses are summarized using a simple weighting algorithm based on the share of scores in each position (1^{st}, 2^{nd}, etc.). The results are summarized in an indicator: ICEE. This indicator serves as a ranking item, both at the general level and specifically for each discipline, since the assigned weights are related to each discipline's distribution of scores (Giménez-Toledo, Tejada-Artigas & Mañana Rodríguez, 2012). The weighting procedure involves no arbitrary intervention from its designers and permits certain normalization per discipline. The ranking is publicly available at (http://ilia.cchs.csic.es/SPI/) and the users can access both discipline-level and general rankings for Spanish and non-Spanish publishers.

The main advantage of this system is the wide population on which it is based (more than 11,000 experts), while the main disadvantage lies in the difficulty to control for possible bias in the surveying process. The ranking was first used for assessment purposes in 2013 and is increasingly being included in the current evaluation framework as a reference for the assessment of SSH books and book chapters, together with other criteria. It is important to note that SPI is a reference tool for assessment exercises. It is meant to inform, not to perform, the research evaluation.
SPI also includes interactive charts as well as a 'specialization profile' of publishers obtained from the DILVE database (collecting the editorial production of Spanish publishers). Specialization is a point where evaluation agencies may focus their attention. In progress is the research into the use of different peer review systems with the use of surveys to book publishers as well as information about the transparency of their websites. These are qualitative indicators which aim is to serve as supporting information in the assessment processes.

Book's evaluation practices at meso or macro-level

Denmark

The performance indicator model (BFI/BRI, the Bibliometric Research Indicator) was started up in 2009. For each year 68 groups of academics selected by the Danish Research Agency from the Danish universities list all available knowledge resources and assign points to peer reviewed journals, publishers and conferences that publish scientific material authored by Danish academics from the previous year. Each of the 68 groups represents an academic field or specialty. The bibliometric research indicator takes into account published peer reviewed research and review articles, monographs as well as anthology and proceedings papers published by the Danish research institutions, which provide the input metadata for the system. In the period 2008–2012 proceedings (and anthology) papers were assigned .75 points. Journal articles received 1.0 point in Level 1 journals and 3.0 points in Level 2 journals, i.e. the leading journals of a field as judged by the relevant researcher group and covering maximum 20% of the field journal output. From 2013 proceedings papers and articles receive similar points as journal articles, depending on the level of the conference or publisher, as assessed by the relevant academic group. Monographs are assessed according to two publisher levels, Level 1 (5 points) and Level 2 (8 points). Anthology papers and chapters receive 0.5 and 2 points depending on publisher level. For each document the points are fractionalized (min 0.1) according to number of collaborating universities, including non-Danish universities. The model encourages collaboration by multiplying the institutional fraction by 1.25. The previous year's cumulated points per university is used to distribute a substantial portion (in 2013 it was 25%) of public basic research funding among the universities the following year. Only the cumulated results are publicly available per university and major academic area, such as the Humanities, Social Sciences, Natural Sciences or Medicine/Health sciences via the Danish Research Agency's web page (https://bfi.fi.dk/). The intermediate or more detailed publication point distributions and document lists per unit and department will be publicly accessible from 2015. This is in difference to Norway where no multiplication of fractions takes place and all the documents and their point assignments are transparent as well as publicly accessible through an open access database. In the Finnish system and in Belgium the Flemish BOF-key applies whole counting at the institutional level (Debackere & Glänzel, 2004; Engels, Ossenblok & Spruyt, 2012). The output of the Danish BRI system can, as a spin-off, be used for assessment purposes. See also Ingwersen & Larsen (2014).

Flanders (Belgium)

The Flemish Academic Bibliographic Database for the Social Sciences and Humanities ('Vlaams Academisch Bestand voor de Sociale en Humane Wetenschappen', or VABB-SHW) has been developed to allow for the inclusion of the peer reviewed academic publication output in the Social Sciences and Humanities (SSH) in the regional performance-based research funding model. As such, in 2015 the VABB-SHW accounts for 6.62% of the University Research Fund (or BOF), distributing over 150 million euro per year over the five universities. As the BOF-key is also re-used for the distribution of other research funding, the actual impact of the VABB-SHW is even greater. In a secondary role, the VABB-SHW supports research assessments at various levels. As all information in the VABB-SHW is available to both the universities and the Flemish national science foundation (FWO), data is harvested and integrated into each institution's repository. In a third role, the VABB-SHW's comprehensive publication coverage (peer reviewed or otherwise) allows for in-depth research on publication practices in the SSH (Engels, Ossenblok, & Spruyt, 2012; Verleysen, Ghesquière, & Engels, 2014). The database covers the comprehensive publication output of academic research in 16 SSH disciplines and 3 general categories. Three types of book publications are included: 1° monographs, 2° edited books, 3° book chapters, weighted 4, 1 and 1 for the funding model, respectively. Journal articles also receive a weight of 1 and proceedings papers a weight of 0.5. No prestige levels are distinguished. For funding calculation, a ten-year timeframe is used. For research purposes, coverage extends back to the year 2000. For books, four aggregation levels are in use: 1° publisher names (as collections of ISBN-roots), 2° book series, 3° books published in Flanders and labeled as Guaranteed Peer Reviewed Content (GPRC-label (Verleysen & Engels, 2013), and 4° individual books identified as peer reviewed by the Authoritative Panel ('Gezaghebbende Panel' or GP, a committee of full professors installed by the government and responsible for decisions regarding the content of the VABB-SHW). The information system is fed through a yearly upload (May 1st) of all SSH publications from the two preceding years newly registered in the five universities' academic bibliographies. Data is managed at the Flemish Centre for R&D monitoring (ECOOM), University of Antwerp, through its custom-built Brocade library services (http://en.wikipedia.org/wiki/Brocade_Library_Services). Each individual publication receives a unique identifier, contributing to maximum granularity and reliability of the data both for funding calculation as well as for retrieval and research. Consolidation processes making use of algorithmic identification allow a systematic de-duplication of records that are submitted more than once. Publications are identified algorithmically at the publisher, series or journal level by their ISBN-prefix or ISSN. Each year all new publishers, series, books and journals are classified by the Authoritative Panel as peer reviewed and presenting new content (or not). At the public interface www.ecoom.be/en/vabb, online access is provided to the database itself, lists of publishers, journals and series, explanation of procedures, FAQ's, and background information.

Finland

In Finland, the use of publications in the performance based funding model is based on two components: the publication metadata consisting of the entire output of universities, and a quality index of outlets. Universities have their own registries of publications, including peer-reviewed and non-peer-reviewed articles in journals, conferences and anthologies, as well as monographs. Universities report their publication data, with full bibliographic details, once a year to the ministry of education and culture (Puuska 2014). The publication data is processed (including deduplication) at CSC - IT Centre for Science, which is a company owned by the ministry. The bibliographic details of publications are matched against the list of serials, conferences and book publishers classified in three quality levels by 23 expert panels

coordinated by the Federation of Finnish Learned Societies (FFLS). This quality index of outlets is called Julkaisufoorumi (JUFO) -luokitus (Publication Forum Classification). The universities' publication metadata collected by the ministry is known as OKM-julkaisuaineisto (MinEdu publication data).

In the Publication Forum classification, published for the first time in 2012, the level 2 comprises 20 % of the leading serials and conferences and 10% of the leading book publishers (Auranen & Pölönen, 2012). Most peer-reviewed outlets belong to the level 1, and those that fail to meet the criteria of scientific publication channel are listed as the level 0. For serials there is also a level 3, in which are classified 25% of the level 2 titles, but in the funding model it is not differentiated from the level 2. Updated classifications have been published in the beginning of 2015. In the new classification, as in Denmark, the level 2 serials and conferences comprise at most 20% share of the world production of articles in each panel's field. The level 3 was added also for book publishers. The new classifications will be applied on articles and books published in 2015. The classification of book publishers is used specifically to determine the level of monographs and articles in anthologies when the publication does not come out in a book series or the series has not been classified. The main rule is that the Finnish book series are classified, while those of foreign book publishers are not classified separately.

In the current funding model for 2015 and 2016, which still uses the 2012 Publication Forum classifications, 13% of all budget-funding is allocated on basis of publications (Ministry of Education and Culture, 2014). The peer-reviewed articles in journals, conferences and anthologies published in the level 0 channels will have the weighting coefficient 1, those of the level 1 have the coefficient 1.5, and for the level 2 and 3 channels the coefficient is 3. The weighting coefficient of non-peer-reviewed (scholarly, professional and general public) articles is 0.1 regardless of outlet. Weighting coefficient of peer-reviewed monographs is four times higher than that of articles: 4 in the level 0, 6 in the level 1, and 12 in the level 2. For non-peer-reviewed monographs, as well as all edited volumes, the weight is 0.4. There is no fractionalization of co-publications at the institutional or author level. The Ministry has instituted a working-group to determine the weights and calculation method of publications used in the funding model from 2017 onwards.

The MinEdu publication data, which covers Finnish universities output since 2010, is openly available through Vipunen-portal (www.vipunen.fi) for statistics, as well as Juuli-portal (www.juuli.fi) for browsing the publication information. The quality index of outlets is openly available on the Publication Forum website (www.tsv.fi/julkaisufoorumi).

Norway

The Norwegian model (Sivertsen, 2010; Sivertsen & Larsen, 2012) consists of three main elements: 1) A national database containing comprehensive and unified bibliographic metadata for the peer reviewed literature in all areas of research; 2) a publication indicator making field-specific publishing traditions comparable in the same measurement; and 3) a performance based funding model.

The national database is called CRISTIN (Current Research Information System in Norway). It is shared by all research organizations in the public sector: universities, university colleges, university hospitals, and independent research institutes. The institutions provide quality-assured and complete bibliographic about articles in journals and series (ISSN), articles in books (ISBN), and books (ISBN) that can be included according to a definition of peer-reviewed scholarly literature.

The indicator is based on a division of publication channels (journals, series, book publishers) in two levels: level 1 and level 2. Level 2 contains the most selective international journals, series and book publishers and may not contain more than 20 per cent of the publications

worldwide in each field of research. Articles in journals and series are given 1 point on level 1 and 3 points on level 2. Articles in books (with ISBN only) are given 0.7 1 points on level 1 and 1 point on level 2. Monographs are given 5 points in level 1 and 8 points on level 2. The points are fractionalized in the level of institutions according to the institution's share of contributing authors.

Although less than two per cent of the total expenses reallocated by the use of the indicator in Norway, it has attracted a lot of attention among researchers and resulted in increased productivity (Aagaard et al., 2014).

Conclusions

One of the first conclusions which stand out is the lack of use of citation metrics in any of the five systems. This might be the result of a lack of fit, lack of acceptance or the irrelevance as a quality indicator for books of the traditional measures for journals. Another element is the incomprehensiveness for many scholarly fields of the current citation indexes. Equally remarkable is the clear convergence as regards criteria and procedures among the Nordic countries and Flanders, not only in the registration of books, but also in the funding and/or assessment policies making use of book data. For assessments, in Northern Europe data is used mainly at the institutional level, despite its collection and registration being nationally coordinated in the context of a performance-based research funding system. This is clearly not the case for Spain, where data is used for assessments at the individual level, while university budgets are not calculated in a performance-based, centralized system. Also, the different policies show great divergences regarding the much higher weight given to scholarly books in the Nordic systems, while in Spain the tendency is just the opposite (more weight is given to papers than is to books). It is also remarkable that the most frequently used aggregation level is that of book publishers, although in the case of Flanders the Guaranteed Peer Reviewed Content-label allows for the inclusion of individual books in the regional system as well, while Finland currently counts with a Peer Review Mark similar to the already mentioned, making feasible that possibility. This involves that the expected coherence in the practices underlying to the concept of quality is sufficient at the level of book publishers, since the congruent use of this level of aggregation (from which the positioning in tiers of each individual contribution is derived) is common to all systems analyzed. Nevertheless, future developments may well see a stronger interest in the registration of book data at lower aggregation levels as well (e.g. that of the book series), as this evidently implies a more fine-grained approach to the comprehensive registration and the validation in assessments of books. In Spain, that specific level of aggregation (book series) is the object of a current initiative by UNE (University Presses Union) in collaboration with three research teams.

Finally, it will be interesting to see whether the on-going internationalization of research and the growing collaboration between scholars worldwide will contribute to a greater harmonization at the European level of the assessment systems for books and book publishers. Such developments could indeed provide scholars with new opportunities to assert the (often under-rated) value of their books, although some hypotheses regarding the role of the book in the scholarly communication shall be addressed in the close future.

Acknowledgements

This research is partially the result of the project 'Evaluación de editoriales científicas (españolas y extranjeras) de libros en Ciencias Humanas y Sociales a través de la opinión de los expertos y del análisis de los procesos HAR2011-30383-C02-01 (Ministerio de Economía y Competitividad. Plan Nacional de I+D+I).

Table 1. Comparison of the main features of the information systems for the assessment of books.

ITEM	SPI	BFI/BRI*	VABB-SHW	MinEdu Data/JUFO	CRISTIN
Country	Spain	Denmark	Flanders	Finland	Norway
Reasons for its development	Assessment at the individual level and research evaluation (unknown uses at institutional level)	Research funds allocation among universities and measures of research activities at institutional levels.	Inclusion of the peer reviewed scholarly publication output in the regional performance-based research funding model.	Funding allocation, research information and quality promotion.	Research information and fund allocation in the public sector. National statistics.
Object of study/ aggregation level	Book publishers / specialization from book-level information.	Book publishers, books and book parts (anthologies); journal articles and proceeding papers.	Book publishers, book series, GPRC**-labeled books published in Flanders and individual books assessed by the Authoritative Panel.	Book publishers and monographic series / peer reviewed monographs and articles in books at university level.	Bibliographic references to all scholarly publications in books, book articles and journal papers.
Stage	Already published and applied in assessment.	Already published and applied in assessment and funding since 2009.	Applied for funding allocation and institution-level assessment since 2010.	Published in 2012 and applied in funding since 2015.	Applied in assessment and funding since 2005.
Coverage	All Spanish and non-Spanish book publishers mentioned by experts in each field.	All scholarly publishers worldwide with publications from Danish scholars since 2009.	The comprehensive peer reviewed publication output of academic research in the Social Sciences and Humanities since 2000.	National and international scholarly book publishers and Finnish book series	All scholarly publishers worldwide with publications from Norwegian scholars since 2004.
Information feeding the system	Survey to experts and book publishers / database analysis.	Metadata for scholarly publications from all Danish universities.	Yearly upload from the academic bibliographies of the five Flemish universities, of all newly registered publications of the previous two years.	Metadata for universities' scholarly publications and new additions suggested by researchers	Metadata for scholarly publications from all Norwegian institutions in (CRISTIN).
Information processing	Votes from respondents are summarized in the ICEE indicator. DILVE database is statistically analyzed. Surveys to book publishers are summarized. Done by ILIA research group (CSIC).	Quality level assessments of publishers and journals by 67 topical peer groups plus a central coordination council, providing authoritative lists from which each publication is assigned a score by the system.	Data input from the universities processed by ECOOM / University of Antwerp Scientific steering and assessment of publication channels by a central Authoritative Panel.	In order to assign weight to universities' publications in the funding model, the metadata of publications is collected and matched against the list of serials, conferences and book publishers classified in quality levels by 23 panels.	Input from the institutions of metadata for individual publications is connected to a centrally monitored dynamic register of approved scholarly publication channels (journals, series, and book publishers)
Operative results	Ranking of book publisher's prestige / specialization charts / peer review info.	Annual number of publications and number of publication points per university and per larger academic topic.	A growing database of 125,000 scholarly peer reviewed and other publications. Publicly available lists of assessed book publishers, book series, journals and conference proceedings.	List of quality-classified outlets and database of universities' all publications from 2011 that can be analyzed by type, field and outlet.	A database of so far 70,000 scholarly publications that can be analyzed by type, field, language, institution, and publication channel
Use for research assessment and aggregation level	Used at the individual level by ANECA and CNEAI, two Spanish assessment agencies.	Funding allocation in the following year; Institutional level; also used as promotion or 'extras' factor (local incentive). Individual level in the future.	Funding allocation to five universities; support of internal assessments at individual universities, and assessments by the Flemish national science foundation (FWO)	Funding allocation to universities; internal assessment and planning at universities (also funding allocation); use for assessment at individual level is discouraged.	Funding allocation, stats for field and/or institution research evaluation, administrative information at institutions and annual reports.
Public availability	Yes (from 2012)	Yes (from 2015)	Yes	Yes	Yes (from 2004)
Book / paper weighting	Approx. 1 to 3 (as defined by assessment agencies, but not by SPI)	From 5 to 8 and from 0.5 to 2 (anthology items) and from 1 to 3.	From 4 to 1 and from 1 to 0.5	From 0.4 to 12 and from 0.1 to 3.	From 8 to 3 and from 3 to 1.

Publications or Citations – Does it Matter? Beneficiaries in Two Different Versions of a National Bibliometric Performance Model, an Existing Publication-based and a Suggested Citation-based Model

Jesper W. Schneider

Abstract

The paper discusses the adoption of the Norwegian Publication Model in a Danish context and examines arguments for supplementing or substitution the current mechanism where reward is based on publication activity with one based on citations. Based on national publication data from 2009 from the Danish model, belonging to the science and technology research area, and corresponding citation data, we examine the Danish universities' relative input when it comes to publications and subsequently examine the relative output from these publications, i.e., the "returns on investment" from the model, either the current publication points, or the alternative, citations. Findings support the claims that high-performing units would benefit more from a citation-based approach, but at the same time also show, contrary to what was conjectured, that in the present case the same university also benefits the most from the current publication model. Based on the findings, we discuss the publication versus citation-based models, or hybrids between them, and argue that citation-based models in performance-based funding context are harder to influence and most likely will support already existing cumulative advantages.

Conference Topic

Science policy and research assessment

Introduction

In recent decades several countries have introduced performance-based research funding among their universities (Hicks, 2012). The performance-based research funding systems (PRFS) vary considerably between countries, from panel-based peer review evaluations, to systems based on citation or publication metrics, or various hybrids of these three basic forms (see Hicks, 2012). Generally, peer review systems are considered superior to systems based on bibliometric indicators (see Gläser & Laudel, 2007). Nevertheless, large-scale panel evaluations are very expensive, and several *post hoc* comparisons between panel results and citation metrics, for example from the UK Research Assessment Exercises, suggest that the latter could be an effective, and cost-effective, supplement or even substitute to peer reviews (e.g., Oppenheim, 1996; Moed, 2008). Among PRFS based on bibliometric indicators, citation-based systems are considered by some to be superior due to the assumption that citation indicators to some extent are able to measure aspects of research quality by focusing on impact (Gläser & Laudel, 2007). But citation indicators also have obvious deficiencies especially when implemented in PRFS which in principle are supposed to cover all fields of research (Schneider, 2009). It is well-known that citation indicators are not equally valid across all fields of research and even where relevant, coverage in the citation databases is also restricted (Moed, 2005). Consequently, PRFS based on citation indicators severely restricts the measurable outcome of research basically to journal articles indexed in one of the two major citation databases. But there are other issues with citation indicators which can be considered inadequate when used in PRFS, especially when such systems are supposed to (re)distribute funding on a regular basis, most often annually, and at the same time also give

universities (and their researchers) incentives to improve performance (e.g., Gläser & Laudel, 2007; Schneider, 2009). Citation indicators reflect research done in the past often a considerable number years prior to the actual funding year. It is also very difficult to directly influence citations when conceived of as an incentive system, in fact the well-known cumulative advantages could be detrimental to such an incentive system if it is supposed to be fair for all involved (Merton, 1988). Such features are seen by some as undesirable if PRFS as supposed to cover all research fields with their different publication traditions, and be able to reflect recent research performance in a dynamic model, as well as give transparent behavioural incentives to change performance (Schneider, 2009; Hicks, 2012).

PRFS based on publication activity have been introduced as an alternative to citation-based systems (Butler, 2002; Schneider, 2009). There are some apparent "benefits" with publication-based systems compared to citation-based systems. They can reflect short-term research activity making them more up-to-date when it comes to redistributing funding. In principle they can encompass all desired publication types and they can provide straightforward behavioural incentives. But it is important to emphasise that the two approaches measure different constructs. It would be naïve to suppose that incentives directed at publication behaviour, i.e., quantity and/or supposed status of the publication outlet, encompass the same aspects of perceived "quality" that citation impact is thought to reflect (Schneider, 2009). Experiences from Australia testify to this. In a succession of papers, Linda Butler demonstrated how researchers in Australia responded when funding, at least partially, was linked to publication counts undifferentiated by any measure of supposed "quality" in the early 1990s (e.g., Butler, 2003a; Butler, 2003b). Australian publication output increased considerably with the highest percentage increase in lower impact journals. For a consecutive number of years, this lead to a general drop in overall citation impact for Australia. Since Butler's documentation of the adverse effects, the experience from Australia has stood as a "warning" for what would most likely happen if funding was linked to publication activity. Nonetheless, in the early 2000s a so-called "quality reform" of the higher education sector in Norway introduced a PRFS where publication activity again was linked to funding. The main political intention with the model was in fact to encourage more research activity and thereby also more publication activity, and preferably more international publication activity, in the university sector[1].

The so-called *Norwegian Publication Model* (NPM) is interesting in in relation to PRFS. Obviously, the designers of the NPM were well-aware of the adverse behavioural effects documented in the Australian case. As a consequence, a slightly more sophisticated model was developed (Schneider, 2009; Sivertsen, 2010). A primacy of the model was to reflect the encouragement to publish in international outlets (i.e., international journals and academic book publishers) and at the same time to counter so-called adverse publication effects like the Australian case, where researchers seek to publish more but with less effort. Hence, a differentiated publication model was constructed where publication channels were classified on two levels. Level one comprises in principle all scholarly eligible publication channels, where eligibility criteria are some basic norms such as a standard external peer review process. Level two, is an exclusive number of publication channels, which are deemed to be leading in a field and preferably with an international audience. Level two is exclusive in as much as the number of publication channels designated at any given time to this level should produce roughly one-fifth of the publications produced in a field "world-wide". Correspondingly, three different types of scholarly publications are included in the model: journal publications (articles and reviews), articles in books (contributions to anthologies and

[1] http://www.uhr.no/documents/Rapport_fra_UHR_prosjektet_4_11_engCJS_endelig_versjon_av_hele_oversettelsen.pdf.

conference papers) and books. A two dimensional point system was implemented where the different publication types yield different points within the same level and between the two levels depending on the outlet status. Hence, the basic idea behind this two-tiered classification system is that publications on level two receive more publication points than publications on level one. Finally, publication points are fractioned $1/n$ so that an institution eventually receives $1/n$ points depending on their number of contributing authors.

Eventually the annual sum of publication points for an institution is exchanged for funds, where the exchange rate is determined by the amount of money available for redistribution and the total number of publication points in the system in a given year. A noticeable assumption in the NPM is that publication behaviour, publication activity and publication types across all fields can be treated identically. Consequently, all research fields' eligible research publications are included in the model, which for example means that a level one journal article with one author is worth the same in physics and literature studies. It is assumed that the differentiated point system together with fractionalized counting will level out the major differences in publication behaviour between the fields and also to some extent will discourage researchers to speculate in "easy publications" resulting in a levelling out effect at the aggregate level. Consequently, in the Norwegian PRFS funding is competitive not only between institutions but also across all fields. Hence, the subject composition within and between the research institutions is interesting as performance improvement in one major area, in principle can lead to improved funding at the expense of another major area due to the basic zero-sum situation.

The NPM has recently been "adopted" in several European countries, for example in Denmark, Finland and Flanders (Hicks, 2012; Verleysen, Ghesquière & Engels, 2014). In the present paper we look at the "adoption" of the indicator in Denmark and examine the overall distributional consequences of focusing on publication activity and not impact.

It is important to accentuate that in Norway the publication model was to a large extent developed to support overall political goals, i.e., more international research activity. As it were, Norway's internationalization in research and general citation impact, were considerably lower, than for example Denmark, at the time of the introduction of the model. Since then Norway's international publication output has risen considerably, albeit rise in citation impact has been meagre (e.g., Aagaard, Bloch & Schneider, 2015). Nonetheless, the NPM was developed and implemented with a legitimate goal which to some extent seems to have been achieved seen from the national policy perspective.

During a reform of the Danish research funding system in the mid-2000s it was decided to implement a PRFS officially in order to enlarge competition among universities for funding, although the board of university rectors probably more saw it as management tool that should legitimize their overall research activity to the public (Schneider & Aagaard, 2012). The political process leading to the "adoption" of the NPM in Denmark is complex and documented in Aagaard (2011). It is not totally clear why the choice fell upon the NPM, although its coverage of all areas, transparency and clear incentive system were no doubt deemed viable, yet some actors actually indicated that it would probably be "the one that would cause the least damage" (Aagaard, 2011). Most interesting, contrary to Norway, there were no immediate strategies or goals for research and publication behaviour behind the "adoption" of the NPM in Denmark.

Denmark was the first country to adopt the NPM at a time when the model was still in its infancy in Norway and little empirical evidence of its potential effects was available. The NPM was adopted with very few moderations, as if the model was a one-size fit all package suitable for all contexts. Most notably, the simple two-tiered classification system was kept and considerations about expanding or adapting the classification to a Danish context were not done. Nevertheless, some seemingly minor moderations turned out to be imperative,

including a maximum fractionalization of contributions at 1/10th; but perhaps most important, performance-based publication activity was locked between the major research areas: science and technology, health sciences, social sciences and humanities. Consequently, in the Danish adoption of the NPM, funding is not competitive across areas only within areas. Further, politically it was decided to more or less keep the old annual allocation model between the areas which effectively meant that a publication point, contrary the Norwegian PRRS, have different monetary values across the four main research areas. This is an extremely important deviation from NPM and it gives rise to some questions about the Danish adoption of the NPM, popularly known by the acronym BFI (bibliometric research indicator).

One can argue that the model is transparent, seemingly coherent and all-inclusive when it comes to research areas. All areas are measured with same indicator. But since competition is restricted to within areas and as a consequence publication points have different values across areas, one could also ask why the model still assumes equality of publication practices across areas? And to go further, with the locking of the competition to within areas, there is basically no reason why fields where citation analysis could be a reasonable and indeed preferred indicator could implement such devices either in combination with a publication model or alone. Of course the latter would muddle the overall model, although it would probably satisfy many of the critics of the publication-based model, arguing for more emphasis on impact.

Indeed, the Technical University of Denmark (DTU) has been an ardent critic of the adoption of the NPM in Denmark. A common argument goes: Why implement an incentive model that reward publication activity in international outlets when "we" already do that and do it well? More generally the critics stated that the behavioural goals with the model in Norway were irrelevant in a Danish context, because Denmark, contrary to Norway, has 1) for decades consistently been among the top five highest performing countries when it comes to impact; 2) has consistently four of its eight universities in the top 200 of the Leiden Ranking[2]; and 3) the Danish research system has had a long trajectory of internationalization (e.g., Karlsson & Persson, 2012). According to DTU, what should be procured and rewarded is impact and not publication activity. While the argument is relevant, it is also self-serving. DTU happens to be the highest performing Danish university when it comes to impact and is ranked in the top 50 of the Leiden Ranking. DTU has a very strong focus upon science and technology and close to no medical, social or humanistic research activities. Also, DTU has the lowest student to researcher ratio in Denmark. Obviously, DTU would fit very-well to a model based on citations. DTU has continued the criticism over the years claiming that they are the actually "losers" in the current Danish PRFS. According to DTU, universities are reward for quantity and not "quality" which should always be the focus in research. Why risk the current impact status by increasing output for some marginal gains? This cannot be a national interest.

So goes the argument - what we examine in this paper is to what extent the argument holds. Who benefits from the current Danish publication-based model and is DTU the current "losers"? What would be the differences if a citation-based approach was applied instead?

The aim of the analysis is to examine the universities' "return on investment". We take a simple approach where we examine the relative input of the universities when it comes to publications and subsequently examine the relative output from these publications, i.e., the rewards in the model, either the current publication points, or the alternative, citations. We keep the analysis simple using basically a zero-sum approach, like the current model, where gains somewhere mean losses elsewhere.

[2] www.leidenranking.com

The next section briefly presents the data and main methods and indicators used for the analyses. The subsequent section presents main results, and the final section contains a brief discussion of the findings.

Data and methods

The paper examines the first full publication year (2009) used for redistributing funds in the Danish model. We are able to measure the citation impact of the Danish journal publications from 2009 and make comparisons between the Danish universities and examine their potential gains and/or losses by using either differentiated publication counts or citations. We compare publication counts and points derived from the BFI model between Danish universities, and we likewise compare the impact between these universities for the 2009 journal publications indexed in Web of Science (WoS). As argued in the introduction section, locking the main research areas in principle means that the current publication-based model could be adapted to specific behaviours and wishes, or even supplemented or exchanged with a citation approach, in the individual areas, although citations would only be relevant in the areas: science and technology and medical and health sciences. In this paper we focus the analysis on the main research area of science and technology. We do this because the issue concerning citation impact versus publication activity raised by DTU is directly linked to this area due to DTUs research profile. We have done a corresponding analysis for the medical and health sciences but due to limited space we will not address them in this paper.

The publication activity in 2009 in the main research area of science and technology is around 8700 publications of all types eligible in the BFI model, books constituted 2%, articles in books 19% and journal articles 79%. It is reasonable to argue that (international) journal publication is the primary publication activity in this area, which means that citation analysis of eligible articles is a sensible endeavour. However, as the area includes some fields known to have their main publication activity in conference proceedings (i.e., articles in books), we do scrutinize the influence of proceedings papers on the total number of BFI points acquired for the individual universities and discuss that in relation to the citation analysis where proceedings papers are excluded. Notice, we do not include conference papers in the citation analysis due to the meagre quality of the current proceedings citation indices.

All journal publications published in 2009 reported by the universities to the BFI-indicator were extracted from the BFI database. Subsequently, paper titles were extracted, and so were first author names and journal names. These parameters were used to match the publications with Danish WoS journal publications from 2009 using CWTS's in house version of WoS. Eligible publication types are research articles and reviews. The match rate is 77% of the initial journal articles. Among the non-matched publications were non-English language articles, as well as false positive articles, articles not eligible for the BFI model, but still succeeded in accruing points.

As indicated in the introduction section, the BFI model applies a fractional counting method at the institutional level where articles are fractioned up to $1/10^{th}$ among the participating institutions. We do not apply the exact same counting formula for the WoS publications going into the citation analysis. Here we simply do a straightforward fractional counting on the institutional level. As will be clear from the results section, this small deviance had no practical relevance on relative publication shares.

We use standard CWTS citation indicators from the Leiden Ranking (www.leidenranking: P_{frac} (fractionalized publications), TNCS (total number of normalized citations), MNCS (mean normalized citation score) and PPtop10% (proportion of papers for a unit among the 10 percent most cited in the database) (Waltman et al., 2012).

Eight universities are included in the Danish PRFS. The universities differ considerable in both subject/faculty composition and size. We have two "old" universities basically covering

all four main research areas included in the BFI model: Copenhagen University (KU) and Aarhus University (AU). These universities are also the largest universities in Denmark with long research traditions and strong science faculties. University of Southern Denmark (SDU) is a younger university, but its subject/faculty composition is basically a reflection of KU and AU, although the size is considerably lower. Roskilde University (RU) and Aalborg University (AAU) are even younger, from the mid-1970s. These universities have regional obligations with a substantial emphasis on teaching. Nevertheless, both universities have developed unique research profiles, both universities have focused on interdisciplinary research, where RU has a strong focus on the social sciences and AAU has focused strongly on engineering. Both universities have science and technology faculties, albeit at RU the size is only comparable to a large department. The Information-Technology University is the youngest and smallest university in Denmark. Their focus is mainly outside the science and technology areas but we include them here for numbers to add up. Likewise, Copenhagen Business School (CBS) is also included for matters of completeness in the analyses, their publication activity in the science and technology area are scanty. Finally, as discussed in the introduction, the Technical University of Denmark (DTU) is basically a "mono-faculty" university, albeit its activities are spread between science and technology. It is important to emphasise that while the university is known for primarily educating engineers, it has a considerable research activity in what would be considered basic natural science fields as well. In fact DTU can be dated back to the early nineteenth century where it was part of Copenhagen University, making it the second oldest university in Denmark. We recapitulate, DTU has been particularly dissatisfied with the Danish PRFS arguing that - for them at least - citations would be a more appropriate and valid performance-based indicator. In the next section we examine the consequences of this claim.

We calculate basic statistics based on individual articles both for the publication-based model and the simple citation approach we apply. As stated in the introduction, we take a simple approach where we examine the relative input of the universities when it comes to publication shares and subsequently examine the relative "rewards" the universities archives from these publications, i.e., the output in the model, either shares of the total publication points, or the alternative, shares of the total number of citations. Also, we keep the analysis simple using basically a zero-sum approach, like the current PRFS, where gains somewhere mean losses elsewhere.

Results

Table 1 below shows the eight universities' total number of matched fractionalized WoS publications belonging to the science and technology area, as well as their accumulated number of normalized citations after four years. Notice, these are fractionalized WoS publications, the absolute number of publications is 6,117.

Table 1 also shows relative citation performance for the eight universities using the MNCS and PPtop10% field normalized indicators.

The three main actors measured by volume is not surprisingly KU (32.9%), DTU (28.7%) and AU (21.4%), the volumes for AAU and SDU are considerably lower, both universities have a share of 7.2% of the total volume. DTU has the largest number of normalized citations among the eight universities. It is noticeable that DTU's share of citations (34.8%) is markedly higher than their share of publications (28.7%). Obviously, this is also reflected in the relative citation indicators. The MNCS at 1.66 is considerably higher than the average of the database and a score that would rank DTU among the top 30 in the Leiden Ranking if we only focused on science and technology, and among the top 50 for all fields combined.

Table 1. Science and technology: Number of fractionalized publications in WoS, total number of citations and relative citation indicators.

	WoS pubs (P_{frac})	TNCS	MNCS	Share of total P_{frac}	Share of total no. of NCS	PPtop10%
AAU	225.3	284.4	1.26	7.2%	6.6%	12.3%
AU	673.0	874.5	1.30	21.4%	20.3%	14.6%
CBS	13.2	12.2	0.93	0.4%	0.3%	
DTU	904.9	1498.8	1.66	28.7%	34.8%	17.0%
ITU	11.5	9.1	0.79	0.4%	0.2%	
KU	1035.9	1281.0	1.24	32.9%	29.7%	13.4%
RU	56.9	61.3	1.08	1.8%	1.4%	10.7%
SDU	227.7	284.8	1.25	7.2%	6.6%	15.8%
Total	3148.2	4306.3		100%	100%	100%

Interestingly, we also see that the minor universities, SDU and AAU, have relative citation indicator scores comparable to the larger universities KU and AU. In fact, SDU has more of their 2009 publications among the 10% most cited in the database compared to KU and AU. Overall, these results confirm what we suspect and are essentially the basis for the argument about including citations in the BFI model advanced by DTU.

In order to examine "return on investment", i.e., the institutions' reward for their publication input, we have calculated their share of BFI publications and BFI points for 2009 for the science and technology area, as well as the shares of fractionalized WoS publications and the total number of field normalized (fractionalized) citations. We thereby assume that shares of BFI points and shares of normalized citations can be treated equally. In the final discussion section we reflect upon this. We do, however, think that the straightforward approach taken can give a rudimentary indication of potential differences in "returns" for the individual institutions if one was to apply a citation based approach instead of or as a supplement to the current differentiated publication-based indicator in the science and technology area.

Table 2 below shows the shares of BFI publications and BFI points, where all publication types used in the science and technology fields are included (e.g., also conference proceedings), as well as shares of fractionalized WoS journal articles and normalized citations.

Table 2. Science and technology: Distribution and shares of BFI-points, BFI-publications, plus fractionalized publications from WoS and total number of normalized citations; notice <u>all</u> BFI-publication types are included.

	BFI-points	BFI-publications (P)	Share of BFI-points	Share of total BFI P	Share of P_{frac} (WoS)	Share of total no. of TNCS
AU	1814.9	1766	19.1%	20.4%	21.4%	20.3%
CBS	6.9	6	0.1%	0.1%	0.4%	0.3%
DTU	2854.1	2378	30.1%	27.5%	28.7%	34.8%
ITU	117.4	107	1.2%	1.2%	0.4%	0.2%
KU	2730.9	2457	28.8%	28.4%	32.9%	29.7%
RUC	185.9	157	2.0%	1.8%	1.8%	1.4%
SDU	571.0	572	6.0%	6.6%	7.2%	6.6%
AAU	1203.6	1219	12.7%	14.1%	7.2%	6.6%
	9484.8	8662	100%	100%	100%	100%

Table 3 below shows the same variables as Table 2, but in this case we *only* use the BFI publication type journal articles and the points derived from these articles. Table 3 is included for comparison because the citation analysis in reality only deals with journal articles. Notice, the BFI journal articles include non-WoS indexed articles, which give points in the indicator, however, the numbers are very low, the coverage of the science area in WoS is very high.

Table 3. Science and technology: Science and Technology: Distribution and shares of BFI-points, BFI-publications, plus fractionalized publications from WoS and total number of normalized citations; notice only the BFI-publication type journal article is included.

	BFI-points (journals only)	BFI-publications (P) (journals only)	Share of BFI-points (journals only)	Share of total BFI P (journals only)	Share of P_{frac} (WoS)	Share of total no. of NCS
AU	1526.2	1515	21.9%	23.5%	21.4%	20.3%
CBS	6.9	6	0.1%	0.1%	0.4%	0.3%
DTU	2007.4	1663	28.8%	25.8%	28.7%	34.8%
ITU	53.3	39	0.8%	0.6%	0.4%	0.2%
KU	2166.8	2047	31.1%	31.8%	32.9%	29.7%
RUC	139.5	126	2.0%	2.0%	1.8%	1.4%
SDU	420.1	442	6.0%	6.9%	7.2%	6.6%
AAU	657.5	596	9.4%	9.3%	7.2%	6.6%
Total	6977.7	6434	100%	100%	100%	100%

For analytical and illustrative reasons we plot the results from Table 2 and 3 in Figures 1 and 2 below. Figure 1 shows the results based on all BFI publication types, whereas Figure 2 shows the results where only BFI journal articles are included.

The figures are simple plots were the shares of the total number of publications (i.e., both BFI publications and fractionalized publications from WoS) for the eight universities constitute the x-axis, this is the "input", i.e. what the individual institutions "invested" in the Danish performance-based model for science and technology in 2009. The y-axis shows the shares of BFI points and citations, this is the "output", i.e. the institutions' "return on their investment" in the Danish performance-based model for science and technology in 2009. The axes are symmetrical and the diagonal shows the point where the institution has the same relative share of input (publications) and output (BFI points or citations). The distance from the university to the diagonal suggests whether input is larger than the return (output), which means that the institution will be below the diagonal, or the return (output) is larger, in which case the university is placed above the diagonal. Further, each university is plotted two times, one for the BFI data and one for the WoS citation data. Significant changes between these two representations for a university up and down the diagonal, suggest that the university receives a substantial number of BFI points from publication types other than journal articles. Notice in order to avoid confusion when examining the figures, shares of BFI publications on the x-axis should be compared to shares of BFI points on the y-axis, and likewise shares of WoS publications on the x-axis should be compared with shares of citations on the y-axis.

It is clear from Figure 1 that RU, CBS and ITU are not interesting for the current analysis as their numbers and shares are too low. We are interested in the other five universities, which all have a faculty of some size within science and technology. Interestingly, from Figure 1, where *all* BFI publication types are included, we can see that DTU actually has a larger output than input with a ratio of 1.09. This is somewhat unexpected and contrary to the conjecture that DTU is not gaining much from the current model. If we then turn to the

citation analysis, then we can see an even larger distance from the diagonal to DTU, compared to the BFI data, but also all other universities. The ratio is 1.25, so in line with the previous findings, DTUs WoS publications receive considerably more citations than the other Danish universities in 2009 but also the average paper in the WoS database. If a citation-based indicator of some sort were constructed where points were given based on citations, as implied in the arguments from DTU, then it seems that DTU would benefit from such a model, obviously conditioned on how it was designed. However, the most interesting finding here is perhaps that DTU within the science and technology area also seems to be the largest beneficiary when it comes to BFI points earned per input publication. Notice, like the current PRFS, we also treat it as a zero-sum game. If all universities improve then we have status quo. As it is in Figure 1, only DTU seems to really benefit from the citation approach. While KU seems to be in balance with the BFI data, they experience a smaller drop in returns on their input in the citation approach. Perhaps the most remarkable result from Figure 1 is the dramatic drop on the diagonal between BFI data and WoS citation data for AAU. We return to this below.

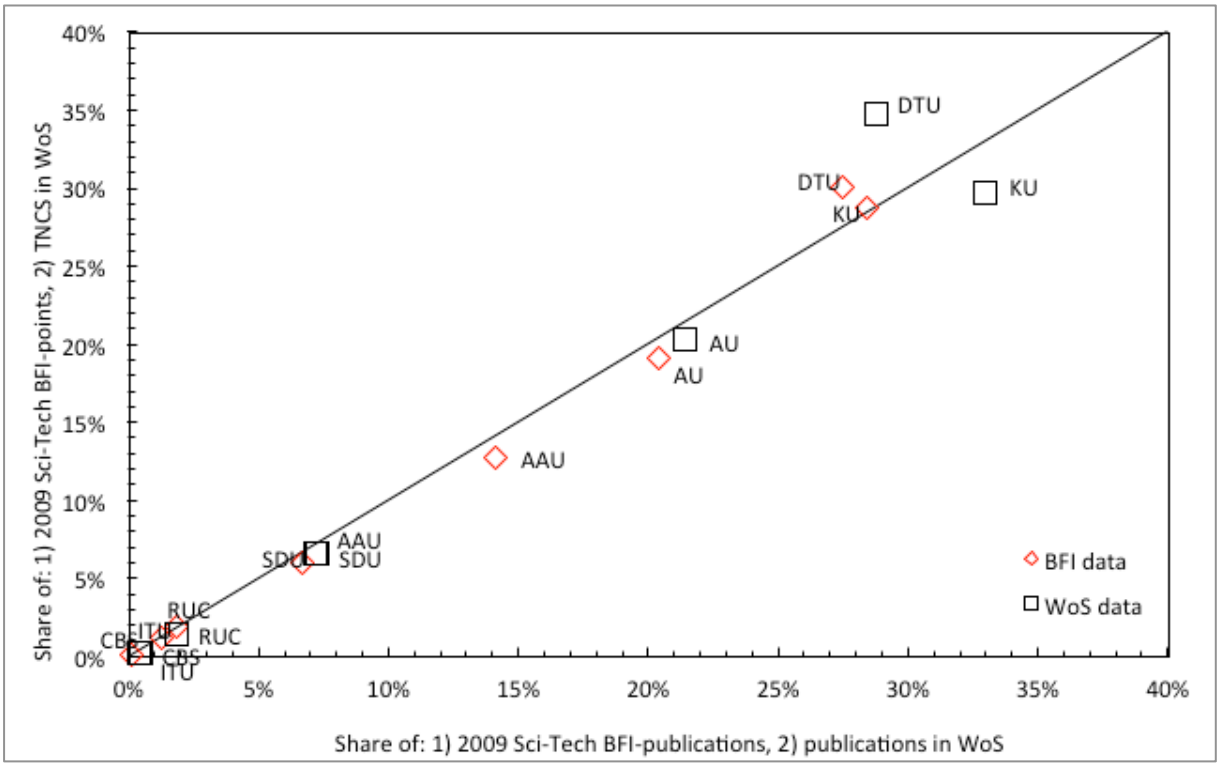

Figure 1. Science and technology: 1) Shares of 2009 Sci-Tech BFI publications as a function of shares of 2009 BFI-points; and 2) Shares of 2009 Sci-Tech WoS publications as a function of shares of total number of citations to these publications; notice BFI data includes all publication types.

Figure 2 depicts the same analysis but this time we have reduced the BFI data to include only journal publications in order to compare like with like, i.e., BFI journal data with WoS journal data. Obviously, the WoS data are identical to Figure 1, what is changing is the relative shares of BFI data (i.e., shares of publications and shares of points). There are some minor repositions, but the two major differences are the large drop on the diagonal for AAU and the corresponding smaller drop above the diagonal for DTU. Notice, the input-output is in balance for AAU, whereas DTU still has a substantial "return on investments" when it comes BFI journal data.

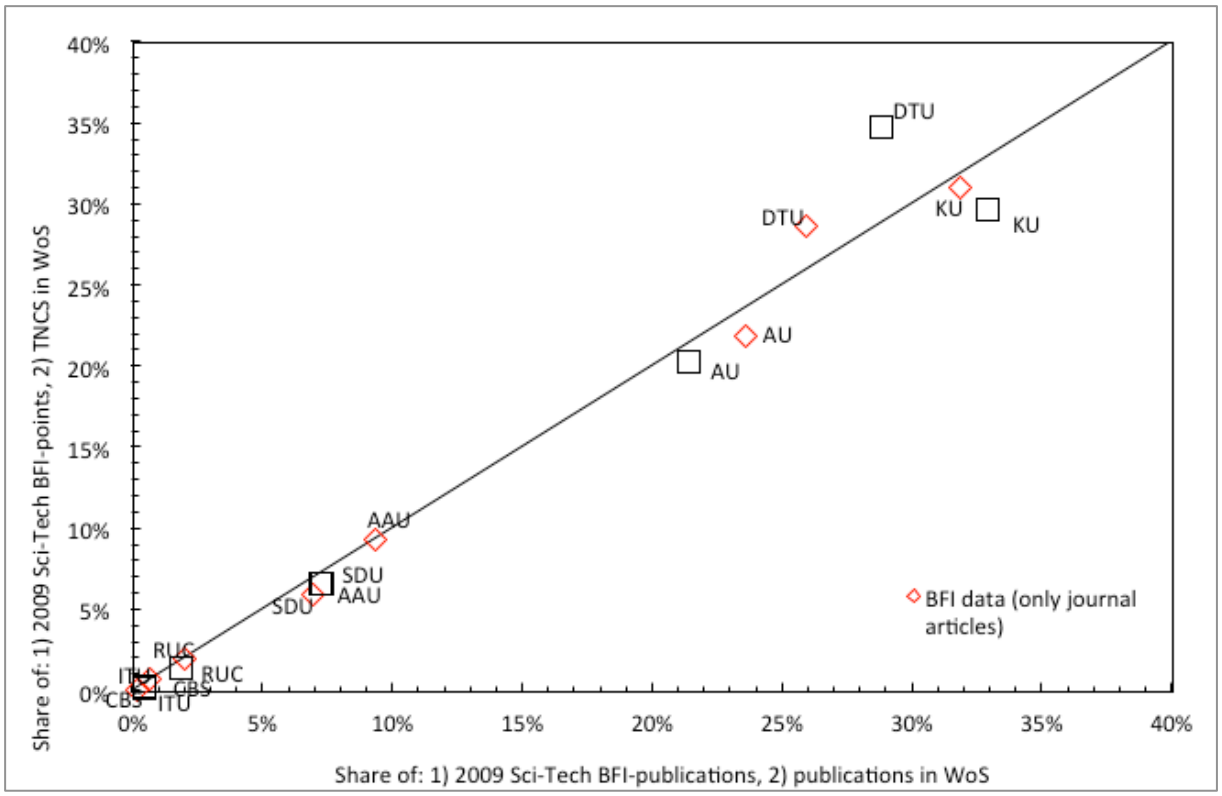

Figure 2. Science and technology: 1) Shares of 2009 Sci-Tech BFI publications as a function of shares of 2009 BFI-points; and 2) Shares of 2009 Sci-Tech WoS publications as a function of shares of total number of citations to these publications; notice BFI data only includes the publication type journal articles.

The drop of AAU along the diagonal was foretold in the WoS data in Figure 1. Here we saw a considerable distance between the BFI data when they included all publication types and the restricted WoS journal data needed for the citation analysis. For obvious reasons, this gap has been shortened considerably in Figure 2 since both data sets are restricted to journal articles.

The discrepancy in Figure 1 and the drop in Figure 2 are caused by the deviant publication profile for AAU compared to the other four universities with substantial publication activity in the science and technology area. Interestingly, 41% of the BFI publication activity in 2009 for AAU is in the category "articles in books", which in this case essentially means conference papers, and 49% is journal articles. For a comparison, 21% of DTUs activity is in "articles in books" and 70% in journal articles. These are both universities with strong focus on the technical sciences where publication in conference proceedings is very important. To contrast these profiles, the three other universities, KU, AU and SDU, all have more traditional science faculties and their relative publication activity in "articles in books" is 9%, 9% and 14% respectively. For these universities, due to their strong focus on science and less focus on technology, journal publication is the main activity 83% for KU, 86% for AU and 77% for SDU. However, we can also see that DTU does indeed have a strong science focus judged from their strong journal publication profile.

Considering the impetus for DTU to argue for a citation model, it is interesting to notice that while DTU clearly has the highest citation performance among the eight universities based on the 2009 journal publications, as we expected, they also have the highest performance when it comes to BFI publication points. Indeed, it seems that DTU would benefit even more in the science and technology area if they were to be rewarded for their relative share of the total number of citations, but contrary to the expected and suggested, DTU also benefit the most when it comes shares of BFI publication points compared to their relative input in the science

and technology area. DTU seems not only to be the most efficient when it comes to citations, this is also the case when it comes to BFI publication points. For example, the size of KUs activity in the science and technology area is larger than DTUs, but DTUs average point per publication is 1.20 for both of the above-mentioned analyses, considerably higher than KUs at 1.11.

Discussion

The main immediate findings in the present case study is that DTU will most probably benefit from a citation model, but perhaps more important, that they also seem to be the relatively most efficient university when it comes to BFI publication points. What are the more general implications of these findings seen in relation the current spread of the NPM to a number of European countries? The Danish case is special because competition is locked within the main areas this opens up for adapted models across areas including citation models where relevant. In Sweden a citation model is currently in use encompassing all fields. This is undesirable for several reasons; one of them is clearly demonstrated in this analysis, the desire to embrace all major publication behaviours, one of the rationales for the original NPM. A citation model alone restricts data to journal articles indexed in one of the two major citation databases. It was clear from Figure 1, that a university with an emphasis on technical sciences, like AAU, will be reduced in relative size when it comes to sharing the output.

The NPM is a differentiated publication indicator where points are graded for where you publish. Incentives to improve performance are clear and straightforward. Citation indicators reflect short term impact upon the scientific communication system. Citation indicators are retrospective and quite stable. It is very difficult to directly try to improve performance when it comes to impact. While one can argue that a publication-based model support the publish and perish culture with the ever increasing publication pressure, one could also argue that a citation model at the university level, due to its stability or conservative nature, and the fact that preferential attachment is at play for some universities, most likely would give cumulative advantages to those "who already have plenty", and potential changes brought about by incentives, are certainly not a short term phenomena.

There have been suggestions in Denmark to meet some of the requirements from DTU to focus more on citation impact. In order to keep the existing differentiated publication model intact, suggestions have been presented to bring in a third level especially in relation to journal outlets. This should be a category for the few hyped journals and publishing in these should be rewarded more lavishly. There may be good reasons for extending the levels in the model, but it is a flawed argument to claim to compensate wishes for more focus on impact by rewarding publication activity in "high impact" outlets. As it is well-known, article citation rates and journal citation impact have meagre correlations and the latter is a rather poor predictor of the former (Seglen, 1997).

A citation-based indicator or a hybrid indicator based on both publications and citations can be conceived in many ways, the question is whether the former or the latter is desirable. As discussed in the introduction, publication activity and citation impact are two different phenomena with substantially different prospects when it comes to incentives and behavioural adjustments. In the present analysis we could of course have experimented with more sophisticated citation-based approaches, for instance by constructing a mirror of the current publication-based model, where an arbitrary system allocates points according to which percentile group in the citation distribution they belonged to. We actually did that with a three-tiered point system, both the results were in line with the ones presented here.

As it is, based on the 2009 data, the BFI model in Denmark seems to work. Claims of more focus on citation impact seem only to speed up the cumulative advantage for "those who

already have" and at the same downgrade the influence of certain publication behaviours and muddling the transparent incentive structure.

The Effect of Having a Research Chair on Scientists' Productivity

Seyed Reza Mirnezami[1] and Catherine Beaudry[2]

Abstract

Having combined data on Quebec scientists' funding and journal publication, this paper tests the effect of having a research chair on the scientists' performance. The novelty of this paper is to use matching technique to understand whether having a research chair is a real cause for better scientific performance. This method compares two different sets of regressions, which are conducted on different data sets: the one with all records and another with records of matched scientists only. Two chair and non-chair scientists are called matched with each other when they have closest propensity score in terms of age, number of articles, and amount of funding. The result shows that research chair is a significant determinant in complete data set but it is insignificant when only matched scientists are kept in data set. In other words, in the case of two scientists with similarity in terms of three mentioned factors, having a chair cannot significantly affect the scientific performance.

Conference Topic

Science policy and research assessment

Introduction

The scientists' academic performance has been extensively discussed and many of its determinants are currently known as potential motives for publishing papers in peer reviewed journals. Among others, age, gender, private and public funding, institutional setting, field and context are the most important determinants. The funding definitely plays the major role in knowledge production and shaping scientific productivity. Its positive effect has been extensively investigated in literature (Crespi & Geuna, 2008; Pavitt, 2000, 2001; Salter & Martin, 2001).

However, having a great academic performance does not depend solely on funding. The networking capability of scientist can also explain the number of journal papers. Most of the studies on the effects of network rely on co-authorship as a proxy of scientific collaboration (Katz & Martin, 1997; Melin & Persson, 1996). In addition to direct collaboration, there are also some other networking measures, which are known in the literature as determinant of publication. For instance, it is possible to show how a researcher links two other researchers by making separate collaborations with them. Newman (2001a, 2001b) finds that in physics, biomedical research, and computer science, most of the authors are connected with each other via one or two of their collaborators, a concept generally referred to as betweenness centrality. Beaudry and Allaoui (2012) also show a positive effect of betweenness centrality on the scientific productivity of Quebec's scientists.

In addition to the above measures of networking effect, the networking capacity of scientists partially depends on prestige of their academic affiliation. Turner and Mairesse (2005) show it for the outstanding performance of 'Grandes Ecoles' in France. Beside the name and brand of academic institutions, centers with specific research orientations such as 'centers for excellence' are also effective. According to Niosi (2002), the government of Canada launched 7 centers for biotechnology sectors in 1988, which financially supports the collaboration of university research, the specialized biotechnology firms, and the governmental laboratories. In addition to the funding support, however, this program comes up with improving intellectual property regulations, and developing human resources.

There are some other desirable factors similar to 'centers for excellence', which increase an individual's research motivation and influence the willingness or ability of scientists for conducting original research. In this paper, we focus on the effect having a 'research chair' as a possible determinant of scientific publication. On the one hand, it helps the holder of this position to absorb more money or to construct more effective network, which results in propelling future knowledge production. On the other hand, it may be the effect of past super performance of scientist, implying the intrinsic ability of scientists in conducting research or referring to the chair-holder extensive networking capacity.

By analysing data in an econometric model, it is possible to test the significant effect of 'being a chair holder' on the scientific productivity. The rest of paper is followings: Section 1 reviews theoretical framework and literature review. Section 2 explains how data is gathered and what the variables represent. In addition, it raises the related hypotheses and explains which econometric models can test these hypotheses. Section 3 presents the results of econometric model and the result of testing hypotheses. A conclusion will summarize the results of the paper.

Section 1 - Theoretical framework

The literature relevant to this article brushes on the importance of having a prestigious academic position or affiliation. Focusing on the role of university prestige in academic performance, Long, Allison, and McGinnis (1979) found a positive and significant correlation between the prestige of the scientist alma matter and prestige of subsequent employment affiliation. The authors also indicated that graduating from a prestigious university has a positive effect on citations (but not on publication counts). The paper also provides a justification for the effect of prestige arguing that the best students are admitted to the most prestigious universities and subsequently the graduates of the prestigious universities are generally recruited by other similar institutions. Furthermore, such scientists who studied in and have been recruited by prestigious universities are better able to interact with new gifted students (Long et al., 1979). This paper tries to argue that academic prestige can push forward research and its quality. More recently, Zhou, Lü, and Li (2012) show that papers cited by prestigious scientists, regardless of the number of citations, are of a higher quality than papers which are cited by 'ordinary' scientists.

The prestige can be seen from the reverse direction of causality. West, Smith, Feng, and Lawthom (1998) investigate the relationship between departmental climate, such as degree of formalization, support for career development and support for innovation on the one hand, and official rated effectiveness of universities on the other hand. They conclude that the causality direction is from former to latter, showing that prestige of universities is an effect and not a cause for appropriate departmental climate and necessary institutional setting for conducting research.

Nevertheless, measuring academic prestige itself is another story. Frey and Rost (2010) compare three types of university ranking based on the number of articles, number of citations, and membership of editorial board or of academic associations. The paper indicates that these rankings are not compatible with each other and suggests the use of multiple measurements. Van Raan (2005) criticize the applicability of university rankings such as the Shanghai ranking for evaluating academic excellence by noting that the 'affiliation', as an important factor reflecting research atmosphere, is not well addressed in those ranking. In addition to the university ranking, it is important to assess individual research productivity to have a better sense of prestige. Henrekson and Waldenström (2007) introduce three types of indicators, measuring research performance: (1) measures based on weighted journal publications, (2) measures based on citations to most cited works, and (3) measures based on the number of publications.

To measure prestige with more robust measure, it is possible to consider the honor as the measure of prestige, which is awarded based on a deliberate assessment in specialized and independent committees. Different types of research chair are example of awards. In Canada, there are three types of research chair: (1) the research chairs which are awarded by industry and called industrial chair; (2) the research chairs which are awarded by Canadian funding agencies such as NSERC, SSHRC, and CIHR; and (3) the 'Canada research chairs', whose holders are assumed to already achieve research excellence in one main fields of research: engineering and the natural sciences, health sciences, humanities, and social sciences. The purpose of this program is to "improve our depth of knowledge and quality of life, strengthen Canada's international competitiveness, and help train the next generation of highly skilled people through student supervision, teaching, and the coordination of other researchers' work".[1] Considering this specific measure of prestige, it is possible to find out the effect of being a 'chair-holder' on scientific productivity. Therefore, our first hypothesis reads as:

Hypothesis 1

Being chair-holder increases the scientist's number of publications.

The hypothesis 1 just tests the performance of chair-holders compared to other scientists and it does not seek for the cause and effect. Considering the fact that the chair-holders are the well-funded scientists too, this hypothesis cannot detach the funding effect of chair from its other effects (mainly from prestige and networking effect). In other words, there are evidences in literature about the benefits and goals of research chair program other than funding, but hypothesis 1 is not able to test them.

Some articles try to highlight the functions and characteristics of research chair. Cantu, Bustani, Molina, and Moreira (2009) show the research chair program would be a good strategy for implementing knowledge-based development. In study on German universities, Schimank (2005) argues that chair-holders are small businessmen with high job security and no bankruptcy in addition to the good level of freedom of teaching and research, indicating that research chair has characteristics of job security and sovereignty.

According to some official documents, affecting scientific productivity is not the direct goal of research chair. In the tenth-year evaluation report for Canada research chair (CRC),[2] the authors conclude that CRC program is an effective way for Canadian universities to "attract and retain leading researchers" from other countries. The report does not say that having a research chair is determinant and cause of chair's scientific production: "the extent to which this success can be related directly to the CRC is difficult to quantify". It is also possible to bring some evidence that having a research chair is not a cause for other factors such as salary. Courty and Sim (2012) show that although having Canada Research Chair (CRC) initially increases the professors' salary, such increase erodes quickly over the time. This means that getting a research chair does not necessarily result in long term salary jump.

Regarding the mentioned points, it is possible to look at the research chair as the effect of scientists' characteristics (including age, number of articles, and number of citations), while it aims to expand academic network and absorb highly skilled talents. To control for the effect of scientist's past performance on having a research chair and to detach the funding advantage of chair, we propose our second hypothesis:

Hypothesis 2

Keeping the main scientists' characteristics (age, number of articles, and amount of grant) constant, having a research chair does not have significant positive effect on scientists' productivity.

[1] http://www.chairs-chaires.gc.ca/about_us-a_notre_sujet/index-eng.aspx

[2] http://www.chairs-chaires.gc.ca/about_us-a_notre_sujet/publications/ten_year_evaluation_e.pdf

This hypothesis can be tested by matching technique, which will be explained in the methodology section. The important note here is that 'being a research chair' cannot be the only determinant in right-hand-side of regression equations. We should look for some control variables, which are mentioned in literature as determinants of scientific production. Among others, age, gender, funding, field, and university characteristics are the most important determinants of scientific production which should be controlled when the effect of research chair on scientific productivity are being tested.

In terms of age, there are two groups of evidences in literature about its effect on scientific productivity. First, some articles assess the life cycle trend in economic activity, referring to the non-linearity of human productivity during life (Becker, 1962). The second group of articles generally find that scientists' academic performance (number of articles and number of citations) decreases as they age (Bonaccorsi & Daraio, 2003; Diamond, 1986; Levin & Stephan, 1991). Some articles like Gonzalez-Brambila and Veloso (2007) also indicate that age does not have any effect on the number of articles but it positively affect the number of citations. Gender effect is known as a significant determinant of scientific productivity in literature. Long (1990) explains that women's opportunities for collaboration are significantly less than those of men's because women have young children. However, in another study, Long (1992) shows that women are less productive in the first decade of their career but are more productive afterwards. Research funding is another important determinant of scientific productivity. Pavitt (2001) also refers to the importance of public support for scientific infrastructure development and highlights its role in the effectiveness of public grants. In another study, Pavitt (2000) argues that fudging for infrastructure of expertise, equipment and networks is necessary for development and implementation of research. A body of literature investigates the effect of university characteristics on the scientific productivity. There are also some papers about the effect of faculty size. Buchmueller, Dominitz, and Lee Hansen (1999) indicate that graduate school faculty size is a significant determinant of the research proficiency of graduates. Jordan, Meador, and Walters (1988, 1989) indicate that research productivity is positively associated with department size but that effect becomes weaker as the size increases. In an opposite direction, Kyvik (1995) rejects both hypotheses that large departments are more productive and that faculty members of large departments better assess the research environment.

There also some evidences about differences between fields and context. Blackburn, Behymer, and Hall (1978) show that the fields of humanities and sciences have different pattern of scientific production. To justify the differences between disciplines, Baird (1986) shows that for instance large research laboratory in chemistry, scholarly apprenticeship approach in history, and research over practice in psychology are important factors in scientists' productivity, which are field-dependent factors. In another comprehensive study, Baird (1991) refers to the productivity and citation pattern differences among disciplines and argues that size, internal university support and federal support can explain such differences. All of the mentioned evidence in literature shows that scientific productivity may have different determinants including academic prestige and other control variables such as funding, gender, age, and university-specific characteristics.

Section 2 - Data and methodology

Data and variables

In order to validate these two hypotheses, we built a data set based on the integration of data on funding and journal publications for Quebec scientists. For publications, Elsevier's Scopus provides information on scientific articles (date of publication, journal name, authors and their affiliations). In terms of funding, there is a database for researchers in Quebec universities

(*Système d'information sur la recherche universitaire* or SIRU) gathered and combined by the Ministry of Education, Leisure and Sports. The SIRU database lists the grants and contracts information, including yearly amount, source, and type during the period of 2000-2010 for all Quebec university scientists. The appendix 1 reviews the names and description of variables in data set.

Methodology and econometrics model

To measure the effect of 'being a research chair' on the scientist's performance, a regression equation is fitted to the available data using a panel regression. In such regression, the left-hand-side (LHS) variable of regression is the number of articles [*ln(nbArticle)*] as a measure of scientific productivity. In terms of right-hand-side (RHS) variable, the main independent variables are the dummy variables of research chair [*dChair1*, *dChair2*, *dChair3*, *dChair4*, *dChair5*]. However, the dependent variable of regression in LHS should be also controlled for the other determinants of articles count. Among others, age [*Age*], gender [*dFemale*], and funding are the important ones. We also control for the fixed effect of university, year, and research field in order to account for any impact that our explanatory variables do not cover.

It is important to note that two variables of [*ln(PublicfundingO)*] and [*ln(nbArticle)*] are determined by each other and co-evolved during time, which is the source of endogeneity. Thus it means that simple ordinary least square or panel models are biased. The main reason for this potential endogeneity is that scientists are assessed for public funding based on their CV and past performance while at the same time, publication and research quality significantly depends on the funding capability of researchers. Using instrumental variables (IV) instead of endogenous variable is a common suggested method in literature to address endogeneity problem. If there is more than one instrument for an endogenous variable, it is necessary to perform a two-stage regression, in which the first stage estimates the endogenous variable (named here as instrumented variable) based on a list of instrumental variables. In the first stage of our model, the amount of public funding [*ln(PublicfundingO)*] is estimated by the rank of scientist in the field in terms of three-year average of funding (for the purpose of operational costs and direct expenditure of research) [*PubORank*], the rank of scientist in the field in terms of three-year average of articles count [*PublRank*], and natural logarithm of three-year average of aggregate public sector funding in the field [*ln(totFund)*]. These three variables play the role of instruments for public funding. It should also be noted that public funding is not determined by the instruments in the same year. Hence the one-year lags of instruments are being used in the first-stage regression. The second stage is similar to the previous model in which there is no endogeneity.

1st stage: $ln(PublicfundingO)_{it} = f(\ PubORank_{it-1}, PublRank_{it-1}, ln(totFund)_{it-1}\ )$

2nd stage: $ln(nbCitation)_{it} = f(\ ln(PublicfundingO)_{it}\ ,\ ln(PrivatefundingO)_{it}\ ,\ ln(NFPfundingO)_{it}\ ,\ (dChair1|dChair2|dChair3|dChair4|dChair5)_{it}$, *dFemale, Age,* Age^2*, research field dummies, year dummies, university dummies)*

The main purpose of this research is to show how much having a research chair as an external support is important and significant in promoting scientific publication. To test the first hypothesis, it is sufficient to run the two-stage panel regression on the whole data set whether 'having a research chair' is a significant RHS variable, either as a real cause or a channel for other variables/causes. According to the chair characteristics, the networking and prestige effect of 'having a research chair' may be mixed with the effect of funding. To address this issue, we use matching technique and compare two chair and non-chair scientists who have close funding to each other (and have some other similar characteristics). Like what Bérubé and Mohnen (2009) did, it is possible to find pairs of chair and non-chair by using the psmatch2 command in Stata and delete the unmatched records. The selection is made by

generating propensity score and choosing the pairs of scientists with closest scores to each other. The new data set consists of twin scientists who are similar to each other in terms of funding, gender, and division of studies.[3]

By controlling the mentioned criteria and keeping matched scientists only, 'having a research chair' becomes a better and more informative signal for the prestige and networking of scientists. In this case, the effect of 'being chair' on scientific productivity does not include funding effect or it is not related to the division or gender of scientist. To test the second hypothesis, only matched pairs of scientists are being used in regression analysis to identify whether having a research chair is a significant cause for scientific productivity.

One of the important stages in matching technique is to check the quality of matching. It means there should be no difference between the averages of mentioned criteria (gender, funding, and division of studies) when the comparison is made between chair and non-chair scientists among the matched pairs. However, there can be a difference when the comparison is made in original database and before any entry deletion. Table 1 summarizes such comparisons to show that the matching is done with an acceptable quality for *dChair3*, *dChair4*, and *dChair5*.

Table 1. Make a comparison between mean to show the quality of matching.

	Comparison over whole database				Comparison over matched scientists "**After Matching**"

Section 3 - Result and discussion

Based on the models presented in methodology section, we need to first run the regressions on the whole dataset (Table 2) which show that all types of chair have positive and significant effect on scientific productivity. However after keeping only matched scientists in dataset, who are similar to each other in terms of gender, funding, and research field, the regression equations indicate significant and positive result only for Canada research chair (Table 3) Industrial chairs and chairs appointed by Canada research council (NSER, SSHRC, and CIHR) do not have an independent positive effect on scientific productivity. Considering the hypotheses in previous section, it possible to validate the first hypothesis and partially validate the second hypothesis. One may question whether research chairs in general are independent cause for research productivity or they are proxy for other known factors in literature. Considering literature and mentioned mission of research chairs in their mandate,

[3] We have three divisions: 'engineering and the natural sciences', 'health sciences', and' humanities, and social sciences'

[4] Test whether dummy variable of Social Science and Humanities is equal to 1.

it is possible to argue that having a chair improve networking capability or funding amount of scientists.

In the second hypothesis we try to make a distinction between the effect of funding and having a research chair. By running regression model only on matched pairs of scientists, having a chair cannot be a proxy for criteria of matching (age, gender, and research field) anymore. We can verify the hypothesis 2 for industrial chair and research chairs appointed by research council but this hypothesis cannot be validated for 'Canada research chair' because its effect is still positive and significant even after matching. Some justification can be provided for this finding. The first is that Canada research chair intends to be prestige sign of research in Canada. Based on its mandate, the Canada research chair program aims to attract and retain some of most accomplished and promising minds in the world. It is more prestigious than other research chairs and other scientists may also have more willingness to conduct collaborative research with the Canada research chair holders. As the second justification, it should be noted that industrial chairs are appointed by firms to promote research, probably with major benefits for firms. In other words, this type of chair is not necessarily and originally designed for the sake of scientific publication. The chairs appointed by research councils may have quite similar characteristic. Looking at these chairs' description, most of chair holders are appointed as industrial chair. There are some evidence in literature indicating that industrial funding forces researchers to shift to more applied research, neglecting their normative responsibilities for knowledge development (Geuna & Nesta, 2003; Partha & David, 1994).

In addition to the effect of chair on scientific productivity, there are also some interesting results for other control variables in econometric model. Funding from different sources is always a significant determinant of scientific productivity, which has positive sign. Funding from private sector and funding from not-for-profit sector are directly put in regression equation while funding from public sector is first estimated by instrumental variables and then inserted to regression model.

The age of scientists seems to affect scientific productivity with an inverted-U shape pattern. However, considering its peak, which is 10 years old and less than the normal age for scientific activity, it is possible to argue that scientific productivity of scientists decreases in age. The gender of scientist, as another individual attribute, shows a significant impact. It indicates that women are less likely to publish journal paper compared with men. Both of these findings have some similar evidence in literature as discussed in previous section for age (Bonaccorsi & Daraio, 2003; Diamond, 1986; Levin & Stephan, 1991) and gender (Long, 1990).

The results verify the fixed effect of university and research discipline in addition to the year-specific effect on scientific production. Our regression analysis also tests the interactive effects of RHS variables. The first interactive effect is the interaction between gender and funding. From technical point of view, it is not possible to estimate the interactive effect with an endogenous variable in 2SLS models because its amount is estimated in the first stage and we are not using the raw value reported in dataset. However, we can estimate the effect of interaction with private funding and not-for-profit funding, which both are not significant. The only exception is in table 2 where the regression is run on whole dataset and interaction of gender and not-for-profit is negative and significant, which means that women may benefit from not-for-profit funding less efficiently compared with men.

The variables measuring interaction between having a chair and amount of funding are the next possible interaction in regression analysis, most of which are not significant. However, if there is significance, it is positive before matching and negative after matching. It refers to the more impact of funding for the chair people in general (complete data set) but when the chairs are compared to scientists, who are similar to them in terms of funding, gender, and research

field, they benefit from the funding less efficiently compared to non-chairs. The last group of interactive variables are the combination of two previous groups: interaction between funding, chair, and gender. There are some negative and significant effects for this type of interaction, showing the combined results of previous interactive variables.

Conclusion

In this article we show that having a research chair is a significant determinant of scientific publication when the regression is run over whole data set. As previously explained, a distinction should be made to clarify different attributes of research chair and their effect on scientific productivity. For instance, it is a fact that research chairs receive more grants due to their chair so the question here is to check if positive effect of research chair on scientific productivity remains significant after controlling for the funding amount of chair. To investigate the causality of this relationship, the matching technique is applied to control for some common characteristics of chair and non-chair scientists and to highlight the channel through which this positive effect has happened.

To conduct this matching technique, we only keep pairs of chair and non-chair scientists, matched together based on funding, gender, and research field, and delete the rest of scientists from data set. This methodology is effective to understand other attributes of research chair (except funding) that have significant and positive effect on scientific productivity. After such matching, the results show that the effect of Canada research chair on scientific productivity remains significant and positive while the effect of industrial chairs and the chairs appointed by Canada research council (NSER, SSHRC, and CIHR) become insignificant. This finding indicates that there are some special attributes in Cana research chair, which do not exist in other chairs. Those attributes may significantly push scientific productivity. Among other attributes, Canada research chairs may have better prestige to absorb talents or they are well designed to conduct scientific research for publication.

Abstract

Social media is increasingly used in higher education settings by researchers, students and institutions. Whether it is researchers conversing with other researchers, or universities seeking to communicate to a wider audience, social media platforms serve as a tool for users to communicate and increase visibility. Scholarly communication in social media and investigations about social media metrics is of increasing interest for scientometric researchers, and to the emergence of altmetrics. Less understood is the role of organizational characteristics in garnering social media visibility, through for instance liking and following mechanisms. In this study we aim to contribute to the understanding of the effect of specific social media use by investigating higher education institutions' presence on Twitter. We investigate the possible connections between followers on Twitter and the use of Twitter and the organizational characteristics of the HEIs. We find that HEIs' social media visibility on Twitter are only partly explained by social media use and that organizational characteristics also play a role in garnering these followers. Although, there is an advantage in garnering followers for those first adopters of Twitter. These findings emphasize the importance of considering a range of factors to understand impact online for organizations and HEIs in particular.

Conference Topic

Science policy and research assessment, Country-level studies, Webometrics, Altmetrics

Introduction

The use of social media increases visibility of users (Constantinides & Zinck, 2011). This online visibility garners success and performance (Schindler & Bickar, 2005; Dellarocas, 2003; Duan et al., 2008). Less understood is the role of offline effects in garnering this visibility. For example, how do organizational characteristics influence an organization's visibility on social media? The understanding of the potential dual role of organizational characteristics and social media use in explaining visibility allows us to delineate how traditional characteristics such as status or reputation of organization play a role in generating attention on social media and how best to measure this impact.

We explore this through the lens of higher education. Social media is increasingly used in scholarly communication. Higher education institutions (HEIs), in particular, are increasingly using social media platforms as tools to communicate to prospective and current students, alumni and society at large (Gibbs, 2002; Helgesen 2008; Hemsley-Brown & Oplatka, 2006). Thus, the case of higher education and institutions' social media use in particular provides a valuable case to explore the possible dual role of organizational characteristics and the use of social media by these institutions in explaining garnered visibility.

In this paper we review literature on visibility of organizations and identify the potential role of social media use and organizational characteristics in explaining this visibility. We propose a number of hypotheses in which social media visibility is dependent on the two. To test these effects, we investigate 137 UK higher education institutions, collecting data of their Twitter activities and characteristics to explain social media visibility. Findings suggest that organizational characteristics of HEIs play a large role in their social media visibilities on

Twitter, compared to social media use alone. This emphasizes the importance of considering a range of factors in understand impact online for both organizations and HEIs in particular. This topic is of interest for scientometric researchers, as it is an additional avenue from bibliometrics to evaluate potential impact of a HEIs. In particular this work contributes to recent research on altmetrics. Altmetrics seeks to investigate the potential use of social media metrics for research evaluation and mapping of scholarly communication (Priem et al., 2010). The delineation of this mechanism advances our understanding of metrics validity and sheds light on the practical questions of how organizations can garner visibility online.

Social media and organizations

Organizational visibility is generated by the organization itself, and the users that engage with organizations. Organizational visibility is partly generated through word-of-mouth (WOM). WOM is the practice of communication where information is spread between individuals about a product or a service of a given organization (Richins, 1983). This mechanism allows individuals to share information and opinions to others about specific products, brands and services (Hawkins, Best, Coney, 2004; Westbrook, 1987) and to attach sentiment to messages. Positive WOM influences the awareness, image, decisions, evaluation and interest of potential consumers and stakeholders (Ozcan & Ramaswamy, 2004; Price, Feick & Guskey, 1995).

Organizations in particular are keen to attempt to achieve or maintain this positive WOM through different strategies of communication about the product or service they offer. With nearly half of all US internet users engaging on social networking sites (Smith, 2011), and with the numbers increasing worldwide, it is not a surprise that organizations are also getting involved in communicating via social media. The use of social media by organizations has largely been seen as marketing strategy to increase visibility (Constantinides & Zinck, 2011).

Social media in particular serve as platforms for electronic WOM where entities spread and share information, but also as a medium where identification of organizational interests is transparent through online liking or following mechanisms (Dellarocas, 2003). Social media platforms serve as sites of social interaction, communication and marketing. This is achieved through socializing and networking online through text, images and videos. These platforms are largely made of user-generated content and facilitated through peer-to-peer communication and participation (Nambisan & Nambisan, 2008; Shankar & Malthouse, 2009).

A number of positive outcomes have been attributed to the use of social media by organizations. The use of social media platforms and thus consequent eWOM around a product or service of an organization influences attitudes, intentions and buying decisions (Schindler & Bickart, 2005; Goldsmith & Horowitz, 2006; Yao, Dresner & Palmer, 2009). The use of social media has also been attributed to increased economic impact (Chevalier & Mayzlin, 2006; Dellarocas, 2003). Recent work has questioned the impact of social media use on outcomes, suggesting that online content is solely a predictor of economic success, and not a factor that influences buying decisions (Chen et al., 2011; Duan et al., 2008). Follow-up studies suggest that user consult the Web for a confirmation of a decision they have made about a product, service or organization (Schindler & Bickart, 2005). Thus, this questions the explanatory power of social media use in garnering different outcomes, suggesting that other information about an organization or its product or service may play a role in understanding this garnered visibility online.

External to social media, the organization has a reputation, status and perceived legitimacy of an organization (Baum & Oliver, 1991; DiMaggio & Powell, 1983). Qualities such as status are said to determine a part of users'/consumers' expectations of future qualities of organizations (Podolny, 1993), which aid in defining the visibility and positions of an

organization in a field (Wry et al., 2009). Consequently, the degree of visibility of higher education institutions is not only dependent on the institution's use of social media for exposure, but also on certain organizational characteristics. Thus, we question: in addition to the use of social media platforms, how do organizational characteristics influence online visibility?

Higher education institutions and social media

In this paper we investigate organizations in the system of higher education. With higher education we mean the organizations that organize education and research, such as universities. Higher education is an industry in which consumers are often under informed in the sense that they cannot objectively evaluate the quality of the service before they actually "purchase it" (Jongbloed, 2003). Thus visibility about the organization is highly dependent on word-of-mouth practices to foster interest of potential students, research funding, and public support.

There is a rise of social media use by higher education institutions as tools in communicating information about the organization to prospective and current students, alumni and society at large (Gibbs, 2002; Helgesen, 2008; Hemsley-Brown & Oplatka, 2006). Social media fill a gap in the information that these groups cannot find in other forms of communication (Hemsley-Brown & Oplatka, 2006) such as alternative contact points for education and campus life (Yu et al., 2010; Mason & Rennie, 2007). Research shows that social media serves to fill a gap in the information that those interested in a university cannot find on the websites (Hemsley-Brown & Oplatka, 2006). Studies have found a significant relationship between those who logged onto the social media platform and the likelihood of them applying to the university (Hayes, Ruschman, & Walker, 2009). Thus, social media by higher education institutions serves said to play a positive role in garnering visibility through different methods.

On the other hand, recent studies in webometric studies of scholarly communication Web indicators or altmetrics have frequently been compared against more traditional indicators of research productivity (such as number of publications) and research impact (citations). Studies on the individual level found significant correlations between traditional bibliometric metrics, for instance research productivity and online visibility (Bar-Ilan, 2004; Thelwall & Tang, 2003). This relationship has been attributed to highly cited scholars producing more content on the web, which then attracted more attention (Thelwall & Harries, 2003). This has also been found in recent studies on HEIs, questioning how social media platforms play a lesser role than other forms of communication in attracting students in particular (Constantinides & Zinck Stagnothe, 2011), as well as the role of geographical proximity in the likelihood of universities in particular to link with other universities (Heimeriks & Van den Besselaar, 2006).

This is not necessarily striking given that HEIs have reputations external to the messages disseminated on social media platforms. Organizations are expected to capitalize on a baseline visibility as scholars have shown that organizations with a central position in the system, related to the organizational size, status and reputation, receive more attention from audiences and stakeholders (Wry et al., 2011, Podolny, 1993). Recent works in webometrics have also demonstrated that core organizational attributes matter in explaining online communication; where status, reputation and size are important predictors of hyperlink connections and centrality (Seeber et al., 2012, Lepori et al., 2013). Thus, using a social media platform does not alone garner visibility or interest from others. Given this we propose:

Hypothesis 1: Social media visibility can be explained by the social media use of the organization.

Hypothesis 2: The social media visibility of the organization can be explained by a HEIs organizational characteristics related to organizational size, status and reputation.
Hypothesis 3: The social media visibility of the organization can be explained by both the HEI's social media activity and organizational characteristics related to organizational size, status and reputation.

Methodology

We explore in this study UK universities, investigating both their Twitter activity and organizational characteristics. In selecting a social media platform where HEIs are active we have selected Twitter. Twitter is especially efficient for word-of-mouth marketing, given the ability to *re-tweet* – forward messages from users (Jansen et al., 2009) In addition tweets often contain expressions of sentiments (ibid), which makes it a valid source for identifying practices driven by potential eWOM. Following the theoretical framework, we assume that followers are a function of the organizational attributes and the social media use of the university.

Sample

Alike most European universities, UK universities are public institutions and the State and related funding bodies represent the most important funding sources.[1] On the other hand, UK universities are autonomous institutions, provided with strong decision making hierarchies and operating in a competitive system, they are expected to be able and in need of developing strategies to actively improve their position in the system (de Boer & Jongbloed, 2012; Seeber, et al., forthcoming). In turn, the UK Higher Education is a suitable case to explore what determines social media visibility in a quasi-market public system. Our sample includes 137 UK HEIs included in the European Micro Data dataset (Eumida) - a database containing the structural characteristics of 2,457 Higher Education institutions in twenty-eight European countries (Bonaccorsi et al., 2010; Eumida, 2009).[2]

Measures

We retrieved data from the HEIs' Twitter accounts manually. This data was collected on 24 November 2014 to measure the dependent variable of visibility and the independent variable - social media use. We also collected data on the organizational characteristics of the institutions, the second independent variable, for measuring a number of characteristics of the HEIs.

Visibility

We focus in this paper on social media visibility. This is a count variable that identifies the number of followers of each UK HEIs.

[1] HESA statistics on finance of UK universities available at: https://www.hesa.ac.uk/
[2] EUMIDA data refer to year 2007. Originally it included 148 universities, although four institutions have merged in the meanwhile, leading to a sample of 144. The Institute of Cancer Research and the London School of Hygiene and Tropical Medicine were excluded, as they are research institutes rather than HEIs; as well as the University of Southampton as it missed a value on coreness, one of the major predicting variables. Four outliers cases in terms of the number of followers were also excluded, leading to a sample of 137 UK HEIs; the University of Oxford, with 175,000 followers, The University of Cambridge 151,000, the Open university 100,000 and the London Business School 69,800, compared to a mean of 20,217 and standard deviation of 21,466.

Social media use

Scholarly communication in social media has been measured in a number of ways. Following literature suggesting a combination of activities we seek to identify attributes of the ways that HEIs use social media. Aguillo (2009) suggested using Web data as indicators related to 1) activity, 2) impact, and 3) usage. Indicators related to activity include measurements of the efforts made to actively create and establish a Web presence, while impact is the mentions on and linking from other websites. Usage is a proxy for the number of downloads or how users engage with the organization on the web. Given these metrics we sought to collect any query-able data on Twitter use. We collected data on the total number of tweets sent, the number of users that the HEIs themselves are following as a measure of their activity. Data was collected the date of HEI's first tweets obtained from the Twitter website[3]. In addition we collected data on the HEIs using Twitter to disseminate and share news and events or targeting students, as indicated by the HEIs in their profiles.

Organizational characteristics

We selected organizational characteristics that are deemed to be particularly relevant for the visibility of universities. We sought to identify on a number of measure of the universities' size, age, resources and status. The organizational features were constructed by using information from Eumida (Bonaccorsi, et al., 2010; Eumida, 2009). We considered, in particular; a) the size of the university, in terms of the number of staff units and undergraduate students; b) the university reputation in the core activities of research, measured through the scientific productivity and the research intensity, and teaching, measured through the teaching burden c) the university status, which is measured through the relational centrality of the university in the system (Owen-Smith & Powell, 2008). As control variables we considered; a) the discipline profile, as some disciplines may attract more attention than others because of the societal salience of the topics addressed, and b) the geographical context, in terms of the urban centrality of the city where the university is located, which may indirectly benefit the university's visibility. Table 1 describes the characteristics of each variable.

Results

Descriptive Statistics

Tables 2 and 3 present respectively the descriptive statistics and the Pearson correlation of the considered variables. The distribution of followers is moderately right skewed, as well as the number of Tweets, whereas the number of following is strongly right skewed. The days on Twitter is left skewed, as most universities started using twitter in early days and a small number of universities are late adopters (Table 2). Pearson correlations show that the number of followers is significantly correlated to most of the considered variables, and in particular to the status-coreness of the university (0.693), size measured by units of staff (0.642) and students (0.477), and scientific productivity (0.452). These organizational characteristics are strongly correlated with each other, so that high status universities are also large, and have a good scientific reputation. Variables of social media use are weakly correlated among each other and the organizational characteristics, with the highest correlations existing between the number of tweets and the size in terms of number of undergraduate students (0.264) (Table 3). The descriptive statistics show that the number of Twitter followers are characterized by over dispersion (i.e., the variance increases faster than the mean).

[3] https://discover.twitter.com/first-tweet#username

Table 1. Description of organizational characteristics.

Size	The *number of total staff* (Full Time Equivalents measured in thousands), including academic as well as administrative and technical staff. The *number of undergraduate students*. (Eumida)
Reputation in research	Universities reputation in research activity is strongly related both to the *scientific productivity*, e.g. the quantity and quality of scientific publications. The indicator results from the product between the total number of publications multiplied by their field-normalized impact factor and divided by the number of academic staff. Data for two-thirds of the universities could be derived from the SCIMAGO institutional rankings for the year 2011 (http://www.scimagoir.com/), which is based on publications from the period 2005-2009; One-third of the universities are not covered since they had less than 100 publications in Scopus in the considered period. For these universities the indicator was set to zero. In fact, the scaling properties of research output (van Raan, 2007) maintain that the individual productivity tend to correlate with the organizational output, so that the indicator approaches zero when the level of output approaches the threshold of 100 publications. A second indicator of reputation in research considers the *research intensity*, as measured by the ratio between the number of PhD students over undergraduate students (Bonaccorsi, et al., 2007). (Eumida)
Reputation in teaching intensity	Teaching quality can be expected to be inversely related to the *teaching burden*, as measured by the ratio between the number of undergraduate students per unit of academic staff. (Eumida)
Status	University status is measured through the relational centrality or *coreness* in the system, estimated by considering web links connections between universities. Weblinks are receiving increasing attention in the study of inter-organizational relationships (Bar-Ilan 2009). European national higher education systems have been shown to conform to a core-periphery structure, where a status hierarchy is in place, core actors holding higher status and the *coreness* measuring the proximity to the network center (Borgatti & Everett, 1999; Lepori, et al., 2013; Owen-Smith & Powell, 2008).
Control: discipline profile	The disciplinary profile is defined by the share of academic staff employed in each of six subject domains considered in Science classification statistics (Eumida, 2009; Uoe, 2006). A Factor Analysis identifies three factors; separately employed as predicting variable. (Eumida)
Control: geographical context	The *Urban centrality* of the city where the university is located is measured through the Globalization and World Cities Network (GARC) scale of cities 2010 (Taylor, 2004) http://www.lboro.ac.uk/gawc/world2010.html). Accordingly, we ranked the universities with a numeric score from 9 (alpha++ cities) to 1 (gamma- cities), setting to zero the cities that are not in the list[1]

Results of models

The dependent variable is represented by the number of Twitter followers, and assume that the number of followers is a function of the organizational attributes and the social media use of the university. Hence, we rely on techniques used for modelling count data for series of non-negative integers. If individual events are independent and their number is sufficiently large, the resulting probability distribution for the counts follows a Poisson distribution. Unlike linear regressions, the Poisson regression model does not assume that observations are normally distributed around the conditional mean, see Table 3. The descriptive statistics show that the number of Twitter followers are characterized by over dispersion (i.e., the variance increases faster than the mean). We then employ a negative binomial regression, which includes a parameter to model over dispersion. Table 4 presents the results of models: i) the empty model; ii) the model including the significant organizational characteristics; iii) the model employing the variables of social media use; iv) the full model including significant organizational characteristics and social media use variables.

Findings show that the social media are significant predictors of the number of followers, with the exception of the *number of following* (Hypothesis 1). In particular the *number of tweets* and *days on Twitter* have a positive effect; the orientation towards *news and events* has a positive and highly significant effect when compared to a *general* orientation. Findings also show that the organizational characteristics are predictive of the number of followers (Hypothesis 2). The *size in terms of undergraduate students* and the *research intensity* have a positive and strongly significant effect. Despite the lower correlation with the number of followers, these two measures are better predictors, respectively than the *size as number of staff units* and the *scientific reputation*. The variable on *status – coreness* is also strongly significant and positive. The *teaching burden,* the *discipline profile* as well as the *urban centrality* of the university' location are not significant predictors.

Comparatively speaking, the organizational characteristics model perform considerably better than the model on social media use.[4] However, the final model (Hypothesis 3) displays that the better fit includes both organizational characteristics and social media use variables as regards the *number of tweets* and the *days on Twitter*.[5] All variables have a positive and strongly significant effect. In order to assess the predictive capability of the full model we cannot rely on usual fit measures, like the R^2, which assume a normal distribution. The model provides expected count values of followers, so that the fit can be judged by: a) computing a pseudo R^2 based on the formula: 1 – (Total Sum Squared/Residual Sum Squared); b) computing the percentage of observed counts correctly predicted. The Pseudo R^2 is 0.66.[6] Further, we consider the capability of the full model to correctly predict values below and above the median of 15,900 followers. The model correctly identifies 92% of the values below the median (*sensitivity*) and, when it predicts a value below the median, it is correct in 79% of the cases (*positive predictive value*). The performance is also good in terms of detecting the values above the median (67%, *specificity*); when the model predicts a value above the median, it is correct in 80% of the cases (*negative predictive value*). In sum, the overall predicting capability of the full model is fairly good. Figure 1. below displays a graphical depiction of these results, related to Twitter followers and organizational characteristics.

Binomial regression coefficients are exponential and multiplicative: if the coefficient for an antecedent is β, then the percentage change in the expected number of counts for unit a

[4] Akaike Information Criterion - AIC (Akaike, 1998) of the null model is 2898.6, social media model AIC 2822.1 vs. organizational characteristics model AIC 2871.3, where lower values indicate a better fit.

[5] Test for multicollinearity, VIF variance inflation factor, all variables well below the threshold of 10, the highest value observed for coreness at 2.62.

[6] Pearson correlation between predicted and actual values is 0.826.

change in the antecedent is e^{β}. For instance, if the university "A" have 8,462 students more than university "B" (one standard deviation), it is predicted that A will have 1.16 times the number of followers of "B" (+16%).[7] The observed coefficients confirm that both organizational characteristics and the specific use of social media have an important impact on the number of followers (Table 5).

Outliers

As a final test, we explore the capability of the full model to predict the four outlier cases that were excluded from the sample in a first stance. Whereas the number of followers of the Open University is reasonably well predicted (129,825 vs. 100,000 followers), the University of Oxford (60,180 vs. 175,000), the University of Cambridge (85,692 vs. 151,000), and the London Business School (12,624 vs. 69,800), attract a much larger number of followers than predicted by the model.

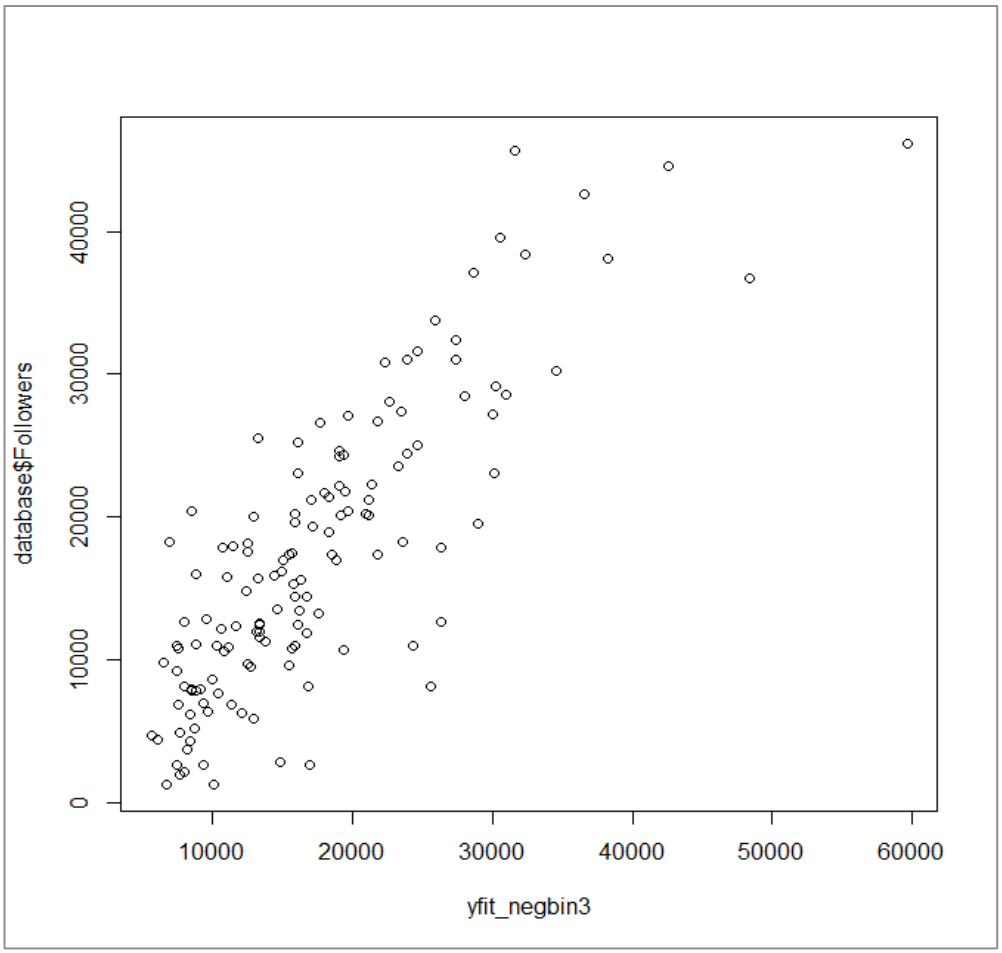

Figure 1. Results from full model.

Discussion and conclusions

Findings indicate that both social media use and organizational characteristics explain the social media visibility of HEIs. Thus, organizations may be successful in garnering followers through their Twitter activity, but these high number of followers is also attributed to the organizational characteristics of size, status, and reputation. Notable is that these characteristics were better predictors of followers than the use of Twitter, suggesting that visibility is highly influenced by offline activities and traditional WOM, compared to eWOM. Although in regards to altmetrics – these online metrics do provide valid proxies for understanding dynamics, the addition of organization characteristics allows us to question how they serve as proxies, as the correlations suggest followers and following seem to be related to organizations size, and reputation, although the organizations own activities of tweeting and experience on Twitter are not related. That does not discard the power of social

media platforms as a tool for garnering visibility, although emphasizes that it is not a replacement for building reputation external to online domains.

Findings show that the social media are significant predictive of the number of followers, with the exception of the *number of following* (Hypothesis 1). In particular the *number of tweets* and *days on twitter* have a positive effect. Findings also show that the combined organizational characteristics are predictive of the number of followers (Hypothesis 2). The *size in terms of undergraduate students* and the *research intensity* have a positive and strongly significant effect. Despite the lower correlation with the number of followers, these two measures are better predictors, respectively than the *size as number of staff units* and the *scientific reputation*. The variable on *status – coreness* is also strongly significant and positive. The *teaching burden,* the *discipline profile* as well as the *urban centrality* of the university's location are not significant predictors.

In addition to the specific a number of notable findings emerged with regards to the specific variables. First, the importance of length of time on Twitter suggests a "first mover advantage", where first adopters have yielded higher numbers of followers. HEIs Twitter accounts that had an orientation towards news and events play a more significant role in garnering online visibility through followers. Secondly, in regards to the organizational characteristics *size in terms of undergraduate students* and *research intensity* played the most significant role in explaining online followers. These two measures reflect the two core tasks of HEIs – research and education. That is HEIs that are able to attract a high number of students as well as sustain a higher number of PhD candidate to conduct research, which again garners increased social media visibility.

This study provides clear support for a causal mechanism that stipulates that both organizational characteristics and social media use explain social media visibility as measure by followers. This provides additional evidence to scientometricians of the importance of considering a combination of metrics in explaining impact and scholar impact in particular. Although, in this research we have analyzed basic descriptors. There is margin for improving explanation of social media use. Future research should investigate, for instance, the content of tweets, as well as the strategies for managing eWOM (Bao & Chang 2014). In addition, the existence of a few outliers suggests that few actors attract a disproportionally high attention from the public. Future research may investigate why this occurs. Given the state of literature we did not have evidence at the onset of our model to suggest an interaction effect, although given that the explanatory power of an organizations social media visibility is explained by both organizational characteristics and social media use, an interaction effect is a natural next step. For example, to investigate the effect of social media use by HEI on (social media) visibility is enhanced in HEIs with a large size, high status and high reputation.

Abstract

A principal tenet of the scientific method is that experiments must be repeatable. This tenet relies on *ceteris paribus* (i.e., all other things being equal). As a scientific community, involved in data sciences, we must investigate ways to establish an environment where experiments can be repeated. We can no longer allude to where the data comes from, we must add rigor to the data collection and management process from which our analysis is conducted. This paper describes a computing environment to support repeatable scientific big data experimentation of world-wide scientific literature, and recommends a system that is housed at the Oak Ridge National Laboratory in order to provide value to investigators from government agencies, academic institutions, and industry entities. The described computing environment also adheres to the recently instituted digital data management plan, which involves all stages of the digital data life cycle including capture, analysis, sharing, and preservation, as mandated by multiple United States government agencies. It particularly focuses on the sharing and preservation of digital research data. The details of this computing environment are explained within the context of cloud services by the three layer classification of "Software as a Service", "Platform as a Service", and "Infrastructure as a Service".

Conference Topic

Science policy and research assessment, Methods and techniques

Introduction[1]

The scientific policy and research assessment community is investigating methods and techniques to establish an environment where experiments can be repeated through the use of data management. This approach attempts to ensure the integrity of scientific findings and the processes from which scientific literature analysis is conducted.

Data Science is the study of the generalizable extraction of knowledge from data (Dhar, 2013). From this definition, scientific development thus becomes the piecemeal process by which these items have been added, singly and in combination, to the ever growing stockpile that constitutes scientific technique and knowledge (Kuhn, 1970). Scientific literature analysis, or Scientometrics, is the study of measuring and analysing science, technology and innovation. Organizations, such as Thomson Reuters, have long used these analyses to identify the most influential papers or researchers in a field. Recently, Foresight and Understanding from Scientific Exposition (Murdick, 2011) takes this further by mining millions of papers and patents in both English and Chinese, two of the most commonly used languages in scientific literature (Readron, 2014).

[1] This manuscript has been authored by UT-Battelle, LLC under Contract No. DE-AC05-00OR22725 with the United States Department of Energy. The United States Government retains and the publisher, by accepting the article for publication, acknowledges that the United States Government retains a non-exclusive, paid-up, irrevocable, world-wide license to publish or reproduce the published form of this manuscript, or allow others to do so, for United States Government purposes. The Department of Energy will provide public access to these results of federally sponsored research in accordance with the DOE Public Access Plan (http://energy.gov/downloads/doe-public-access-plan).

Scientometrics and its related research activities in today's world make extensive use of digital research data. The data management of this digital research data is, in essence, the quintessential requirement for repeatable scientific experimentation. This term, digital research data, encompasses a wide variety of information stored in digital form including: experimental, observational, and simulation data, codes, software and algorithms, text, numeric information, images, video, audio, and associated metadata. It also encompasses information in a variety of different forms including raw, processed, and analysed data, and published and archived data ("Statement on Digital Data Management," 2014). More specifically, research data are defined in regulation ("Intangible property - Code of Federal Regulations 2 CFR 200.315," 2014), continuing the definition in further statues and United States Government Directives ("2 CFR 215 - Uniform Administration Requirements for Grants and Agreements With Institutions of Higher Education, Hospitals, and Other Non-Profit Organizations (OMB Circular A-110) ", 2012) as follows:

- "Research data is defined as the recorded factual material commonly accepted in the scientific community as necessary to validate research findings, but not any of the following: preliminary analyses, drafts of scientific papers, plans for future research, peer reviews, or communications with colleagues. This 'recorded' material excludes physical objects (e.g., laboratory samples). Research data also do not include:
    - Trade secrets, commercial information, materials necessary to be held confidential by a researcher until they are published, or similar information which is protected under law; and
    - Personnel and medical information and similar information, which the disclosure would constitute a clearly unwarranted invasion of personal privacy, such as information that could be used to identify a particular person in a research study."

Purpose of the Study

When addressing the reality of allocating the scarce resources of the current research budget constraints, the current institutions of science today operate, essentially the same, as from the time period just after the Second World War (Azoulay, 2012). Azoulay further argues it would be a fortuitous coincidence if the systems that served us so well in the twentieth century were equally adapted to twenty-first-century needs. Such is not the case. To leverage these finite resources and to adhere to the principle of the scientific method that all experiments must be repeatable, we, as a scientific community must investigate ways to establish environments where experiments can be repeated. We can no longer allude to from where the data come, we must add rigor to the data collection and data management process from which our analysis is conducted.

Data management involves all stages of the digital data life cycle including capture, analysis, sharing, and preservation. The focus of this statement is the sharing and preservation of digital research data. The following principles apply to the effective management of digital research data ("Statement on Digital Data Management," 2014):

- Effective data management has the potential to increase the pace of scientific discovery and promote more efficient and effective use of government funding and resources. Data management planning should be an integral part of research planning.
- Sharing and preserving data are central to protecting the integrity of science by facilitating validation of results and to advancing science by broadening the value of research data to disciplines other than the originating one and to society at large. To the greatest extent and with the fewest constraints possible, and consistent with the requirements and other principles of this statement, data sharing should make digital

research data available to and useful for the scientific community, industry, and the public.

- Not all data need to be shared or preserved. The costs and benefits of doing so should be considered in data management planning.

Procedure for a Computing Environment to Support Repeatable Scientific Big Data Experimentation

A data management plan is a formal document that outlines how a research institution and program will handle data both during research and after the project is completed ("Data management plan," 2014). The goal of a data management plan is to consider the many aspects of data management, metadata generation, data preservation, and analysis before the project begins. This ensures that data are well-managed in the present and prepared for preservation in the future. Multiple United States government agencies now require proposals submitted to include a supplementary document labelled “Data Management Plan” (Collins, 2014; "Dissemination and Sharing of Research Results," 2010). These supplementary documents describe how the proposal will conform to scientific policy on the dissemination and sharing of research results.

FUSEnet is a data analytics cloud specializing in managing both data and computational processes for assessing technical knowledge for identifying emergent technologies and capabilities. Under a multi-year United States Government research effort sponsored by Intelligence Advanced Research Projects Activity (IARPA), the overall goal of the FUSE program is to produce a new capability to accelerate the process of identifying and prioritizing emerging technologies across the globe (Murdick, 2011). The FUSE Program was established to develop automated methods that aid in the systematic, continuous, and comprehensive assessment of technical emergence using information found in published scientific, technical, and patent literature. A concise description is as follows (Murdick, 2011):

> A fundamental hypothesis of the FUSE Program is that real-world processes of technical emergence leave discernible traces in the public scientific, technical, and patent literature. FUSE envisions a system that can (1) process the massive, multi-discipline, growing, noisy, and multilingual body of full-text scientific, technical, and patent literature from around the world; (2) automatically generate and prioritize technical terms within emerging technical areas, nominate those that exhibit technical emergence, and provide compelling evidence for the emergence; and (3) provide this capability for literature in English and at least two non-English languages. Technology developed from the FUSE Program would automatically nominate both known and novel technical areas based on quantified indicators of technical emergence with sufficient supporting evidence and arguments for that nomination. The FUSE Program also addresses the vital challenge of validating such a system, using real world data.

FUSEnet is currently a government system hosted by ORNL that stores unclassified, copyright-protected scientific information and provides remote access for approved users to analyse the stored data within a cloud computing environment to satisfy the research objectives of the IARPA FUSE Program. A key tenet within FUSEnet is that data integrity and availability is maintained. An ORNL developed “data diode” embedded within FUSEnet gateways allows access to protected data, but prevents data removal by users. As necessary, a mechanism for approved data export is built into the system architecture. Also by design, the activities and work products of individual user teams are segregated from each other in the cloud computing virtual environment.

FUSEnet Capabilities

The FUSEnet computing environment is based on the Cloud service model. These models are usually described by a three layer classification called SPI for **S**aaS, **P**aaS, and **I**aaS (Tian & Zhao, 2015) and adapted as follows:

- SaaS – Software as a Service: applications that are available on-demand.
- PaaS – Platform as a Service: refers to a computing platform of software components and middleware that are used by end-users to develop and manage their cloud applications. Typically, cloud providers at this layer offer databases, web servers, development environments, and application monitoring tools.
- IaaS – Infrastructure as a Service: physical or virtual machines with access to data storage and other operating system services. The cloud user is typically expected to install and maintain operating-system images.

The unique processing capabilities of FUSEnet are in the SaaS and PaaS levels. The IaaS capabilities were established with off-the-shelf software and hardware solutions as a result of understanding the operational needs of FUSEnet users, big data analytics, and optimizing central processing unit (CPU) and input/output (I/O) performance. One of the major challenges with the computing environment is with moving large volumes of data (terabytes) to and from the disk storage to the CPUs for processing. This challenge is met with ever increasing improvements and replacements for the IaaS without having any operating impact on the SaaS or PaaS layers. FUSEnet demonstrated this with an improvement in the data I/O transfer by replacing the disk storage system over its earlier version. Further, FUSEnet SaaS and PaaS software can be hosted on commercial IaaS platforms that meet the requirements for its intended usage.

A summary of the FUSEnet benefits and capabilities that support repeatability of big data experiments includes:

- An organized repository of 100 million published scientific and patent documents,
- Technical in-house expertise for maintenance of data pertaining to integrity and availability, pedigree, and version control,
- Reliable data sources including data provided by, Thomson Reuters, Lexis-Nexis, Elsevier, Institute of Electrical and Electronics Engineers (IEEE), Nature Publishing Group, PubMed Central, and others,
- Technical expertise with the format and details of the data, and
- Four analytical software applications with evidentiary traceability and indicators for assessing repeatability:
    - Assess and forecast technical research and technology developments,
    - Reverse-search the events contributing to a technology or development,
    - Drill down the evidence supporting the assessment and forecast,
    - Remote end-user workspaces ready-to-run the applications and the analytics platform,
    - Multiple analytics capabilities including Natural Language Processing (NLP), Parts-of-Speech (PoS) detectors, deduplication, belief network modelling, and machine learning,
    - Operation of the system with 24/7 and 99.8% availability within domain-specific expertise with the current ORNL technical staff,
    - Rapid custom development to meet unique end-user analytics requirements, and
    - Immediate data protection for the repository and custom end-user data.

The FUSEnet SaaS Level

At the SaaS level, four unique software applications perform automated technical assessments for supporting the detection and forecasting. Each of these applications process and analyse published scientific and engineering papers that are made available in the FUSEnet data repository. Unlike previous approaches to detecting emergence, which are based on the citation analysis of papers and patents (Bettencourt et al., 2008; Huang et al., 2014), the following application systems extract information from the text of publications and patents, identifying authors, their affiliations, addresses, as well as classifying types of organizations and publications. Although these applications have the same objectives, their analytical techniques are uniquely different and hence provide different insights into the organization and search of the data (Babko-Malaya et al., 2013). These analysis techniques include: feature extraction (Michaelis et al., 2012), time series analysis, sentiment and network analysis (Fürstenau & Rambow, 2012), and emergent detection and prediction (Brock et al., 2012), among others. The four main applications developed within the FUSEnet system are ARBITER from BAE Systems, Copernicus from SRI International, Emerge from BBN, and DETAiLS from Columbia University.

The FUSEnet PaaS Level

The aforementioned SaaS applications use a variety of tools and libraries at the PaaS level. While the SaaS level in FUSEnet is the automated assessment, the FUSEnet PaaS computing platform can best be described as a "Network Analysis" (Otto & Rousseau, 2002) and text analytics platform. Text analysis uses statistical pattern learning to find patterns and trends from text data (in our case, scientific literature and patents). A summary of several key tools that FUSEnet provides are in Table 1. A selection of software libraries for network analysis and text analysis in FUSEnet, available for ensuing that experiments can be repeated, is shown in Table 2.

The FUSE Program licensed and installed a large number of scientific papers and patents from several suppliers in multiple languages including English and Chinese. The data sets include bibliographic citations of journal articles (108+ million), full text journal articles (5+ million), patent backfile records (14+ million at beginning of 2013 for the US and China), and updates to the patent backfile records, (51+ million for the US and China). A backfile is a single file containing the original patent application data plus all updates to the patent (both by the originator and by the patent office) up to the time the backfile was created.

Fig. 1 illustrates the large increase in scientific journal articles and patent applications as included in the FUSE research system during the past two decades. The number of Chinese patent applications is increasing dramatically and has now surpassed the number of US patent applications. Also, the number of Chinese journal articles is increasing at a rate faster than the rest of the world.

Table 1. FUSEnet PaaS support software packages.

	FUSEnet PaaS Analytics Tool	*Technical Usage*	*SaaS application that uses it*
1	MySQL[2]	SQL[3] database typically used to store document, term, and author data.	Emerge, ARBITER
2	MongoDB[4]	Document-oriented, NoSQL database used to store extracted entities and indicator-specific data.	Emerge, Copernicus
3	MALLET	Machine Learning and NLP[5] Toolkit for Java. Provides topic modelling for document clustering.	Emerge
4	Sofia-ml	Fast incremental machine learning algorithm. Provides clustering of documents from topic models generated by MALLET.	Emerge
5	Lucene IR system	Used for its indexing engine.	Emerge
6	Scikit-learn	Machine learning models.	Emerge
7	Tomcat/Solr Web Server	Used for Term indexing.	ARBITER
8	Apache ActiveMQ[6]	Messaging and integration patterns.	ARBITER
9	Cassandra	NoSQL database.	ARBITER
10	Virtuoso	RDF[7] triple storage.	ARBITER
11	OpenRDF/Sesame	RDF processing including parsing, storing, reasoning and querying.	ARBITER
12	Spring Framework	Used for Integration using JMS.	ARBITER
13	Lucene/Solr	Document level information search, retrieval and storage engine.	ARBITER, DETAiLS
14	Open NLP	Machine learning based toolkit for processing natural language text.	ARBITER
15	Netica	Used for working with belief networks and influence diagrams.	ARBITER
16	Elasticsearch	Extension on Lucene that provides search and analytics.	Copernicus
17	Hadoop 2+	Used for extract, transform, and load (ETL) and de-duplication processing.	Copernicus
18	Berkeley Parser	Sorts and assigns words in sentences into subjects, verbs, and objects.	DETAiLS
19	Duke	Deduplication engine written in Java operating with Lucene.	DETAiLS
20	Stanford Chinese Word Segmenter	Split Chinese text into a sequence of words.	DETAiLS
21	Stanford Part-of-Speech (POS) Tagger	Reads text and assigns parts of speech to each word (noun, verb, adjective, etc.).	DETAiLS
22	UIMA	Unstructured Information Management Architecture (UIMA) is a general framework for analysis of unstructured information and its integration with search technologies.	DETAiLS
23	Weka	Machine learning software written in Java for data analysis and predictive modelling.	DETAiLS

[2] MySQL is a well-known relational database manager used in a wide variety of systems, including Twitter, Wikipedia, Facebook, Google, Wordpress, and countless more websites and other applications.
[3] SQL (Structured Query Language) is a special-purpose programming language designed for managing data held in a relational database management system (RDBMS),
[4] MongoDB is a document-oriented, NoSQL database.
[5] NLP is Natural Language Processing where algorithms are used to derive meaning from human language.
[6] Apache ActiveMQ is an open source message broker written in Java together with a full Java Message Service (JMS) client.
[7] RDF is Resource Description Framework and is used to express data in subject-predicate-object expressions.

Table 2. Subset of FUSEnet software libraries for social network and text analysis.

	Library/Package	*Description*	*SaaS application that uses it*
1	Arpack	Linear algebra routines for Java	Emerge
2	JDOM	XML processing library for Java	Emerge
3	Jwnl	Java WordNet library	Emerge, ARBITER
4	Matrix-toolkits-java	Linear algebra data structures for Java	Emerge
5	BLAS	Linear algebra subroutines	Emerge
6	LAPACK	Linear algebra data structures and subroutines	Emerge
7	Libquadmath	High-precision math libraries	Emerge
8	Beanshell	Scripting for Java	Emerge
9	Trove4j	High-performance data structures for Java	Emerge
10	JGrapht	Graphical data structures and algorithms for Java	Emerge
11	JUNG	Java Universal Network/Graph Framework	ARBITER
12	R	Development environment for statistical computing and graphics	ARBITER

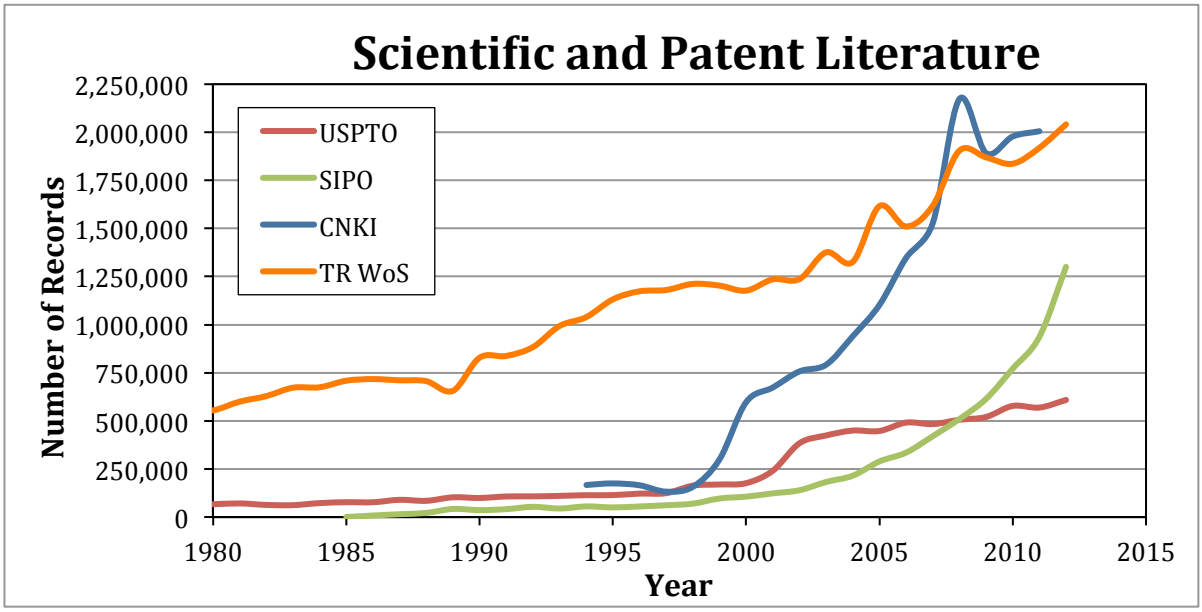

Figure 1. Number of records per year for the four largest datasets in the FUSEnet collection including patent records from the US (USPTO) and Chinese (SIPO) patent offices (i.e. number of backfile records at the beginning of 2013) and journal article citations from China (CNKI) and Thomson Reuters' Web of Science (TR WoS).

The FUSEnet IaaS Level

The deployed second generation FUSEnet at ORNL has the following summary specifications:

- 770 gigaFLOPS[8] of maximum performance,
- 16 blade servers (plus 2 support blades), each with 2 CPUs, each with 6 cores, totalling 192 cores, or processors; additional blade with USB 3.0 for dedicated data transfer/export,
- 3.07 TB of RAM w/ 192 GB per node,
- Disks:
    - EMC Isilon: 340 TB (useable; includes 6.4 TB SSD) running NFS over 10 Gb/s Ethernet,
    - HP LeftHand: 260 TB of effective disk storage; will be reconfigured for backup and
    - Isilon disk I/O up to 1 gigabyte/sec per blade,
- Networking: Flex-10 modules totalling 160 Gbits/sec bandwidth per enclosure x 2 enclosures (theoretical maximum),
- Virtualized computing space through VMware[9],
- Access and control policies enforced by ORNL Computing Data Center, and
- Call Center and metrics for service quality.

Table 3. Characteristics of cloud providers and applicability to FUSEnet requirements.

	Vendors	*Cloud Offering Overview*	*Applicability to FUSEnet*
1	Amazon Web Services	Overall market leader offering virtual servers, MapReduce (Hadoop) for search engine, large data storage, SQL databases, NoSQL databases, mobile integration, business applications including email, payment systems, and workflow.	PaaS (databases), IaaS
2	Google Cloud Platform	App Engine web application platform (PaaS), virtual machines, file storage, SQL databases, NoSQL, big dataset support, mobile integration.	PaaS (databases, web apps), IaaS
3	IBM SmartCloud	SaaS including data warehousing and analytics, business analytics engine, business process management, financial modelling, payment systems, medical analysis, social media analysis, transportation management, medical analytics, SQL databases, NoSQL databases, mobile integration.	SaaS (social media analysis), PaaS (databases, web apps), IaaS
4	Microsoft Azure	Windows or Linux virtual machines, messaging, scheduling, SQL databases, NoSQL databases, mobile integration.	PaaS (databases), IaaS
5	Rackspace Cloud	High bandwidth networking, virtual machines, data storage, process load balancing.	IaaS

Analysis of Technical Requirements and Alternatives versus Commercial Cloud Providers

Representative current cloud solution offerings from commercial vendors include but are not limited to the following: Amazon Web Services (AWS), IBM SmartCloud, Microsoft Azure, Google Cloud Platform, and Rackspace Cloud Servers. Considering the data management, experimentation requirements and the strategic issues, the question arises, "Are the IaaS and

[8] In computing, FLOPS (for FLoating-point Operations per Second) is a measure of computer performance, useful in fields of scientific calculations that make heavy use of floating-point calculations. For such cases, it is a more accurate measure than the generic instructions per second. Computers capable of performing greater than 1 Giga FLOPS are termed as supercomputers.

[9] VMware, Inc. is a software company that provides cloud and virtualization software and service.

PaaS from these selected vendors sufficient for hosting and maintaining the FUSEnet SaaS and PaaS?" A summary of the cloud providers and the offering are described in Table 3.

Analysis of SaaS Technical Alternatives

FUSEnet consists of four unique technical emergence software applications. Current cloud providers are not in the business of providing this niche capability. Cloud providers offer more general SaaS services such as Enterprise Resource Planning (ERP), general accounting, medical, and financial applications for managing business administration operations. If FUSEnet were to be employed on a 3rd party cloud, unique, domain-specific expertise would be required to operate and manage the FUSEnet software applications.

Analysis of PaaS Technical Alternatives

FUSEnet consists of several framework and middleware solutions combined with math-based libraries that are unique to network and text analysis. With the exception of IBM SmartCloud, current cloud providers are not in the business of exclusively providing this niche capability. Cloud providers offer more general PaaS software such as databases, email, and web servers. The features of the network and social analytics tools in SmartCloud should be further evaluated.

Analysis of IaaS Technical Alternatives

FUSEnet is operated in a secured, cloud environment at the Data Computing Center at ORNL. It currently operates on the hardware infrastructure described above. This FUSEnet hardware was performance tested to determine its disk I/O (input/output) throughput under various load conditions. Software programs were used to perform these tests at a low level or 'raw' I/O set of read and write tests and at the application layer with tests that simulated application disk usage. From these initial test results and further repeated testing, the FUSEnet disk I/O was optimized for handling the volume and type of data used in the system. Further tests were performed to compare FUSEnet with another commercial cloud offering, which demonstrated similar or better performance for FUSEnet depending on the operating conditions selected. Currently, the FUSEnet storage system is in its second generation as a result of these performance tests and evaluations. The FUSEnet software and data can be operated on 3rd party (IaaS) environments that can meet the overall system requirements as follows:

- Handle big data that is mixed structured and unstructured and continuously growing.
- Protect selected data and apps (commercial, proprietary) that remain in the cloud.
- Rapidly deploy software solutions to the data.
- Provide virtualization for operating systems including common Linux distributions, Windows and Mac OS.
- Rapidly ingest data into the system.
- Provide the computing performance involving big data analytics software services.
- Provide an easy-to-use big data analytics platform.
- Provide high-performance big data storage and retrieval up to 500 TBs and continue to scale.
- Provide robust, state-of-the-practice cyber security.

In general, commercial firms are advised to consider strategic issues with regards to cloud scope, service levels, and deployment needs. For the FUSEnet environment, Table 4 summarizes these strategic concerns.

The overall need for a secured FUSEnet environment involves the capability to employ software services, such as the analytics described earlier, that uses the data within the FUSEnet cloud, but cannot copy the data out of the cloud. FUSEnet is equipped with custom

middleware software within the PaaS called a Data Diode that monitors activities and prevents the exfiltration of data. Thus, the commercial and proprietary data is protected from being taken outside the FUSEnet enclave (Abercrombie, MacIntyre, & Schlicher, 2011). The Data Diode involves a change to the Linux distro (distribution)[10] so that an IaaS provider must approve the customer to host their own virtualized and configurable operating system (MacIntyre, Paul, & Schlicher, 2011).

Table 4. Strategic issues for the FUSEnet environment.

	Strategic Issue	*Description*	*Assessment for FUSEnet*
1	Cloud Scope – what is the design to meet the need?	Identifies the availability, performance, and security needs; sufficient and planned computing power, storage, and bandwidth.	FUSEnet is monitored daily and reported monthly with the current operational stats: Availability: 99.8%; CPU usage: 12-18%; Memory usage: 56-65%; Storage usage: 69%. FUSEnet is installed with a Data Diode that protects against data exfiltration of its repository. FUSEnet is a virtual environment with separated computing enclaves. Each user or user group within an enclave has the freedom to compose and perform their needed computational research without directly impacting other users.
2	Service Levels	Identifies the expected workload, admin support, service delivery needs, timing and I/O response.	FUSEnet Test and Evaluation (T&E) simulates heavy end-user loading. This is measured to be an increase of 5-10% of the daily load. For its initial usage, FUSEnet could simultaneously host 3-4 heavy end-users loading. The Admin support is at two levels: operating system and the virtual layer through VMware.
3	Deployment Needs	Identifies the integration needs with infrastructure services.	FUSEnet operates on VMware that isolates the PaaS from dependencies on the hardware and the Operating System. The current FUSEnet system, including the number of cores, performance of the cores, memory, and the Isilon storage, is a proven baseline for simultaneously hosting 3-4 heavy end-user loading.

Discussion and Conclusions

This paper addresses science policy with a method and a technique to assess research, increasing its value to the US national scientific community by making available a computing environment to support repeatable scientific big data experimentation of world-wide scientific literature. The computational capability ensures the integrity, availability and confidentiality of new technologies and new technical knowledge. This will position scientific investigators (academic, commercial, and government) with an advantage to address the technical and political challenges all three entities face. FUSEnet offers this unique capability and this paper describes a computing environment necessary to support repeatable experimentation, and recommends a system that is housed at the ORNL Data Center in order to provide value to investigators from a variety of sources while adhering to recently mandated Data Management Planning.

[10] A Linux distribution (often called a distro for short) is an operating system made as a collection of software based around the Linux kernel and often around a package management system

Is Italy a Highly Efficient Country in Science?

Aparna Basu[1]

Abstract
In an earlier study on measuring national efficiencies in the production of scientific papers and patents of several developed and developing countries (Basu, 2013; 2014a), we found that Italy has the highest efficiency in the production of papers. While this has not gone unnoticed in the literature (Daraio and Moed, 2011) they have taken it as an 'overcompensation effect' and an indication of decline. By examining the work of several authors, we find instances where the information put forward, when taken together, support our findings – that Italy has a high efficiency in scientific publication but only an average efficiency in patenting. We note that Italy's profile along a host of parameters is quite distinct with respect to the OECD average (DeJaeger, 2012). Using a typology of countries based on their publication and patenting efficiencies (Basu, 2014b) we infer that Italy is not one of the countries that have shifted national priorities from publications to patents, like USA, Japan, Germany, or Korea.

Conference Topic
Science policy and research assessment

Introduction
According to Hollanders and Soete, investment on R&D (GERD) is a correlate of development (Hollanders and Soete, 2010). Developed countries have higher GERD shares as compared to GDP shares, the Gross Expenditure on R&D (GERD) being the expenditure on the creation of new knowledge. Countries that have increased R&D expenditures, such that GERD share/GDP share tends to or exceeds unity, are on the path of development. How do increased investments of resources translate into outputs? Do developed countries make more efficient use of their resources? Efficiency of scientific productivity at the national level has been considered earlier by several authors (May, 1997; Rousseau, 1998; King, 2004, Vinkler, 2005, 2008; Shelton, 2008; Leydesdorff & Wagner, 2009; Wendt et al., 2012), who also point out difficulties in making cross-national comparisons. Primarily, they have dealt with publications and citations as compared to research expenditure or GNP and have considered mostly European countries, the US, Japan and China. Rousseau has considered both publications and patents. More recently, Shelton and Leydesdorff have also considered outputs such as patents and number of graduates in addition to papers, using regression models to predict outputs for a given set of inputs (Shelton and Leydesdorff, 2011). Some papers that have used different techniques such as Data Envelopment Analysis (DEA) to study national research productivity and efficiency are Rousseau (1998), Sharma and Thomas (2008) and Lee (2005). According to Hu et al., who used the distance function approach, intellectual property rights protection, technological cooperation among business sectors, knowledge transfer between business sectors and higher education institutions, agglomeration of R&D facilities, and involvement of the government sector in R&D activities significantly improve national R&D efficiency (Hu, et al., 2014)
In our earlier study on the efficiencies of nations in the production of scientific outputs with respect to inputs such as manpower and expenditure in science, we found significant variation in their efficiencies (Basu, 2013, Basu, 2014a). In particular, we noted that the efficiency of production of papers with respect to both expenditure on R&D (GERD) and manpower were the highest for Italy. This fact has not gone unnoticed the literature on Italian science. Daraio

and Moed (2011) did an extensive study on manpower, research expenditure, publications and citations to compare Italy with other productive EU countries. They called Italy "a Cathedral in the desert", but at the same time chose to focus on other factors to argue that Italian science was in decline. Our attempt here is to see if there were other indications in the literature which could have pointed to the fact of Italy's high efficiency, but were missed at the time.

Data and Methodology

Data on scientific papers and patents is taken from the SCI-Expanded and USPTO for the years 2008 and 2007. (The data and analysis are from our earlier papers (Basu, 2013, 2014a) and reproduced here for convenience.) Restricting to the USPTO, the United States Patent Office, gives a bias in favour of the USA termed as the 'home advantage'. Ideally data from some of the other major patent databases such as the European Patent Office EPO should be included in the analysis. However for this preliminary study we have only considered the USPTO.

The Gross Domestic Product GDP and Gross Expenditure on Research and Development GERD for the years 2002 and 2007, are both adjusted to Purchasing Power Parity (PPP) in order to make local investments comparable across countries. Manpower is measured in terms of Full Time Equivalents (FTEs) engaged in R&D. Data is obtained from the UNESCO Science Report 2010 (UNESCO, 2010).

The share of GERD and the share of GDP are shown for a selected set of developing and developed countries Table 1. The GERD/GDP share is an indicator of development (Hollanders & Soete, 2010).

Table 1. GERD and GDP shares of selected countries (2002 and 2007).

Definitions

To define efficiency we have considered some inputs and outputs in the science system, and their ratio ouput/input. The inputs have been taken as the expenditure and manpower in research. The outputs are scientific patents and papers published by the nations. For two inputs and two outputs there are four possible components of efficiency (Basu, 2013).

The efficiency for paper production for each country has two values *EE(Pap)* and *ME(Pap),* defined for expenditure and manpower as,

$$\textit{Expenditure Efficiency EE(Pap)} = \textit{Papers/GERD} \quad (1)$$

$$\textit{Manpower Efficiency ME(Pap)} = \textit{Papers/Manpower} \quad (2)$$

where GERD is the national expenditure on R&D (in PPP), and the manpower is in terms of full time equivalents in R&D (FTE's).

The efficiency for patent production also has two values *EE(Pat)* and *ME(Pat),*

$$\textit{Patent Expenditure Efficiency EE(Pat)} = \textit{Patents/GERD} \quad (3)$$

$$\textit{Patent Manpower Efficiency ME(Pat)} = \textit{Patents/Manpower} \quad (4)$$

While papers and patents are homogeneous entities, GERD is made up of several components such as HERD, BERD, GOVERD, which are the expenditures on the Higher Education sector, the business sector and the government sector. Each of these components contributes in a different way to output of papers and patents. For example, expenditure in the business sector is expected to give rise to patents rather than papers, Higher education and government expenditures give rise to primarily papers, while defence expenditure, which is part of expenditure in the government sector does not produce many papers or patents. While this indicates that questions of efficiency are more complex than what has been considered here, in the present study we will use GERD as a single homogeneous entity.

Analysis

In Table 1 we see the inputs made by a set of selected countries in the years 2002 and 2007 to R&D (GERD), expressed as a share. A country is taken to be a developed country if its share of GERD is higher than its share of GDP (GERD share/GDP share >1; Hollanders & Soete, 2010). Using this criterion we see from Table 1 that in both 2002 and 2007 the EU as a whole, USA, Japan, Germany, France, UK, Australia and Korea had GERD share/GDP share >1, and would be termed developed countries. We note that Italy is missing from this list, although it is a part of the EU. It is listed along with China, India, Brazil, Mexico, Russia for which GERRD/GDP is less than 1. The data indicates that expenditure on R&D in Italy is lower than would be expected for a developed country.

A plot of Expenditure efficiency and Manpower efficiency in the production of scientific papers shows that Italy has the highest efficiency in both directions (Fig. 1). This implies for the amount of money invested and manpower deployed in the R&D system, Italy has the highest efficiency. This observation makes Italy and its science system an interesting object of study.

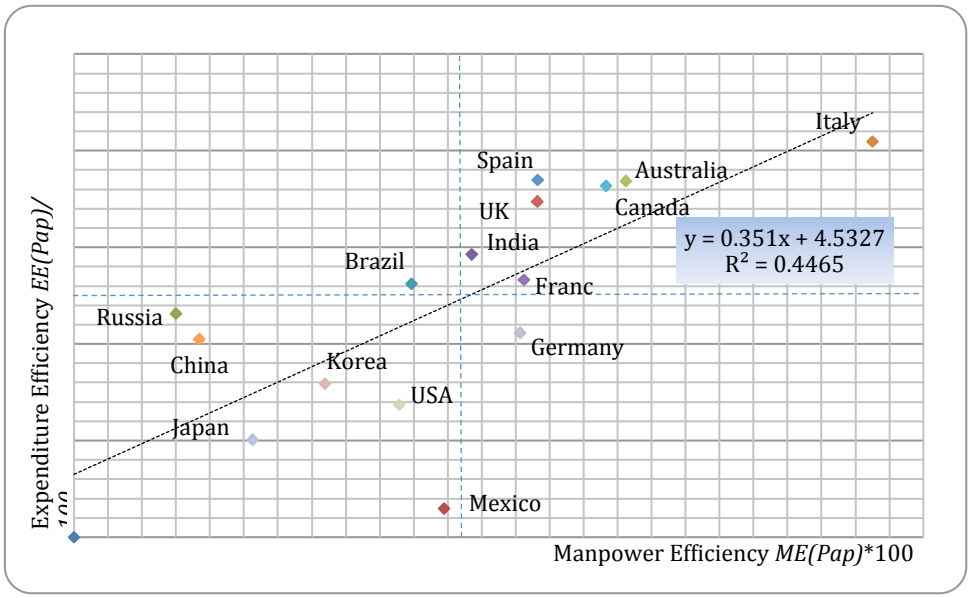

Figure 1. Efficiency of paper production with respect to expenditure EE(Pap) and manpower ME(Pap). Note that Italy scores very high on both dimensions.

For patent production we have the corresponding quantities EE(Pat) and ME(Pat) calculated using Eqns 3 and 4, and plotted in Figure 2. Here we note that USA, Japan are at the highest level in patenting efficiency, while Germany, Korea and Canada are at a medium level. UK and Australia are just above average and Italy and France are somewhat above the average (blue dotted lines) on manpower efficiency ME(Pat) but below average on expenditure efficiency EE(Pat). China, India, Spain, Mexico, Brazil and Russia are below average in patenting efficiency.

The high degree of collinearity (R^2=0.9) in the graph suggests that manpower and expenditure are correlated, which is not surprising since a large fraction of the expenditure usually goes toward salaries. This is also true to some extent of the efficiencies of paper production (Fig. 1).

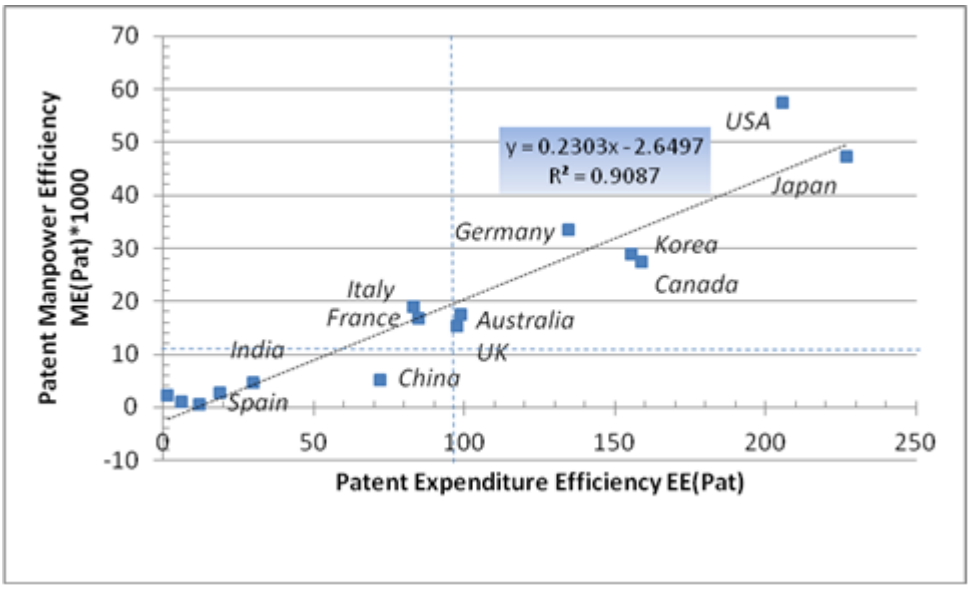

Figure 2. Efficiency of patent production with respect to expenditure EE(Pat) and manpower ME(Pat). Countries in left corner are Russia, Mexico and Brazil.

It should be emphasized that since there are 4 dimensions, two-dimensional graphs give only a partial picture of the similarity of profiles of the different countries.

The case of Italy

The case of Italy is somewhat unusual because of the very high values of efficiency of paper production with respect to both manpower and expenditure (Fig. 1). While this has not been explicitly stated in the literature, it is possible that there were indications of it in the work of others (Daraio & Moed, 2011; Foland & Shelton, 2010). Our attempt will be to trace such instances that support our finding. Firstly, we consider expenditure and recall that Italy had GERD share/GDP share less than unity, which categorises it with developing countries (Table 1). In Figure 3 we look at the GERD values of some countries (OECD data, 2012). Among a set of European countries together with US and Japan, Italy has the lowest value of the input GERD as a percentage of GDP. Since efficiency is the ratio of output to input, a low value of input raises efficiency. Spain also has a low value of expenditure, which makes its publication efficiency with respect to expenditure high. However its publication efficiency with respect to manpower is low (Fig. 1)

In terms of the business component of GERD (BERD) and the Government expenditure (GOVERD) the same trend prevails (Figs. 4 & 5) showing that Italy has almost the lowest values among these countries. This has also been noted in Daraio and Moed (2011).

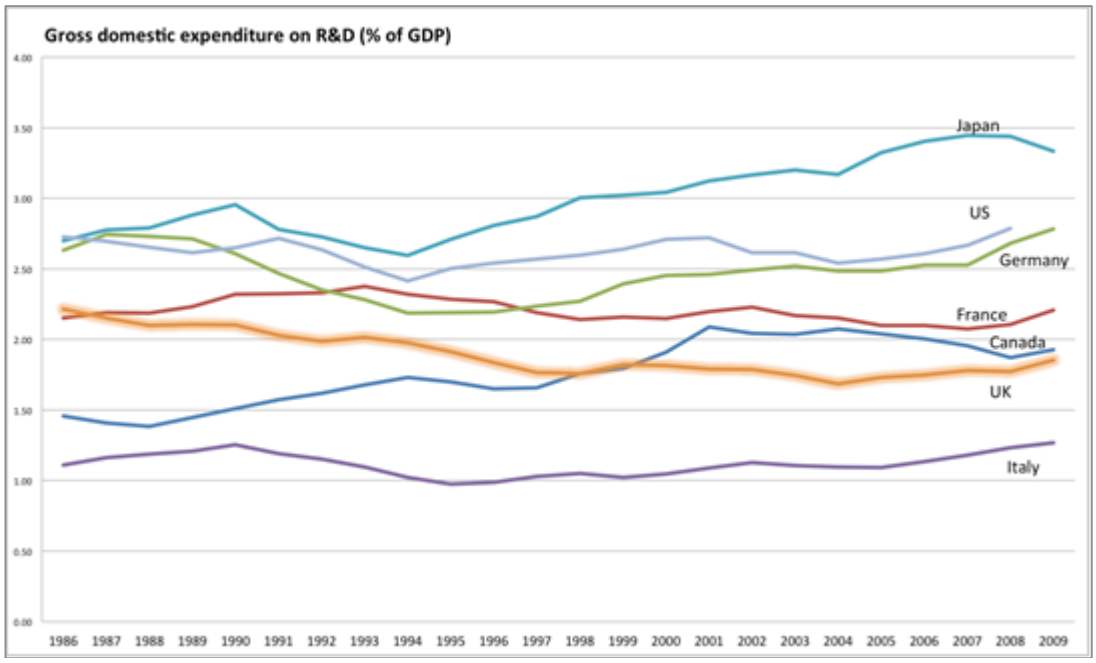

Figure 3. Gross domestic Expenditure on R&D (Source: OECD data, 2012).

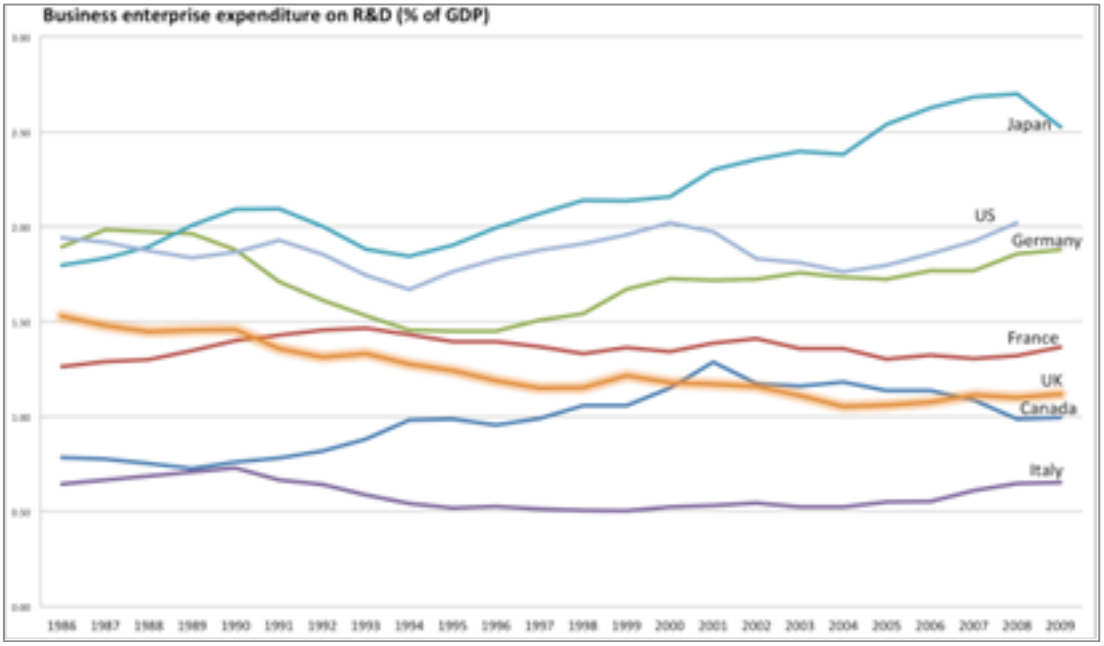

Figure 4. Business Enterprise data BERD (Source: OECD data, 2012).

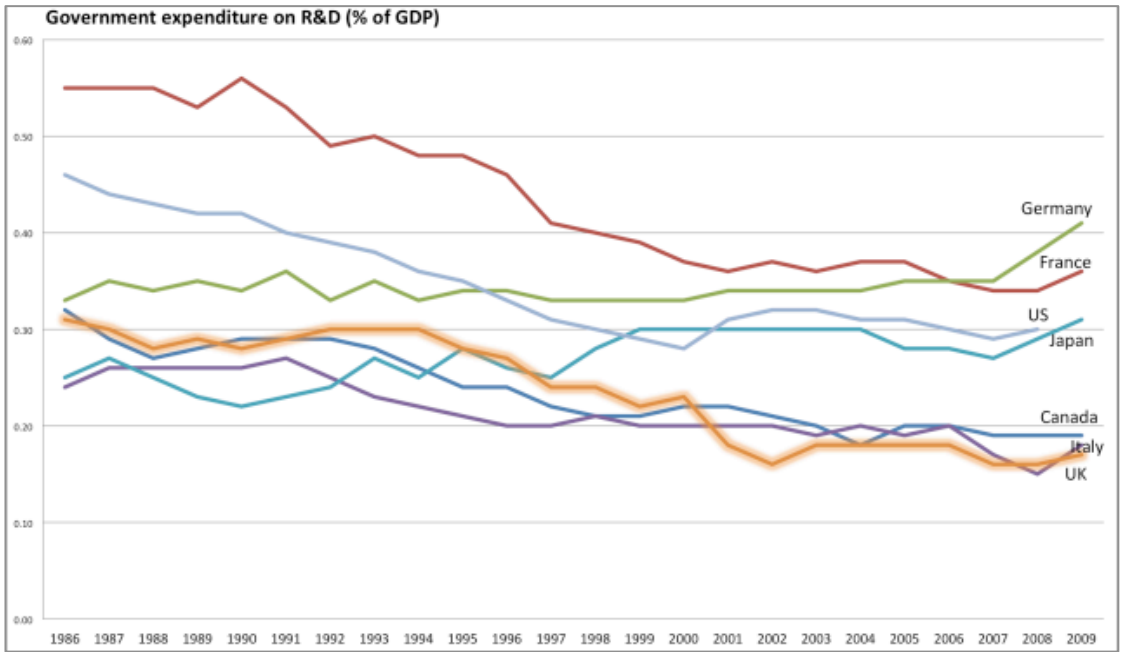

Figure 5. Government Expenditure on R&D, GOVERD (Source: OECD data, 2012).

Figures. 3-5 show that Italy has one of the lowest values of R&D expenditure as a share of GDP among all the countries shown. It also had the lowest expenditure on military R&D spending, a sector not expected to produce many papers or patents, as seen from Figure 6 reproduced from Foland and Shelton (2010).

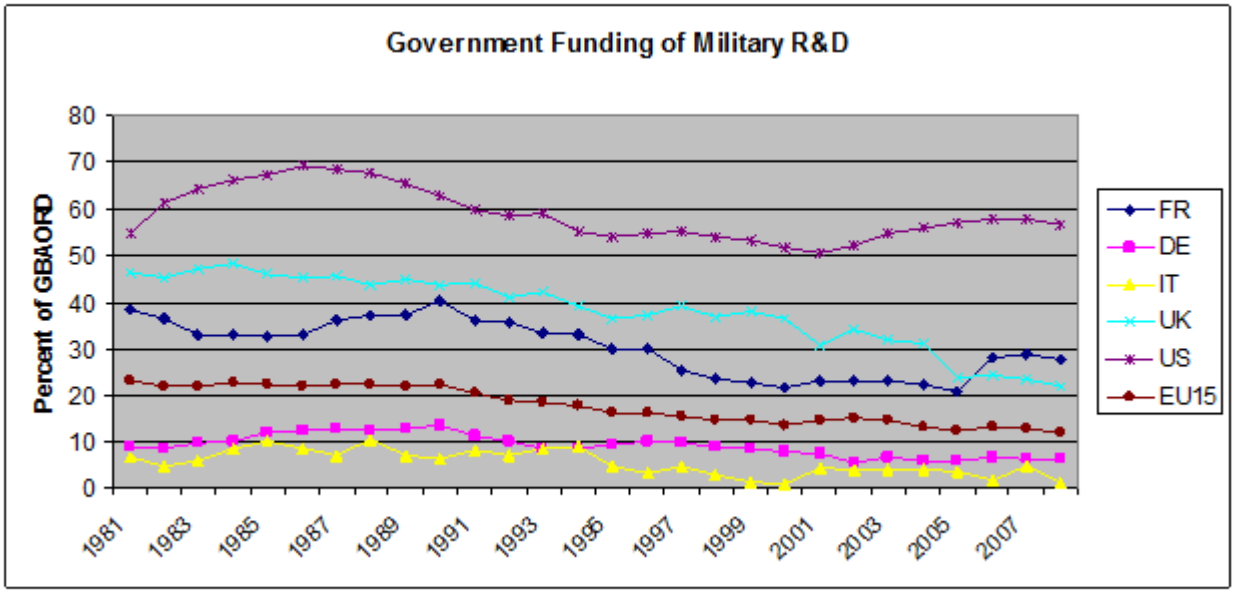

Figure 6. Government Funding of military R&D, showing that Italy has one of the lowest military spending (Source: Foland and Shelton, 2010).

At the same time, in a graph by the same authors showing growth rates of published papers for different countries, it is clearly seen that Italy had the highest growth rate over two successive decades (Fig. 7). Thus it would appear that there has been an efficiency increase with respect to expenditure for Italy, both due to lowered expenditure on R&D as well as increases in publication output.

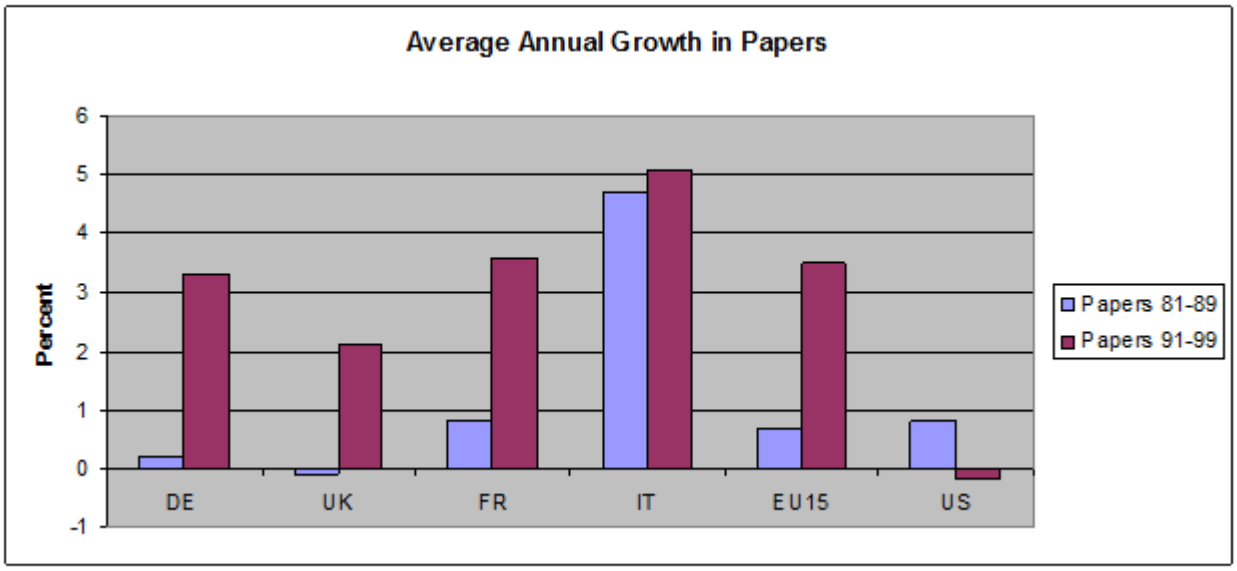

Figure 7. Average annual growth in papers, for a few selected countries (Source: Foland & Shelton, 2010).

Finally, we find more detailed information in a series of country profiles created by DeJaeger (2010) for 39 OECD countries and some developing countries. From Italy's profile a comparison of Italy's outputs with other countries shows some interesting points. DeJaeger's profile of Italy is reproduced below (Fig. 8).

The GERD is low, about 1.26% of GDP, about half the OECD average and more in line with the R&D intensity of emerging economies, as seen earlier.

The manpower values are also lower than OECD average. At the same time the output of papers is on par with the average output of the group of OECD countries. This would give Italy a higher efficiency of publication with respect to manpower as compared to the average. Daraio and Moed (2010) also note in their paper that Italy's publications grew in the period 1980-2009, till it had the highest publication output per researcher amongst other European countries (*see Figure 8 in Daraio and Moed; they however, they prefer to use papers per thousand population as an index instead, and predict a decline for Italy based on a lack of correlation between citation impact and manpower values.*)

In brief, while the number of researchers per thousand total employment is low compared to the average, Italy's output of papers per million population is on par with the average of the other countries, making its efficiency high for publications (Fig. 8). Triadic patents per million population is very low compared to other countries (Fig. 8), which coupled with low values of expenditure and research manpower lead to a medium value for patenting efficiency (Fig. 2).

Another point of interest is the high percentage of foreign funding in GERD as compared to other countries. DeJaeger (2012) notes that internationalization in Italy is high. About 41% of scientific articles and 13% of PCT patents were produced with international collaboration. In 2009, industry funded 44% of GERD, Government funding was 42% and 9% was funded from abroad. Regarding international collaboration Daraio and Moed find that Italy's share of internationally co-authored bilateral papers is lower than other OECD countries and their role (vis a vis first authorship) is like the developing countries (Fig. 4 in Daraio & Moed, 2011). From Figure 8 we also see that Italy has a higher number of foreign co-inventors as compared to other countries. It is possible that foreign funds apply to these sectors.

In summary Italy appears to be a country, which has achieved a high efficiency of publication of papers funded with low funds a substantial part of which is from foreign sources. Its

expenditure in the business sector is also low, but its patenting is close to average again indicating medium efficiency.

One limitation of our study is that citations have not been considered in the definition of efficiency. Even though Italy's citations appear to be favorable in some studies (Aspen Report, 2012, Dario & Moed, 2011), it is possible that considering citations would give a different picture. Other caveats common to most bibliometric studies refer to the use of publications as homogeneous units without reference to disciplinary biases in productivity and efficiency, difficulties in comparing expenditures (should one use Purchasing Power Parity, PPP $?), as well as manpower due to differing conventions in different countries (Wendt, et al, 2011).

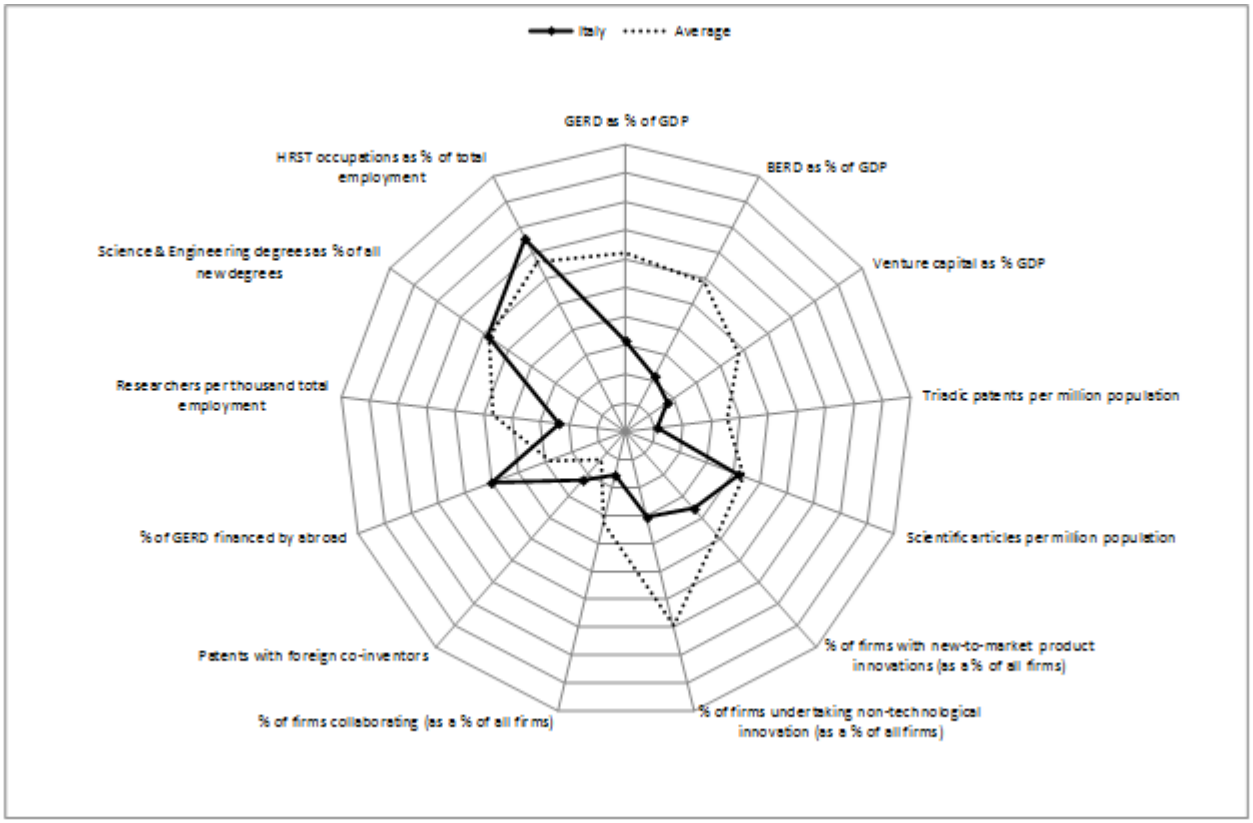

Figure 8. Italy's position vis-à-vis OECD countries on several parameters related to science (Source: De Jaeger, 2012).

Discussion

Efficiency of different countries in the production of papers and patents with respect to manpower and expenditure were calculated by us to obtain a national comparison of R&D efficiency. Unlike many earlier studies on efficiency that included only OECD and other developed countries and Japan and China, we have included several developed and developing countries (see also Basu, 2014, a, b). It was found that Italy had the highest efficiency in the production of papers as compared to the developed and developing countries (Fig. 1). We concluded that Italy has an unusual profile which though noticed in the literature, has not been further investigated (Aspen Report, 2012; Daraio & Moed, 2011). In Italy, research expenditure as a fraction of GDP was found to be low, not only in comparison with other OECD countries, but actually in line with developing countries as noted by us here. At the same time scientific articles per million population are on par with the average OECD value (Fig 8). Italy's expenditure on the military R&D sector is also low (Foland & Shelton; 2010). This may be contrasted with the US where 50% of the government expenditure goes to

the military. Since the defence sector is one that does not produce papers or patents, this gives an advantage to Italy in the computation of efficiency in terms of scientific publication output. In other words, Italy spends much less of its GDP on R&D as compared to other developed countries, at the same time achieving the same rate of publications per million population as other OECD countries (OECD figures; Figure 8). Dario and Moed (2011) refer to this as the 'Çathedral in the desert'.

Research manpower as a proportion of total employees is also much lower than the average OECD value, but science degrees are at the average OECD value (Fig. 8). We note here that the OECD makes a distinction between researchers and human resources in S&T (HRST) where the latter would include technical staff. HRST figures as a proportion of total employees in Italy are much higher than average OECD values (Fig. 8). The possible implication of this is that in Italy, the mix of research staff (academic, research, technical) may be different compared to other countries, with a higher component of technical staff. Since a large part of research expenditure goes towards salaries, and technical staff is likely to be less well paid, this may be a contributing factor toward economy in research expenditure. This conjecture needs to be validated by further research.

All of these features where output is average but inputs are low contribute to high efficiency, which is what we have observed in the case of Italy. In case it should appear that high efficiency in the case of Italy is only because of low inputs, it should be pointed out that growth in the output of papers was the highest for Italy over two successive decades (Foland & Shelton, 2010; Daraio & Moed, 2011). Another possible factor in achieving higher levels of publication than expected from low investments in R&D could be international funding and high collaboration. A substantial part of GERD in Italy comes from foreign sources (Fig. 6).

However, the number of patents are low, not only in the USTPO as seen in our study but also for Triadic patents as seen in the country profiles by De Jaeger. Since the expenditure outlay is also low in the business sector which contributes more to patents (BERD; Figure 4), the efficiency in patenting given by their ratio is close to average (Fig. 2). At the same time the number of foreign co-inventors is high, almost double the OECD value (Fig. 6).

In addition to the observations above regarding possible explanations for the high efficiency in science and relatively lower efficiency in patenting in Italy, we refer to our recent paper on a typology of countries based on research efficiency (Basu, 2014b). According to Basu, as national priorities shift from publications to patents as they appear to have done, fuelled by large increases in the business component of GERD, countries have witnessed a fall in publications (not only through the "displacement effect" due to the rise of China) coupled by a rise in patent efficiency. Countries that have moved in this direction are the USA, Japan, and Germany. Italy apparently has not made this transition, and is characterized by very low levels of investments by the business sector and low efficiency in patenting, but a high efficiency in publication. (Shelton and Leydesdorff have used expenditure in the government and business sectors and shown their relation to different outputs, Shelton & Leydesdorff 2011).

While Shelton and Ali (2011) have noted other countries like Turkey, Greece, Poland and Slovakia as being scientifically efficient, Italy appears to have been missed. Daraio and Moed (2011) in their detailed study 'Is Italian science declining?', observed that Italy had the highest productivity per researcher, and among the lowest levels of R&D expenditure for a selected set of EU countries, (for the period around 2007-2008), but instead of regarding it as efficiency, they argued on the basis of lower levels of foreign collaboration and publication output per 1000 inhabitants and detailed policy analysis that Italy was on the verge of a decline in science. They attributed the performance to an 'overcompensation effect', and state that the "the productivity of the system is often used in the political debate to justify a further cut in spending", underlining their apprehensions.

In summary, it appears that Italy has produced over 3% of the world's papers and shown the highest growth rate in two decades (amongst EU countries) with a modest outlay (in line with less developed countries), both in terms of expenditure and manpower in a demonstration of high efficiency in basic science. Of greater concern is the fact that Italy is only average in patenting efficiency, and falls below OECD averages in BERD, venture capital, technological firms undertaking innovative activities or with technological products to market. On the international front, it has much higher contribution to GERD from foreign funds and has almost twice as many co-inventors as compared to other OECD countries.

Abstract

The subject of deriving a measure of efficiency of public-funded organizations (primarily not-for-profit organizations) and of ranking these efficiency measures have been major subjects of debate and discussion. In the present study, the methodology of data envelopment analysis (DEA) has been used to analyze the relative performances of public funded R&D organizations across multiple countries working in similar research streams with multiple measures of inputs and outputs. The keywords highlighting the major research areas in the field of non-metrology conducted by National Physical Laboratory (NPL) in India were utilized to select the global comparators working in similar research streams. These global comparators were three R&D organizations located in the USA and one each located in Germany and Japan. The relative efficiencies of the organizations were assessed with variables such as external cash flow (ECF) earned, technologies transferred, publications and patents as outputs and grants received from the parent body and scientific personnel as inputs. The study indicates suggested measures and a set of targets to achieve the best possible performance for NPL and other R&D organizations.

Conference Topic

Science Policy and Research Assessment

Introduction

Public funded research and development (R&D) organizations utilize public money either through government-supported research programs or other public supported activities. These organizations carry out scientific research, deliver technological services to the society and play a fundamental role in an increasingly knowledge-based society ushering in innovations necessary for the development of a competitive industrial system. Research and innovation have become strategic resources and assets to foster competitive national economies (Coccia, 2005). The ability to attract, develop and retain high quality scientific and technical manpower as well as self-sustenance by means of minimizing its dependence on state funding assume vital importance as it impacts delivery that not only addresses national needs but also ensures traction on a global scale.

Globally, public R&D organizations are currently striving to improve their performance as a result of enhanced competition due to liberalization and globalization, increasing demands on the existing resources and being accountable for optimum allocation of these resources. As the R&D process utilizes scarce resources, it becomes crucial to assess the efficiency of this process (Sharma & Thomas, 2008). In the recent past government efficiency concerns have increased, more so in the light of diminishing funds (Gupta et al., 2000). The emerging demand for evaluating the performance of R&D organizations is the result of relentless growth in global competition (Tassey, 2009). However, the provision of quality information

to decision makers through a performance measurement system assumes criticality in such a scenario (Cook et al., 1995).

One major problem in evaluating the efficiency of public institutions is the lack of a good estimate of the production function. The breakthrough came in the research work undertaken by Charnes, Cooper and Rhodes (1978), the first paper using the technique of data envelopment analysis (DEA), even though they never named it that way. The present study makes an attempt to assess the relative efficiency of the National Physical Laboratory (NPL), a constituent establishment of the Council of Scientific and Industrial Research (CSIR), India, with five selected global comparators working in the same research streams located in three countries - the USA, Japan and Germany. Finally, suggesting measures have been proposed highlighting a set of targets to achieve the best possible performance for those R&D organizations, which are less efficient.

Literature Review

It is difficult to measure the performance of an R&D organization because the nature of these organizations and the functions these organizations perform are complex, risky, and uncertain. As opined by Chiesa and Masella (1996), Bremser and Barsky (2004), Loch and Tapper (2001), Brown and Svenson (1998), and Jain and Triandis (1997), it is difficult to identify, measure and compare the performance of R&D organizations. Further, researchers have found it difficult to identify the various outputs/inputs as multiple parameters are involved in the system. As per the existing literature, there exists only a few studies that have been conducted on performance measurement of R&D organizations (Roy, Mitra & Debnath, 2013; Garg et al*.,* 2005).

R&D Output

Considering individual firms as the sample of their study, Pandit, Wasley and Zach (2011) consider R&D as an input to the innovation process and measures the productivity of a firm's innovative activities in terms of the number and the quality of patents. They argue that both of these variables are measures of innovation output or success, and proxy for the economic value of innovation. Chen, Hu and Yang (2011) suggest a multi-dimensional measurement schema including patents, royalties and licensing fees and journal articles. In their study on R&D and the national innovation system, Hu, Yang and Chen (2014) compare R&D efficiency among 24 nations during 1998-2005. In their multiple input-output framework, the input variables are R&D expenditure stock and R&D manpower and the output variables are patents, scientific journal articles, and royalty and licensing fees. Considering public research institutes, Matsumoto et al. (2010) have carried out case studies on market-impact creation outputs from the National Institute of Advanced Industrial Science and Technology, and have modelled R&D output generating economic impact along four stages – R&D output, technology transfer, commercialization, and market impact. This is in line with Roy et al.'s (2003) earlier study where a model to measure the effectiveness of research units was conceptualized. Likewise, research carried out by Laliene and Sakalas (2014) and Agostino et al. (2012) refer to the development of conceptual frameworks for R&D productivity assessment in public research organizations. Lee et al. (2011) have presented an R&D performance monitoring, evaluation and management system for national R&D to mirror not only short-term but also long-term R&D outcomes.

Methodology

Data envelopment analysis (DEA) as developed by Charnes et al. (1978) and extended by Banker et al. (BCC) (1984) has opened up new possibilities in evaluating the performances of many different kinds of entities (referred to as decision making units, DMU), engaged in

different activities and contexts (Cooper et al., 2004). DEA has been used widely to evaluate the performances of countries and regions (Rousseau and Rousseau, 1997, 1998), banks (Brockett et al., 1997), US air force wings (Charnes et al., 1985a), universities (Reichmann, 2004), Japanese manufacturing firms (Goto & Suzuki, 1989), journals (Lozano & Salmeron, 2005), R&D funding on education (Garg et al., 2005), etc. Publications and patents are used extensively to measure R&D efficiency and innovation (Pavitt, 1985). Evaluation of R&D efficiency could be advantageous to identify the better performers for benchmarking and choose better ways to improve efficiency highlighting areas of weakness (Sharma & Thomas, 2008). Charnes et al. (1985) have characterized a unit as influential if it is frequently used in the calculation of efficiency scores.

Researchers who have adopted the DEA methodology to evaluate performances of public research institutes include Rama Mohan (2005) and Roy, Mitra and Debnath (2013). Kim and Oh (2002) conducted a study on designing an R&D measurement system for Korean researchers. Wang et al. (2005) have developed extensive evaluation criteria for multidisciplinary R&D projects in China for ranking and rewarding. Roy et al. (2007) have earlier carried out a study on CSIR exploring the impact of age, research area, and rank on its scientific productivity, again using DEA as one of the methodologies.

Contextual Background of the Study

National Physical Laboratory (NPL), a premier institute of the Council of Scientific and Industrial Research (CSIR), India, has had a commendable track record of contributions and accomplishments since its inception and its scientists have received recognition for their contributions. Though maintenance and up-gradation of national standards of measurements remains the statutory responsibility of the organization, it is also involved in advanced non-metrology related research activities including engineering and electronic materials, material characterization, radio and atmospheric sciences, superconductivity and cryogenics.

A participatory workshop was conducted to diagnose NPL's R&D operations and to focus on aspects related to R&D performance. A particular research area (non-metrology) was selected for the purpose of the current analysis, and accordingly, the keywords, highlighting the organization's major research areas in this field, were utilized to shortlist global comparators. The keywords were searched in the SCOPUS database for a five-year period and global R&D organizations working on similar research streams were shortlisted. Five public R&D organizations were selected based on higher number of publications. These global comparators were the following:

1) National Institute for Materials Science, Japan (NIMS-JP, DMU-A),
2) National Renewable Energy Laboratory, USA (NREL-US, DMU-B),
3) Fritz Haber Institute of the Max Planck Society, Germany (FHI-DE, DMU-C),
4) National Centre for Atmospheric Research, USA (NCAR-US, DMU-D), and
5) Oak Ridge National Laboratory, USA (ORNL-US, DMU-E).

Data structure

The data regarding the inputs and outputs were collected for each DMU including NPL for a five-year period and are presented in Table 1. To ensure confidentiality, the exact period of the data cannot be revealed. Input variables considered in this study were: (1) grants received from the parent body, and (2) the number of scientific personnel (SP) whereas the output variables were: (1) business generated from the industry *i.e.,* external cash flow (ECF) earned, (2) technologies transferred (TT), (3) publications, and (4) number of patents filed.

The methodology to compare performance of any set of research institutes as suggested by Rama Mohan (2005) has been adopted in the present study. To illustrate the results on

efficiency assessment of public R&D organizations including NPL, one input variable and two output variables were considered at the same time.

Table 1. Input and output of different public R&D organizations (five year data).

Public R&D Organization	*Input*		*Output*			
	Grants (Million USD)	*Scientific Personnel (No.)*	*Technologies Transferred (no.)*	*Publication (No.)*	*Patents (No.)*	*ECF (Million USD)*
NIMS-JP - A	94	675	95	7480	195	20
NREL-US - B	141	307	53	2012	99	15
FHI-DE - C	72	206	1	1225	6	3
NCAR-US - D	185	310	5	2345	14	17
ORNL-US - E	107	1075	83	9144	90	23
NPL, India	47	216	3	1024	13	4

The DEAOS software was used for analysis. It analyzes relative performance of business units performing similar functions with an easy to use interface. It provides numerical and graphical output for easy interpretation and communication of results. Some of the key features of DEAOS are:

- The possibility to deal with 25 to 'unlimited' decision making units.
- Flexible facilities – importing from Excel file and direct entry of the data.
- Provides flexible input data management - possibility of addition and deletion of DMUs as well as rows and columns.
- Model input/output orientation selection.
- Provides a tabular scores report (with a variety of sorting methods) and a graphical summary.

Results

ECF generated and technologies transferred vs. scientific personnel

Ratios were calculated for each organization (Table 2) along two dimensions viz., ECF generated per scientific personnel and technologies transferred per scientific personnel. Figure 1 clearly shows that NREL-US (DMU-B) and NCAR-US (DMU-D) are the best performers exhibiting 100% relative efficiency. The efficient frontier, which envelops NIMS-JP (DMU-A), FHI-DE (DMU-C), ORNL-US (DMU-E) and NPL, represents relative efficiency of those organizations. It is observed that NIMS-JP, FHI-DE, ORNL-US and NPL exhibited relative efficiencies of 82, 28, 45 and 36 % respectively. To enhance efficiency from 36 to 46%, NPL is assumed to increase the input-output ratios from the current level of 0.86 to 1.10 (ECF/scientific personnel) and 0.014 to 0.018 (technologies transferred/scientific personnel). An improvement target of 10 %, keeping input (scientific personnel) constant, can be achieved during the next year, if NPL is in a position to increase its ECF to 1.6 M USD and transfer at least 1 technology (Table 3).

Table 2. External cash flow (ECF) and technologies transferred vs. scientific personnel.

Public R&D Organization	*ECF / Scientific Personnel*	*Technology Transferred / Scientific Personnel*
NIMS-JP - A	1.32	0.14
NREL-US - B	2.13	0.17
FHI-DE - C	0.69	0.00
NCAR-US - D	2.44	0.02
ORNL-US - E	0.94	0.08
NPL, India	0.86	0.01

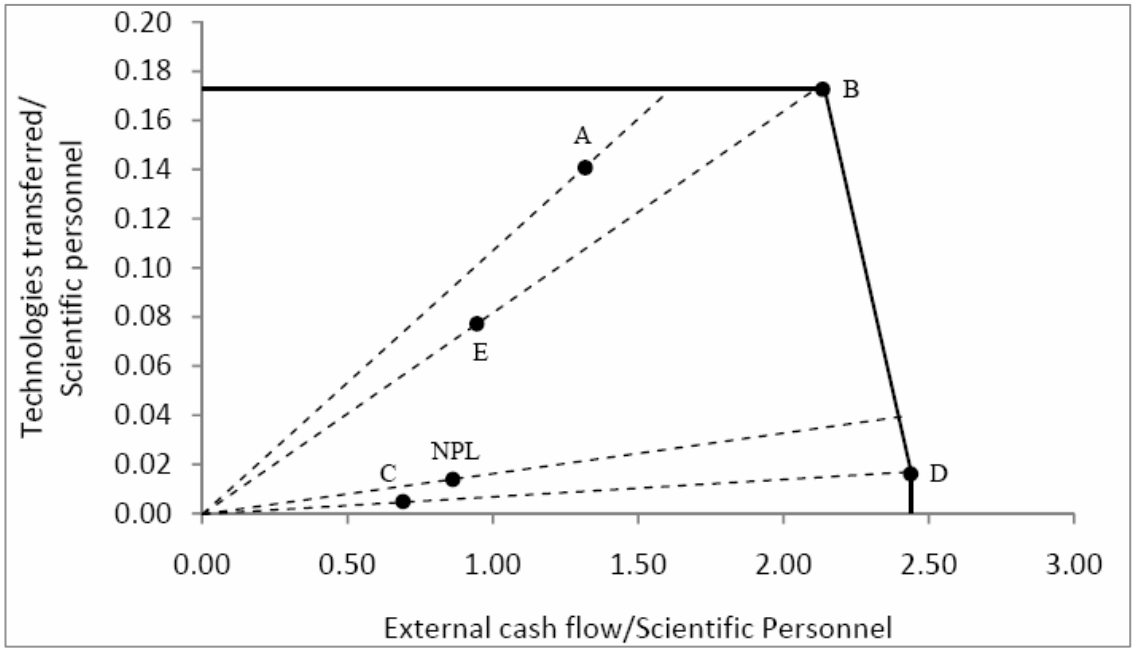

Figure 1. ECF generated and technologies transferred vs. scientific personnel.

Publications and patents vs. scientific personnel

To assess the relative performance of the R&D organizations, publications per scientific personnel and patents per scientific personnel were calculated (Table 4) and graphically represented in Figure 2. NIMS-JP (DMU-A) and NREL-US (DMU-B) show best performance exhibiting 100% efficiency in generating sufficient number of publications and patents per scientific personnel. Performance was found higher in case of ORNL-US (DMU-E) (77%) and NCAR-US (DMU-D) (67%) whereas FHI-DE (DMU-C) (54%) and NPL (43%) perform moderately. However, NIMS-JP is the reference laboratory all the organizations. To achieve improved targets by 10% during the next year, NPL and FHI-DE each would require to publish 240 and 230 papers and 9 and 12 patents respectively (Table 5).

Table 3. Targets for the R&D organizations to improve efficiency by 10%

(Scientific personnel count remaining constant)

Public R&D Organization	*ECF to earn (Million USD)*	*Technology to transfer*
NIMS-JP - A	6.8	12
FHI-DE - C	1.1	0.4
ORNL-US - E	5.1	19
NPL, India	1.6	0.8

Table 4. Pubclications and patents vs. scientific personnel

NCAR-US - D	347	23
ORNL-US - E	1204	96
NPL, India	240	9

ECF generated and technology transferred vs. grants

Next, relative efficiencies of the R&D organizations have been calculated along two outputs (ECF generated and technologies transferred) and one input (grants received from the parent body), (Table 6) and plotted in Figure 3. NIMS-JP (DMU-A) and ORNL-US (DMU-E) show best performance exhibiting 100% efficiency in generating sufficient amounts of ECF and number of technologies transferred per grants received. All the other organizations have ORNL-US in their reference set. To achieve efficiency by 10% during the next year, FHI-DE has to earn 1.5 M USD ECF and to transfer 7 technologies (Table 7).

Table 6. ECF earned and technologies transferred vs. grants received from parent body.

Public R&D Organization	*ECF / Grants*	*Technologies Transferred / Grants*
NIMS-JP - A	0.21	0.02
NREL-US - B	0.10	0.01
FHI-DE - C	0.04	0.00
NCAR-US - D	0.09	0.00
ORNL-US - E	0.21	0.02
NPL, India	0.09	0.00

Table 7. Targets for the R&D organization to improve efficiency by 10% (Grants received from the parent body remaining constant).

Public R&D Organization	*ECF to earn (Million USD)*	*Technology to transfer*
NREL-US - B	3	11
FHI-DE - C	1.5	7
NCAR-US - D	3.9	24
NPL, India	0.8	5

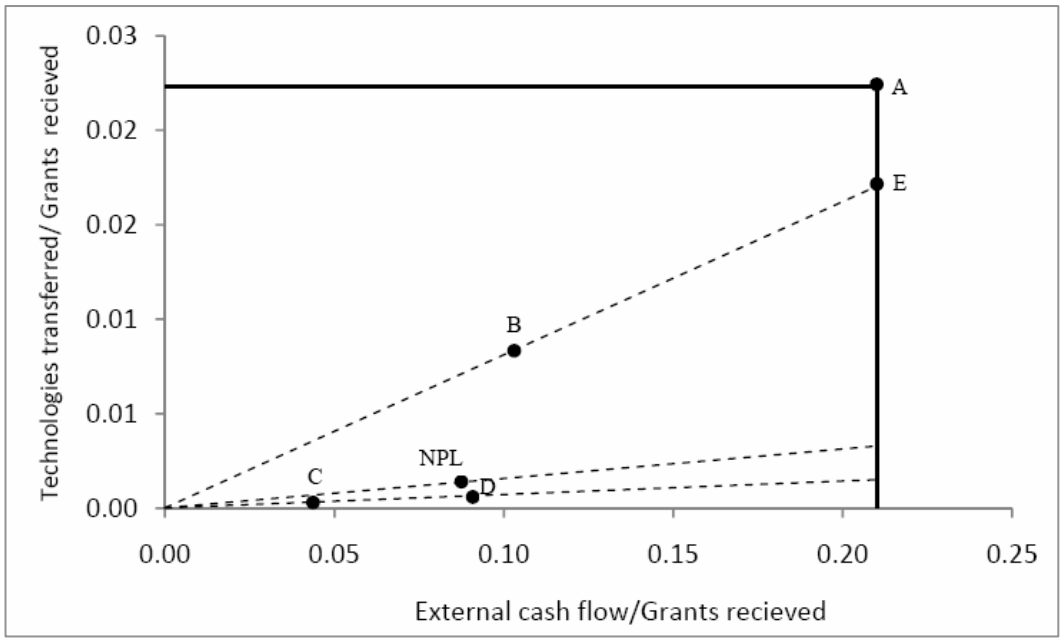

Figure 3. ECF generated and technologies transferred vs. grants received.

Publications and patents vs. grants

To assess the relative performance of the R&D organizations, ratios were calculated for publications per grants received and patents per grants received (Table 8) and graphically represented in Figure 4. NIMS-JP (DMU-A) and ORNL-US (DMU-E) show the best performance exhibiting 100% efficiency. NPL has both NIMS-JP and ORNL-US in its reference set whereas FHI-DE (DMU-C) and NCAR-US (DMU-D) relate only to ORNL-US whereas NREL-US (DMU-B) has only NIMS-JP in its reference set. To achieve efficiency by 10% during the next year, FHI-DE, NCAR-US and NPL have to increase their number of patents by a count of 7, 17 and 5 respectively from the current level (Table 9).

Table 8. Publications and patents vs. grants received from parent body.

Public R&D Organization	*Publication / Grants*	*Patent / Grants*
NIMS-JP - A	1.77	0.05
NREL-US - B	0.32	0.02
FHI-DE - C	0.38	0.00
NCAR-US - D	0.28	0.00
ORNL-US - E	1.89	0.02
NPL, India	0.48	0.01

Publication, patents, ECF generated and technology transferred vs. scientific personnel & grants

The relative efficiencies of R&D organizations on multi-input-multi-output six dimensional model keeping two inputs (*viz.,* scientific personnel & grants received) and four outputs (*viz.,* publication, patents, ECF generated and technology transferred) data have been calculated and the performance of each R&D organization under study is compared with that of every other one following the output oriented measure of efficiency at constant return to scale (CRS), variable return to scale (VRS) along with scale efficiencies (SE). The empirical analysis has been given in Table 10.

Table 9. Targets for the R&D organization to improve efficiency by 10 % (Grants received from the parent body remaining constant).

Public R&D Organization	*Publications*	*Patents*

Table 10. Relative efficiency percentage of different public R&D organizations.

Public R&D Organization	*ECF & TT/SP*			*Pub. & Pat./SP*			*ECF & TT/Grants*			*Pub. & Pat./Grants*			*Pub., Pat., ECF & TT/SP & Grants*		
	CRS	*VRS*	*SE*	*CRS*	*VRS*	*SE*	*CRS*	*VRS*	*SE*	*CRS*	*VRS*	*SE*	*CRS*	*VRS*	*SE*
NIMS-JP - A	82	100	0.82	100	100	1.00	100	100	1.00	100	100	1.00	100	100	1.00
NREL-US - B	100	100	1.00	100	100	1.00	49	65	0.75	34	51	0.67	100	100	1.00
FHI-DE - C	28	100	0.28	54	100	0.54	21	25	0.84	20	27	0.74	54	100	0.54
NCAR-US- D	100	100	1.00	67	90	0.74	43	74	0.58	15	26	0.58	100	100	1.00
ORNL-US - E	45	100	0.45	77	100	0.77	100	100	1.00	100	100	1.00	100	100	1.00
NPL, India	36	94	0.38	43	85	0.51	42	100	0.42	26	100	0.26	57	100	0.57

Note: CRS: constant return to scale, VRS: variable return to scale SE: scale efficiency; (SE=CRS/VRS)

Technical efficiencies estimated under the CRS model are found to be less than the technical efficiencies coming from the more flexible VRS model. Under the CRS assumption, less average efficiency is found in case of FHI-DE (DMU-C) (54%) followed by NPL (57%) while under VRS, it was found that average technical efficiency score for all the DMUs is 100%, which implies that on an average DMUs could have used resources judicially to produce the same amount of output. However, under the scale efficiency (SE), the average score is found to be 0.54 in case of FHI-DE and 0.57 in case of NPL, which indicate that on an average the actual scale of production has diverged from the most productive scale size. In SE, the score 1 indicates that the DMU is operating at the most efficient scale or optimal size whereas SE less than 1 would be due to decreasing returns to scale (over production) or increasing returns to scale (under production).

Discussion and Conclusions

Over the past three decades, a variety of approaches, parametric and non-parametric, have been developed to investigate the failure of producers to achieve the same level of efficiency (Kalirajan and Shand, 1999). DEA which offers a non-parametric alternative to parametric frontier production function analysis has two advantages over the econometric one in measuring productivity change (Grosskopf, 1986). First, it compares the states to the 'best' practice technology rather than 'average' practice technology as is done by econometric studies. Second, it does not require the specification of an ad hoc functional form or error structure. In DEA, the less-performing units need more inputs to produce the same amount of output (Andersen & Petersen, 1993). DEA produces a piecewise empirical extreme production surface which in economic terms represents the revealed best-practice production frontier (Charnes et al., 1994).

In this study, the performance of each R&D organization (here the DMU) under study is compared with that of every other one following the output oriented measure of efficiency at constant return to scale (CRS), variable return to scale (VRS) along with scale efficiencies (SE). DEA has been used to analyze the relative efficiencies of the public funded R&D organizations keeping one input and two outputs at a time and results have been demonstrated in four possible dimensions. Secondly, the relative efficiencies of R&D organizations on multi-input-multi-output six dimensional model keeping two inputs and four outputs data have also been calculated. Comparatively less efficiency of NPL (0.57) that is a cause for concern might be due to its lower efficiency in generating sufficient amounts of external cash flow, number of technologies assumed to be transferred to the industry per scientific personnel as well as number of papers published and patents filed per grants received from the parent body.

The significance of the work presented in the paper stems from the fact that this is perhaps the first multinational study of relative performance assessment of R&D organizations, all of whom work on similar research themes. Relative performance assessment of different R&D organizations have been ascertained in the past (Roy, Mitra & Debnath, 2013) but the R&D organizations in question were working on diverse research streams. The focus of the current study, therefore, seems much more relevant as absolute comparators were first identified and thereafter assessed in terms of their performance characteristics. The present work has opened up new avenues for further research in this area.

Abstract
Scientific activity of Social Sciences and Humanities researcher's comprises an assorted set of publication channels such as books, book chapters and national and international journal articles. Since knowledge dissemination in the field is characterised by a greater use of national journals and local languages, international bibliographic databases do not offer a suitable coverage. This work pursues to draw a comprehensive picture of the publication behaviour of CSIC researchers in the Social Sciences and Humanities from a micro-level perspective. For this purpose, Web of Science and an internal CSIC database called 'ConCiencia' were used along with a set of indicators describing the activity profile of researchers as well as the prestige of publication channels. Differences in the publication pattern of researchers in SSH were explored, and the relationship between their research performance and personal features such as age, gender and professional rank were analysed. In the Humanities, researchers with higher academic rank and age showed greater activity in books and non-WoS articles, whereas in the Social Sciences, higher rank was related to internationally-oriented scientific publications and a more collaborative activity. Considering only WoS articles would shrink meaningfully the visibility of CSIC researchers.

Conference Topic
Science policy and research assessment

Introduction
Outlining the scholarly work of researchers in the Social Sciences and Humanities (SSH) is often regarded as a challenge in bibliometrics, since the predominant publication types in these fields are not well covered by large bibliographic databases such as Web of Science or Scopus (Hicks, 2004). At this point, it is quite clear that dealing with journal publications, it is not enough for the SSH (Archambault et al., 2006; Sivertsen & Larsen, 2012) remaining books and books chapters as a major communication channel, chiefly in the Humanities. Moreover, due to the more local orientation of research in the SSH, knowledge dissemination in the field is characterized by a greater use of national journals and local languages (van Leeuwen, 2013). On the other hand, even though there has been a certain trend to consider SSH as a whole, different behavior between both communities can be expected (Mañana-Rodríguez & Giménez-Toledo, 2013).

The aforesaid factors hinder the potential capacity of the traditional bibliometric analyses to provide a reliable picture of the scientific activity of the SSH researchers and the development of national or regional databases to obtain full coverage of publications in the SSH has been suggested (Martin et al. 2010). This type of database has been developed in some countries such as Norway, Denmark, Finland and Belgium (Flanders), motivated by the need to monitor the performance of university scholars and in line with the development of performance-based

funding of university research (Sivertsen, 2010). Studying the activity of SSH researchers in Spain is difficult, because there is not such a full coverage national bibliographic database, but it can be addressed at the institutional level because many institutions collect the scientific output of their researchers, mainly with evaluative purposes.

This study focuses on the scientific activity of SSH researchers at the Spanish National Research Council (CSIC), the largest public institution dedicated to research in Spain which makes up more than 4,000 researchers and 125 institutes spread all over the country. This work pursues to draw a comprehensive picture of the publication behaviour of CSIC researchers in SSH from a micro-level perspective. An assorted set of publication channels such as books, books chapters, international and national journal articles are considered and specific indicators to assess the prestige of the different publication channels are introduced. Differences in the publication pattern of researchers in SSH are explored, and the relationship between their research performance and personal features such as age, gender and professional rank are analyzed.

Methodology

This study analyses the scientific output of 268 active researchers in 2007 in the SSH area affiliated to the Spanish National Research Council (CSIC) and comprises both permanent researchers and postdoctoral research fellows. The time span under analysis is 2007-2011. Publications were collected from two different sources: Web of Science (WoS) (SSCI+AHCI+SCIE), which was used to download the more international articles; and an internal CSIC database called 'ConCiencia', to obtain other publication types not covered by WoS (books, books chapters and non-WoS journal articles). To cope with names inconsistencies and achieve a proper allocation of the publications to the researchers, different algorithms were used. A manual revision of the output collected, especially for the 'ConCiencia' database, was done. Based on the information retrieved, the following indicators were computed:

a) Activity profile of researchers

- % Books: proportion of books published by a researcher with regard to its total number of publications. In the same way, the next three indicators were calculated.
- % Book chapters.
- % WoS articles.
- % Non-WoS articles.
- Sum of publications: the total number of publications published by each researcher, including books, chapters in books and journal articles.
- Average number of authors/paper: this indicator measures the average number of authors per publication for the total output of a given researcher (WTI2, 2014).
- % International collaboration: share of the total output of each researcher co-authored with researchers affiliated with one or more foreign institutions.
- % English: proportion of a researcher´s output published in English.

b) Prestige of publication channels

- Top books and chapters (pptop10% Books & Chapters): proportion of books and chapters of a given researcher published by the top 10% publishers according to the Scholarly Publisher Indicators Project (SPI) (Giménez-Toledo, Tejada-Artigas & Mañana-Rodriguez, 2013). This project describes the Indicator of Quality of Publishers according to Experts (ICEE), which is based on a quality assessment of publishers rated by Spanish researchers in a national survey.

- Proportion of papers in first quartile journals (Q1): share of papers published in the top 25% journals of the impact factor journal ranking by subject category (source: Journal Citation Reports).
- Proportion of papers in top non-WoS journals (pptop10% non-WoS articles): % of non-WoS papers published in top journals according to the Integrated Scientific Journal Classification (CIRC) (Torres-Salinas et al. 2010). CIRC is a proposal for a categorization of journals in SSH developed by a group of experts in bibliometrics in Spain. It distinguishes four categories of journals (A, B, C and D) according to their visibility measured integrating the results of different journal classifications and assessments tools. For the purposes of this paper, "top journals" are those included in the categories "A" and "B".

Table 1. Impact indicators for the different types of publication channels.

Type of publication channel	*Indicators of impact/prestige*
WoS articles	Impact factor (25% top journals by impact factor)
Non-WoS articles	CIRC (categories A and B)
Books/Book chapters	SPI (10% top publishers by expert opinion)

c) Personal data: age, professional rank (P=postdoctoral research fellow, TS=tenured scientist, RS=research scientist and RP=research professor) and gender of researchers were provided by CSIC.

A preliminary inspection of the similarity between variables was explored by means of Multidimensional Scaling (MDS). Non-linear Principal Component Analysis (NLPCA) was used to explore the relationship between personal features of researchers and their performance. Statistical analyses were performed with SPSS (v.20).

Findings

A total of 268 researchers had at least one publication in the period 2007-2011. In the whole SSH area, men represented 59% of all researchers, average age of researchers was 50 years old, and half of the researchers were in the lowest scientific category (tenured scientist). Postdoctoral research fellows accounted for only 7% of researchers in the area. Small differences between the Humanities and Social Sciences can be observed in Table 2.

Table 2. Personal features and scientific rank of researchers in SSH.

		Humanities (N=192)		*Social Sciences (N=76)*		*Total (N=268)*	
Gender	Men	115	60%	42	55%	157	59%
	Women	77	40%	34	45%	111	41%
Rank 2007	Post-doc	12	6%	6	8%	18	7%
	Tenured scientists	98	51%	42	55%	140	52%
	Research scientists	46	24%	13	17%	59	22%
	Research professors	36	19%	15	20%	51	19%
Age		50 ± 9 (28-70)		49 ± 10 (32-70)		50 ± 9 (28-70)	

Note: age expressed as average ± standard deviation (min-max).

A total of 3,004 documents were published by CSIC researchers in SSH during 2007-2011. Differences between Humanities and Social Sciences in the main publication types used are observed: WoS articles predominate in the Social Sciences while book chapters are the most frequent publication channel in the Humanities (Table 3).

Table 3. Share of publication channels by area.

	Books	*Chapters*	*Non-WoS Articles*	*WoS Articles*	*Total*
Humanities	14% (397)	47 % (1,313)	26% (717)	13% (352)	2,779
Social Sciences	8% (65)	27% (214)	29% (227)	36% (289)	795
Total	13% (462)	43% (1,527)	26% (944)	18% (641)	3,574

Note: the total is higher than 3,004, because the publication count is made at the individual level.

Publication profile of researchers

A MDS was applied to the set of variables which make up the activity profile of researchers to reveal their underlying structure. In terms of similarity, the plot gives away greater levels of international collaboration and English-written publications for WoS articles. The patterns for the remaining publications types (books, chapters and non- WoS articles) seems to be mainly related to higher levels of productivity and being written in national languages (Figure 1).

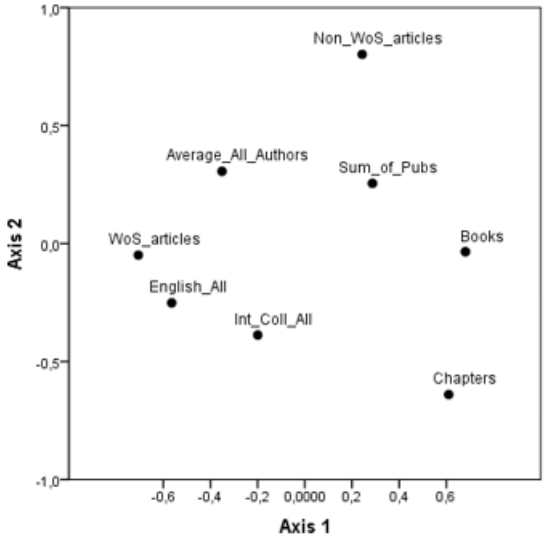

Figure 1. MDS for the scientific activity profile.

The diversity of publication channels in the output of researchers is the norm in SSH. Around 1/3 of the researchers presented output of the four different types considered: articles covered by WoS, non-WoS articles, books and book chapters. Three and two types of publication channels were observed in 40% and 17% of the researchers respectively, while only 12% of researchers had results of a single type. Several differences between Social Sciences and Humanities can be put forward: researchers who disseminate research among the four different types of publication channels considered are more frequent in Humanities (36% vs 24%), while using only WoS-covered journals is more common among Social Sciences researchers (16% vs 4). Finally, it is interesting to remark that around 22% of Social Sciences researchers and 41% of those in the Humanities may remain invisible in Web of Science-based studies since they do not show any publication covered by this database.

Research performance of scientists

Main statistics concerning research performance of scientists in SSH are shown in Table 4. A higher number of total publications is observed for researchers in the Humanities (15.1 vs 10.8), especially due to their high number of book chapters. Researchers in the Humanities exhibit a higher use of top publishers for books and chapters, while Social Sciences researchers present a greater share of articles in high impact factor journals.

Table 4. Description of the research performance of researchers in SSH.

	Humanities		*Social Sciences*	
	Mean	*SD*	*Mean*	*SD*
No. Books	2.1	2.5	0.9	1.0
No. Chapters	7.1	5.7	2.9	3.3
No. WoS Articles	1.9	4.3	3.9	4.1
No Non-WoS Articles	3.9	4.7	3.1	3.7
Sum of Publications	15.1	12.2	10.8	7.5
pptop10%_Books & Chapters	35.9	26.5	23.7	28.9
pptop10%_Non_WoS_Articles	32.8	35.3	37.3	37.9
% Q1 WoS Articles	12.9	29.7	33.4	36.5
Average number authors/publication	1.7	1.4	2.6	1.1
% International. collaboration	16.9	23.0	24.1	29.8
% English	14.0	19.0	38.6	32.7

To explore the possible relations between personal features of researchers and their performance NLPCA was used, which allows reducing a large number of variables to a smaller number of uncorrelated non-linear combinations of these variables with miminum loss of information (principal components). Two different studies are conducted, since researchers in Social Sciences and Humanities are analysed separately. Preliminary results concerning the plots of component loadings (two-dimensional solution) are shown in Figure 2.

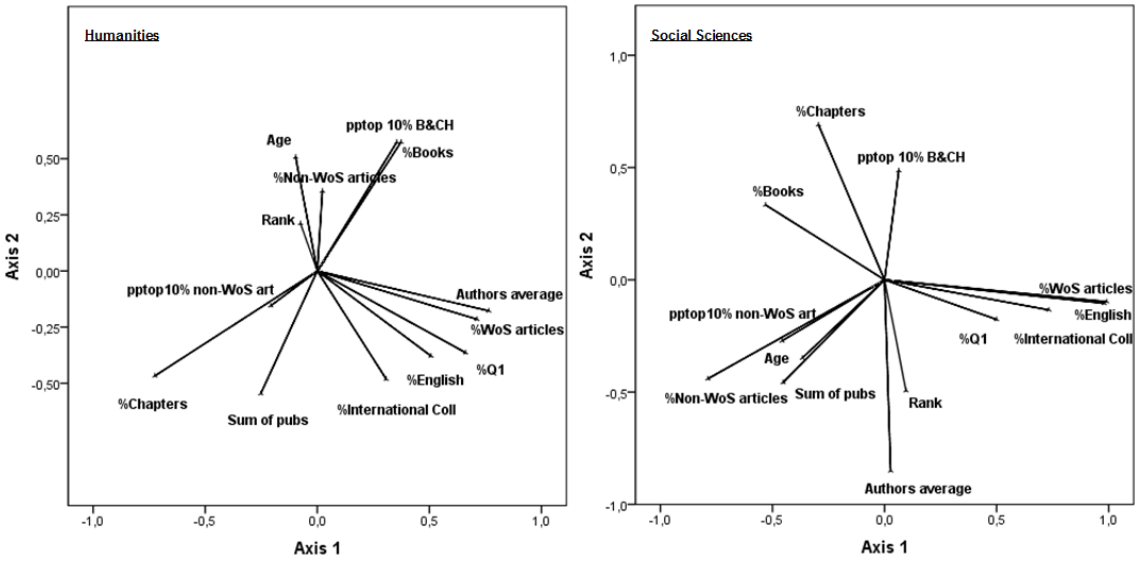

Figure 2. Component loadings in: a) Humanities; b) Social Sciences.

Note: only researchers with 2 or more publications considered

Discussion and conclusions

At this point, some preliminary results can be pointed out in an attempt to provide a comprehensive picture of the activity of CSIC researchers in SSH from a micro-level perspective:

- Taking into account only WoS articles would shrink meaningfully the visibility of CSIC researchers in SSH, in particular in the Humanities.
- Different constraints of the 'ConCiencia' system are identified. More rigour in the input of data (carried out by researches themselves) as well as in the cleaning and validation processes (by the institution) would be advisable.

- In the Humanities, researchers who hold a higher rank and age present greater activity in books and non-WoS articles. However, a high number of total publications is apparently not associated to a higher rank.
- In the Social Sciences, a higher academic rank is associated to internationally-oriented scientific publications (high share of WoS articles) as well as a high productivity (high number of publications) and collaborative activity (high number of co-authors).
- Differences between the Social Sciences and Humanities are observed, but even within each of these fields different typologies of researchers according to their publication pattern, collaboration practices and international/national orientation may exist. These factors are being explored at present.
- Although our study focuses on four different types of academic output, it is still not comprehensive, since it does not consider the non-scholarly literature, which may have an important societal impact.

Acknowledgments

Adrián A. Díaz-Faes is granted with a JAE predoctoral fellowship by the Spanish National Research Council (CSIC).

A Bibliometric Assessment of ASEAN's Output, Influence and Collaboration in Plant Biotechnology

Jane G. Payumo[1] and Taurean C. Sutton[2]

Abstract

This research uses 10-year (2004-2013) publication and citation data related to plant biotechnology to assess the research performance, impact, and collaboration of member states of the ASEAN in plant biotechnology. Findings indicate increased scientific output of ASEAN countries in plant biotechnology as well as increased research collaborations by individual member states and with international partners throughout the 10-year period. The nature of collaboration by ASEAN is linked with the status of economic development of each country. Domestic and international collaborations are strong and are increasing through the years, regional collaboration on the other hand is found to be limited. This limited regional partnership can be a concern for the region's goal of economic integration. Further studies using bibliometric data analysis is suggested for policy diagnosis in plant biotechnology cooperation, knowledge flows, and effect of plant biotechnology research in economic development between ASEAN countries.

Conference Topic

Bibliometrics and research evaluation

Introduction

The Association of Southeast Asean Nations (ASEAN) has declared biotechnology as the main area of cooperation in science and technology. ASEAN, a regional association composed of 10 countries namely: Brunei, Cambodia, Indonesia, Laos, Malaysia, Myanmar (Burma), Philippines, Singapore, Thailand, and Vietnam, considers plant biotechnology as the next pillar of regional economic growth (Hautea & Escaler, 2004; Erbisch & Maredia, 1998) and the answer to their food security needs. If ASEAN will continue to invest in plant biotechnology in the next years, it will be beneficial to have information on the current state of research and collaboration for strategic direction setting. This research drawing on bibliometric data, hence, will add to understanding the level and nature of collaboration, including research performance of ASEAN countries in plant biotechnology. This is relevant for ASEAN policy makers in charge of setting direction and designing strategies for research cooperation, and planning research investments, especially on biotechnology, at the country and regional levels.

Methodology

This research is based on 2004-2013 publications in plant biotechnology authored and co-authored by 10 member states of ASEAN. The data were extracted from Elsevier's Scopus database, the world's largest abstract and citation database of peer-reviewed literature (Elsevier B.V., 2014). Different keyword combinations were used to locate plant biotechnology-related publications guided by the glossary of biotech terms by the U.S. National Institute for Food and Agriculture (NIFA, 2014) and the National Agricultural Library Agricultural Thesaurus (National Agricultural Library, 2014). Additional filter was then set according to affiliation country to include only the publications published by the 10

ASEAN countries. No filter was set for the type of publication; all document type, namely: article, review, conference paper, short survey, note, editorial, letter, book chapter, book, and article in press were included. This research also highlights the use of a home-grown open-source 'publication parser' tool (Sutton, 2013); this tool was useful in parsing extracted files from Scopus for analysis of various indicators of interest at the country, institutional, and individual levels. The methodology, including interpretation of the different indicators, builds on best practices on indicators research that have been developed throughout the years (Moed, Glänzel, & Schmoch, 2004).

Results and Discussion

Publication output and citation impact

During the 10-year period (2004-2013), ASEAN researchers produced an overall total of 7,907 papers related to plant biotechnology; this output has increased 15% per year. These publications were written by more than 13,000 unique authors. The number of researchers producing knowledge for the region has increased steadily throughout the years with numbers reaching close to 8,000 authors in 2013 compared to less than 2,000 authors in 2004. Interestingly, ASEAN's plant biotechnology publications have mostly been published in open source journals such as Plos One. ASEAN's plant biotechnology publications have been cited more than 117,000 times with the highest citation count observed in 2007. The average citation per publication for plant biotechnology publications of ASEAN (19.81) is more than twice higher than the average CPP of all ASEAN publications (8.4) indicating higher influence of plant biotechnology publications than publications in other research areas.

Country output and ASEAN research investments

We then classified the 10 ASEAN countries into three groups based on expenditures on research and development (R&D) (UNESCO Institute for Statistics, 2015): (1) high income countries (HIC) with R&D spending more than 1% of gross domestic product (GDP); (2) middle income countries (MIC) with R&D spending of 0.1 to 0.9% of GDP; and (2) lower middle-income countries (LMIC) with R&D spending of 0.0 to 0.09% of GDP. A significant difference on the publication output in plant biotechnology of HICs with larger R&D investments was noted compared with that of LMICs with less research investments (Table 1). Thailand produced the most number of publications (n = 2489). Malaysia and Singapore are the other top three ASEAN producers with more than 150 PPY and CAGR of 29% and 9%, respectively. Philippines with a CAGR of 8% and Vietnam with a CAGR of 19% produced an average of 75 and 41 PPY, respectively. LMICs, namely Brunei Darussalam, Cambodia, Laos, and Myanmar experienced no growth during the ten-year period and have only produced an average of 1-2 papers per year. Interestingly, Indonesia despite its low R&D investments, hence, classified as a LMIC here, was able to produce 61 PPY and is growing at 12% CAGR. The number of authors contributing to ASEAN publications except the LMICs namely: Brunei Darussalam, Cambodia, and Laos, is growing. An increase in the number of contributing authors was especially noted for Malaysia; the country's number of authors from 2004 to 2013 has increased almost 15 fold.

HICs with higher number of publications received more total citations than lower income countries. Singapore is the most highly cited in plant biotechnology followed by Thailand, Malaysia, and Philippines. With the exception of Indonesia, other LMICs received the least amount of citations for their plant biotechnology publications during the last two decades.

Table 1. Comparison of 2004 and 2013 article output, CAGR, and citation count for ASEAN.

Country	Country classification	Publication output	2004	2013	CAGR	No. of authors	Citation count
Malaysia	MIC	2,199	39	510	29%	10,511	14,584
Vietnam	MIC	418	14	83	19%	2,474	3,957
Thailand	MIC	2,489	108	377	13%	12,688	27,863
Indonesia	LMIC	611	33	104	12%	3,421	7,208
Myanmar	LMIC	23	1	3	12%	100	180
Singapore	HIC	1,594	101	234	9%	10,953	49,094
Philippines	MIC	757	46	104	8%	4,444	14,492
Cambodia	LMIC	6	1	0	-100%	64	135
Brunei	LMIC	35	0	0		30	157
Laos	LMIC	10	0	3		136	186
Total		7,907					117,856

Note: CAGR of Cambodia and Brunei resulted in undefined values and left blank in this table. Source: Scopus

The topmost institution publishing plant biotechnology-related articles in the region are mostly local public research universities (e.g. University Brunei (Brunei), Bogor Agricultural University (Indonesia), National University of Laos (Laos), University of Malaya (Malaysia), Yezin Agricultural University (Myanmar), National University of Singapore (Singapore), and Mahidol University (Thailand). For Cambodia, Vietnam and Philippines, the top producers of publications on plant biotechnology were research institutions and include Cambodian Agricultural Research and Development Institute, Institute of Biotechnology, and International Rice Research Institute (IRRI). The two former institutions are national leading research institutions in bioscience and plant biotechnology while IRRI is an international research organization.

Collaboration

Guided by a decision tree adapted from Lan (2014), we distinguished four types of research collaboration: (1) domestic - in which all authors are in the same country; (2) regional – in which one ASEAN author co-authored with another ASEAN country; and (3) international – in which authors in the ASEAN countries published together with at least one author from another country besides the ASEAN countries. Single authorship and publications that involved intra-institutional co-authorship are not classified as collaboration in this research.

Single author publications and publications that involved intra-institutional co-authorship for ASEAN is very limited; they only constitute 15% of ASEAN's total publications in plant biotechnology. Eighty five percent of ASEAN's total publications in plant biotechnology, on the other hand, involved research collaboration, growing at a CAGR of 15%. Interestingly, the most active institutions that engaged in collaborations in ASEAN are the public universities and institutions of higher education; these institutions have also been noted earlier to be publishing most and the active generators of knowledge for ASEAN. These results confirm observation that plant biotechnology research in ASEAN countries is increasingly conducted now by a group of collaborating researchers rather than by a single researcher (Katz & Martin, 1997; Glänzel, 2001).

The region's co-authored publications that involved domestic partnership are growing at a CAGR of 15%. Six ASEAN members were engaged in domestic collaborations with

Malaysia, Thailand, and Singapore having the highest % shares of domestic collaborations at 42%, 37%, and 20%, respectively. Brunei Darussalam, Cambodia, Laos, and Myanmar have no record of domestic collaborations.

ASEAN publications that involved regional collaboration are very limited with less than 1% of the total collaborations of ASEAN. The highest number of publications that involved regional collaborations was recorded in 2013 (n = 21); there was no regional collaboration noted for 2007 and 2008. Ironically, 2007-2008 were the early years of the adoption of ASEAN's Economic Blueprint, which serve as the guide for the establishment of the ASEAN Economic Community. All the higher income countries have co-authored with another ASEAN country although numbers are quite limited (Figure 1). Philippines and Thailand have collaborated mostly with all of the ASEAN countries except Brunei Darussalam. Laos and Myanmar are two of the most active in regional collaborations despite their late membership to the regional association. Both countries have strong regional collaborations with Thailand, their closest ASEAN neighbor; Laos and Thailand used to belong to one country (Siam) and have basically the same language. Brunei has no record of collaborations with any of the ASEAN members.

The region has a very high rate of international collaboration in plant biotechnology research during 2004-2013 at 65% and the rate of collaboration is growing at a CAGR of 11 %. Similar with domestic and regional collaborations, the highest number of publications that involved international collaborations was recorded in 2013 (n = 227) while the least was recorded in 2004 (n = 717). ASEAN has partnered with 115 countries that are in varying stages of economic development. U.S. remains to be the main international research partner of choice among ASEAN countries. ASEAN is also tapping into the research expertise and resources of other Asian nations like Japan, China, South Korea, and India and advanced countries like United Kingdom, France, Germany, Canada, and The Netherlands. Arunachalam and Doss (2000) had the same observation and stated that Asian countries are fast increasing their share of worldwide international collaboration in science and expanding its collaboration beyond the traditional collaboration with advanced nations such as the United States.

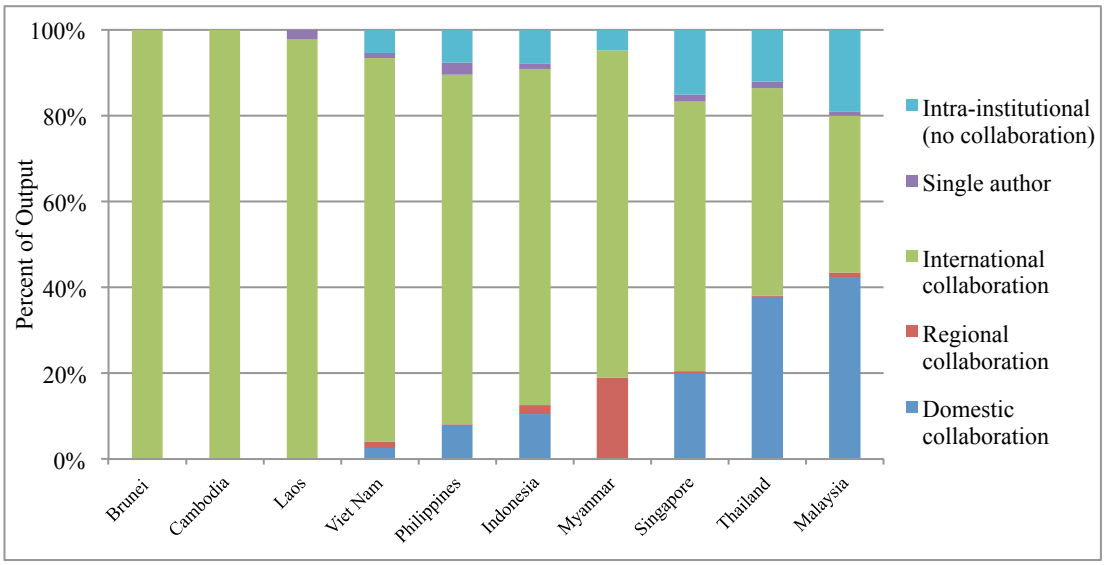

Figure 1. Percentage of different types of collaboration for individual ASEAN countries in plant biotechnology, 2004-2013. Source: Scopus

Brunei Darussalam, Cambodia and Laos are particularly noted for very high international collaboration. There are many justifications for this high collaboration rate and may include

the need for complementary and synergistic research expertise, greater visibility in the international plant biotechnology arena, and greater research output despite limited research investments. Interestingly, the higher income countries and the top ASEAN producers, namely Malaysia, Thailand, and Singapore have lower scientific output with the international community compared with other ASEAN countries, which validates observation that these countries have now higher domestic research capability, hence, would not need as much international collaboration as lower income countries. As expected, ASEAN publications that involved international partnerships received the highest citation count (n = 86,423) supporting earlier research while publications that involved regional collaborations received the least citation count (n = 547). It is interesting to note that despite the regional collaborations involving more authors and one or more ASEAN countries, the citation count was lower compared to single authored publications. This can indicate the less quality and influence of publications resulting from regional partnerships.

Conclusion and Recommendations

Using bibliometric data for the period 2004-2013 sourced from the research abstract database, Scopus, and deconstructed through a non-commercial home-grown publication parser tool, this paper investigates ASEAN's research output, influence and research collaboration in the area of plant biotechnology. Analysis of the 10-year period indicated an increase in ASEAN plant biotechnology-related scientific output. The publication activity obviously varies from country to country but evident that it is linked with R&D investments: higher income countries such as Singapore produced more publication than lower middle-income countries such as Brunei Darussalam. Most of the knowledge producers of ASEAN were from local research institutions, which are a good indication of improvements in domestic research capability and increase knowledge generation activity among this group. The relatively stable trend of publication generation and increasing R&D investments in countries such as Singapore, Thailand and Malaysia, likewise, provides a good indication that more research output can be expected from these countries. The growth of the publication records especially of Indonesia and Vietnam supports the increasing commitment of these countries and their researchers to contribute in advancing the plant biotechnology field. Philippines need to push and incentivize its local research and academic institutions to produce more and increase their scientific output and not rely on international institution to boost the country's scientific productivity. Brunei Darussalam, Cambodia, Laos, and Myanmar need to improve their research infrastructure and level up their research investments to catch up with other ASEAN countries.

The increasing number of collaborative research teams and number of contributing authors based on co-authorship data in ASEAN publications over the course of the 10-year period, however, is an encouraging result. It represents an increase in the pool of researchers and a change in the balance of research focused more on collaborative research teams among ASEAN researchers and their partners and not on lone scientist.

All the 10 ASEAN countries are actively engaged in research collaboration in plant biotechnology although in varying degrees. The publication output by countries in terms of the collaboration types: domestic, regional and international, differ and is also noted to be linked with status of economic development. Domestic collaborations are very strong for higher income countries with higher R&D investments while lower income countries with lower research investments tend to publish more with their international counterparts. There is more preference for collaboration with more advanced nations but at least the region has expanded its collaboration beyond the United States.

Regional partnerships are, however, very limited, and can be a concern for ASEAN's goal of integration. ASEAN regional collaboration still lag behind in terms of productivity and

quality research in plant biotechnology, which is very evident from the region's low research output and citation count for publications co-authored among ASEAN researchers. Higher regional collaboration rate is only observed to countries that are in close proximity to each other, with common language, and with historical links. Kumar, Rohani, & Ratnavelu (2014) found the same scenario after doing bibliometric work in the field of economics. The low regional collaboration was also mentioned in one of the latest reports by the Asian Development Bank, Regional Cooperation and Cross-Border Collaboration in Higher Education in Asia: Ensuring that Everyone Wins (Asian Development Bank, 2012). Hence, it remains to be seen whether regional collaboration will serve as an important platform for continuing to modernize plant science in ASEAN and sharing knowledge in plant biotechnology. More investments in research cooperation, funding mechanisms for regional plant biotechnology research, and other regional incentives need to be setup so ASEAN can realize the goal of its regionalization agenda. Regular quantitative monitoring of inputs and outcomes of research in ASEAN is likewise encouraged to monitor research performance and help in developing research management and science policies, particularly in economic development. Additional research focused on mapping of research collaboration network among ASEAN researchers and their global partners, and a brain circulation study can be done to understand the mobility of ASEAN researchers and whether such movement helps in increasing regional productivity and collaborations and whether such benefits flow back to ASEAN. Furthermore, a qualitative study that would determine other factors that influence an ASEAN researcher to collaborate with another ASEAN researcher or a global partner is suggested.

Abstract
This paper aims to propose a research agenda that explores the problems that emerge when S&T indicators are used in peripheral contexts, that is, in geographical or social spaces that are somehow marginal to the centres of scientific activity. In these situations evaluators and decision-makers are likely to use indicators that were designed to reflect variables relevant in the dominant social and geographical contexts --i.e. in the leading countries, languages, disciplines, etc.--, but that are usually not adequate in peripheral contexts. We propose to examine various dimensions of periphery. First, the cognitive dimension: areas of research, such as the humanities that capture less attention (and resources) than the more prestigious disciplines, such as molecular biology. Second, the geographical dimension: e.g. global south vs. global north, regions vs. metropolises. Third, the social group dimension: women, the poor, or perhaps the elderly have social needs that are different from those of richer or more powerful groups --and the problems affecting the former tend be less researched than those of the later. The research agenda proposed would investigate the mechanisms by which performance indicators tend to be biased against the peripheries (e.g. bias in language, journal or topic coverage in conventional databases). We suggest how these biases may suppress scientific diversity and shift research towards a higher degree of homogeneity.

Conference Topic
Science policy and research assessment

Introduction
Science and technology indicators are becoming increasingly used over a wide variety of contexts as research activities become prominent in a larger range of countries, a broader set of organisations, and over a wider range of disciplines or topics (Sa, Kretz et al., 2013). Given that the indicators used in new contexts are often the same, or close adaptations of the indicators used in the traditional disciplines, elite universities and dominant scientific countries, one may wonder about their validity (i.e. adequacy of the indicator to the concept/object is supposed to measure) and their robustness (or sensitivity to contingency in the measuring conditions) (Gingras, 2014).

In this work-in-progress contribution, we propose that many of the new contexts where indicators are used constitute what we call the peripheries or the margin of the research system: spaces that have less visibility, less prestige and/or less resources. As peripheries, these spaces have not had the capacity or influence to develop home-grown indicators suited for their activities -- and are instead relying on indicators borrowed from the central or dominant disciplines and/or countries. For example, it is a recurrent debate in policy to which extent scientometric indicators can be used in the social sciences and humanities (Martin, Tang and Morgan, 2010). Another recurrent example is the case of peripheral countries such as Brazil, where studies have showed that publication practices and citations differed significantly from those in the leading scientific nations, given that they "are significantly influenced by factors "external" to the scientific realm and, thus, reflect neither simply the

quality, influence nor even the impact of the research work referred to." (Velho, 1986, p. 71; see also Velho & Krigge, 1984).

In this contribution we explore dimensions in which the use of indicators in peripheral contexts may be problematic, providing misleading information for research assessment or strategy development. In these contexts, we propose that alternative methods should be explored and potentially developed to create new indicators that are fit for purpose.

This exploration will be developed into the central research agenda for a joint conference of the networks RICYT (the Ibero-American network of Science and Technology Indicators, http://www.ricyt.org) and ENID (the European Network of Indicators Designers, http://enid-europe.org) to be celebrated in Valencia between 14 to 16 December 2014.

A relational and multidimensional conceptualisation of periphery

The Oxford English Dictionary defines "periphery" as

"The region, space, or area surrounding something; a fringe, margin. Now chiefly: the outlying areas of a region, most distant from or least influenced by some political, cultural, or economic centre."

Its cousin, the Oxford Dictionary of English provides a slightly different definition:

"A marginal or secondary position in, or aspect of, a group, subject, or sphere of activity."

There is already a long history of grappling with the question of peripheries in relation to global social and economic change and development (Prebisch, 1949). Science studies in Latin America have long discussed their peripheral situation and how it meant that their scientific knowledge was dependent, "transplanted" and thus often not properly adapted to their domestic needs -- rather the needs of the Northern countries exploiting their economic resources. For example Vessuri (2004, p. 174) explains that:

> *"Irrespectively of their capabilities, these scientific thinkers were "peripheral" in three senses: in their marginal position in the outer ridges of European culture; in their partial commitment to the scientific endeavour (forced by the immediate pressures for survival in the middle of often unstable contexts, and the economic and political urgencies of new nations); and in their role as agents for the exploitation of natural resources of economic interest for the European centres of power, who gave them legitimacy and support." (Our translation from Spanish)*

A noticeable characteristic of this description is the multidimensional nature of the "sense" or spaces of the peripheries of Latin American scientists: culturally (or cognitively), institutionally (partial commitment), in economic terms (unstable resources and dependent on European funding) and in the topics addressed (those of interest to the centres of power).

These definitions suggest two important traits of the notion of periphery, as illustrated by Vessuri's quote above. First, it refers to a situation that is somehow marginal, far from the centre, and where, consequently, less attention is paid. The periphery is therefore *always defined in relation to a centre* where the main locus of the relevant activity resides.

Second, the concept can *relate to many different dimensions* (political, cultural, economic, different "spheres of activity"). In turn these dimensions may or may not be linked with a geographic location; for instance a centre of economic activity will be a specific geographic location. Geographic locations tend to be centre (or periphery) for a variety of dimensions: it is common for political, economic and cultural activities to cluster around geographical centres of power and influence. Similarly, peripheral regions will be peripheral along several dimensions and so the application of the term peripheral to a region has come to indicate a situation of structural disadvantage with broad economic, political and social implications. Developing countries were long ago described as "the" periphery, but within every geographical region we can also encounter peripheral zones (Southern European and Eastern European countries as peripheral to the European Union, or relatively poor regions as

peripheral within their country). Yet, not all dimensions will be correlated for a specific locality. Cambridge is a geographic centre of learning and research (a centre in a cognitive dimension) but, as a city, it is not a centre of political power, although the social group of Cambridge alumni, lecturers and researchers are part of both a political and a cognitive centre.
Also, not all relevant dimensions need to have a geographical expression. One can think for instance of social dimensions like gender or class that can be interpreted under the lenses of centre and periphery but are not associated with specific geographic localities. We can therefore refer to peripheral social groups (the disenfranchised, the poor…) whose economic and social needs will be different from those of richer or more powerful communities, even when part of this groups may be located in centres of political power (e.g. the poor neighbourhoods in Washington DC).
Similarly, cognitive dimensions are not necessarily associated with geographic locations; for instance, cognitive peripheries would include areas of research that do not capture the attention of mainstream politicians and receive more limited resources. From this perspective, many fields in the humanities could be considered a peripheral field of knowledge when compared to mainstream natural or engineering sciences.

How conventional indicators are problematic in the peripheries

As we have seen, the notion of a periphery is thus fundamentally a relational one. A periphery is always constituted in relation to a centre, or core. From an indicator perspective, the same entity may thus be peripheral or central depending on the frame of analysis. A particular region may be the centre of nanomaterials research in a particular country, but peripheral in relation to global nanomaterials research, for example. Whether the region is depicted as periphery or centre depends on the frame of comparison. A problem with the *use of indicators* is thus the risk of inappropriate comparisons that can render important activities as relatively trivial.
A second problem relates to whether what is being measured about a particular entity is relevant knowledge in terms of the needs, objectives or valued activities of that entity. The application of an indicator constructed to reflect the needs, objectives or valued activities of another entity may not produce useful information – only a mismatched comparison. A problem with the *content of indicators* is thus the risk of inappropriate comparisons that can
render important activities as relatively invisible or lacking in impact. The use of indicators can thus play a role in *constituting peripheries*.
Our goal in this section is to analyse how indicators developed to assess policies and activities related to Science and Technology address peripheral spaces and whether they have constitutive (intended or unintended) effects on these peripheries. We therefore need to identify the dimensions that are relevant to the conduct of S&T.
Each periphery faces its own knowledge generation and application context and may be better analysed using specific, tailored indicators. Yet, by and large they need to rely on indicators, and analytical models developed for the studies of "centre" spaces. Evaluators and decision-makers are likely to use indicators that were designed to reflect variables relevant in the dominant social and geographical contexts --i.e. in core regions, languages, disciplines, etc.--, but that are usually not adequate in peripheral spaces.
Let us see some examples of dimensions where use of indicators in the periphery is problematic.

Language

Language has long been known to be a major problem for performance measures, given that non-English articles tend to be much less cited. Van Leeuwen et al. (2001) showed that the inclusion or not of non-English publications in the analysis of citation impact has a major influence in the outcomes of indicators. Van Raan et al. (2011) showed that this also had

major effects in university rankings. Vasconcelos et al. (2008) showed that language proficiency is highly correlated with citation impact and h-index of researchers. This means that for the purposes of comparison, non-English publication should be excluded in most analysis.

Gender

In many fields of science, women tend to publish less and accrue less citations than men. However, various studies have consistently found that women tend to do more interdisciplinary research (e.g. Leahey, 2007; Van Rijnsoever and Hessels, 2011). Hence, the effect of gender on performance depends on the indicators choice: if publications and citations are taken as a measure of the value of a contribution, the indicators will tend to disadvantage female researchers.

Basic vs. applied vs. research

Applied studies tend to cite fundamental studies more than the reverse. As a result, fundamental research tends to appear as more central in global science maps (Rafols, Porter and Leydesdoff, 2010). This is possibly a perception bias without serious repercussions. The serious problem is that even within a given scientific field as defined by conventional classifications such as Web of Science Categories, applied research tends to be significantly less cited than fundamental research (van Eck et al., 2013).

Interdisciplinary research

Interdisciplinary research can be thought of as peripheral to the extent that it is published in areas outside the disciplinary cores. It turns out that interdisciplinary research tends to be published in journals with lower rating in journal rankings and, within a field, with journals with a lower Journal Impact Factor (Rafols et al., 2012). As a result interdisciplinary research tends to be in a disadvantage when using this type of journal-based indicators (with citation indicators, the effect may vary as it depends on relative citation rates between fields that are being cross-fertilised).

Conclusions

S&T indicators tend to be biased against organisations, countries or disciplines in the periphery. This is possibly due to the fact that indicators were not initially designed for the peripheries. At the same time, the use of these indicators in assessments linked to the distribution of resources can have constitutive effects, reinforcing for instance the peripheral character of a region or discipline. These remain unresolved problems for S&T indicators and their use in evaluation. In this contribution we shed light on this bias in multiple dimensions, in order to foster critical awareness of the problems caused by biases as well as the development of context sensitive indicators (Lepori & Reale, 2012).

Acknowledgments

Ismael Rafols thanks Diego Chavarro (who is doing a thesis on the Journal Indexing Systems in Latin America) for many illuminating discussions on indicators in developing countries.

Patterns of Internationalization and Criteria for Research Assessment in the Social Sciences and Humanities

Gunnar Sivertsen

gunnar.sivertsen@nifu.no
Nordic Institute for Studies in Innovation, Research and Education
(NIFU) P.O. Box 5183 Majorstuen, N-0302 Oslo (Norway)

Abstract

This paper investigates the developments during the last decades in the use of languages, publication types, and publication channels, in the social sciences and humanities (SSH). The purpose of the study is to develop an understanding of the processes of internationalization and to apply this understanding in a critical examination of an often used criterion in research evaluations in the SSH: Coverage in Scopus or Web of Science is seen in itself as an expression of research quality and of internationalization. This extrinsic 'coverage criterion' is beyond the control of academia and without support in analysis of how research quality and relevance is achieved through scholarly publishing in the SSH. It needs to be replaced by intrinsic criteria based on the SSH's own concepts of field-specific research excellence and societal relevance. The study will demonstrate this by using data from scholarly publishing in the SSH that go beyond the coverage in the commercial data sources by giving a more comprehensive representation of the SSH.

Conference Topic

Science policy and research assessment

Introduction

The presence of publications in Scopus or Web of Science (WoS) has increasingly become a criterion in evaluations of research in the social sciences and humanities (SSH). Some countries have even installed protocols for research evaluation or performance-based funding models where publications that are indexed by the commercial databases are treated separately in indicators of "internationalization" and "research quality". In other countries, there is a general belief that research quality can be promoted in the SSH by expecting more publications in the limited number of international journals that have been selected for indexing. Consequently, for several years already, Elsevier and Thomson Reuters have experienced a pressure from researchers in the SSH to have more journals indexed. Both providers have responded by increasing the coverage of journals and book series, and, recently, even of books in the SSH. However, the coverage of the scholarly publication output in the SSH is still limited (Sivertsen, 2014). The shortage is mainly due to the more heterogeneous scholarly publication patterns in the SSH where publishing in international journals is supplemented by book publishing and the use of journals in the native languages (Hicks, 2004; Archambault et al, 2006; Engels, Ossenblok & Spruyt, 2012; Sivertsen & Larsen, 2012; Sivertsen, 2014).

Just as with the abuse of Journal Impact Factors in research assessment in science, technology and medicine (STM), the 'coverage criterion' in the SSH represents an artefact which is external to and beyond the control of the scholarly norms and standards that it is sought to represent. It creates unnecessary tensions between fields in the SSH with different degrees of coverage in the databases. It also creates debates about what will happen to the use of books and native languages in the SSH. In these debates, the general development towards publishing in journals covered by Scopus or Web of Science is often perceived as "inevitable" and driven by new evaluation regimes, not by internal scholarly standards. In this study, I will develop an understanding of the processes of internationalization in the SSH which is

independent of the 'coverage criterion' and instead related to concepts of field-specific research excellence and societal relevance in the SSH.

Methods

For the purpose of this study, data are needed that give a complete representation of scholarly publishing it the SSH, also of publications in books, series and journals not covered by Scopus or Web of Science. In 2005, Norway was the first country to establish a national information system with complete quality-assured bibliographic data covering all peer-reviewed scholarly publishing in the total higher education sector (Schneider, 2009; Sivertsen, 2010). This national system, which is now called CRISTIN (Current Research Information System in Norway) and has been expanded beyond the higher education sector, provides the main source of data for this study.

The methodology of the bibliographic data collection in the Norwegian CRISTIN database (www.cristin.no) has been published earlier (Sivertsen, 2010; Sivertsen & Larsen, 2012; Sivertsen, 2014). Scientific and scholarly publications of all fields are covered completely according to an agreed definition. Among other criteria, the definition demands originality and scholarly format in the publication and peer-review in its publication channels. All publication channels (journals, series, book publishers) and publication types (see below) are standardized in the database.

Humanities is defined in our study as the disciplines included in this major area in the OECD Field Classification.[1] The *Social Sciences* are defined in the same way with the exception of Psychology, which we have not included in this study. Note that Law and Educational Research are classified as social sciences by OECD.

Two supplementing data sets (A, B) will be used, each of them for a more specific purpose:

A. For the analysis of publication patterns in the SSH down to the level of individual researchers, we use data from the above-mentioned CRISTIN system which cover the four years 2010-2013. The unit of analysis is publications per researcher within a variable of three publication types (articles in journals or series with ISSN; articles in books; books) and a dichotomous variable of languages (Norwegian (the native language); International languages). The data include 1,895 unique researchers in the humanities with 7,145 unique publications, and 3,229 unique researchers in the social sciences with 11,817 unique publications.
B. For the analysis of the development of publication patterns in the SSH over time, we use data that are defined and collected in the same way as in data set A, but aggregated at the level of disciplines. The data cover the years 2005-2011. The unit of analysis is publication per discipline (and major area) with the same variables of publication types and languages as in data set A. Data set B includes 14,558 unique publications in the humanities and 19,450 unique publications in the social sciences.

Results, Part I: Characteristics of the Publication Patterns in the SSH

As seen in *Table 1*, publications in journals and series represent a little more than half of the publications in the humanities and two thirds of the publications in the social sciences, indicating that book publishing is important as well, especially in the form of articles in books (edited volumes). There are, however, just as wide differences *within* each of the two major areas: Only 45 per cent of the publications in History are in journals, compared to 61 per cent in Linguistics. In Sociology, only 46 per cent of the publications are in journals, compared to 75 per cent in Economics.

[1] OECD: REVISED FIELD OF SCIENCE AND TECHNOLOGY (FOS) CLASSIFICATION IN THE FRASCATI MANUAL, version 26-Feb-2007, DSTI/EAS/STP/NESTI (2006)19/FINAL.

Table 1. Number and percentage publications per publication type. Based on data set A.

	Humanities N	*Humanities %*	*Soc Sci N*	*Soc Sci %*
Books	328	4.6 %	273	2.3 %
Articles in books	2,861	40.0 %	3,640	30.8 %
Articles in journals or series	3,956	55.4 %	7,904	66.9 %
Total	7,145	100.0 %	11,817	100.0 %

The scholarly publication types in the SSH are often discussed as if they represent alternatives to each other: Is the use of one of the publication types increasing at the cost of the others? Are monographs becoming obsolete in the SSH? Before we study the trends, we shall observe an indication that the publication types are supplementing each other rather than competing with each other. As seen in Table 2, the numbers and percentages of *the researchers* that actually use a certain publication type are significantly higher than in Table 1, indicating that more than one publication type is often present in the publishing profile of an individual researcher. As an example, although less than a third of the publications in the social sciences are articles in books, more than half of the researchers are using this publication type.

Table 2. Number and percentage of the researchers using a publication type within four years. Based on data set A.

	Humanities N	*Humanities %*	*Soc Sci N*	*Soc Sci %*
Books	297	15.7 %	273	8.5 %
Articles in books	1,187	62.6 %	1,676	51.9 %
Articles in journals or series	1,537	81.1 %	2,775	85.9 %
Total (unique researchers)	1,895		3,229	

Table 3 demonstrates to what degree the publishing profiles of individual researchers include more than one publication type. Even in the social sciences, where journal articles represent two thirds of the output, almost half of the researchers who publish these articles also use other publication types.

Table 3. Number and percentage of the researchers using a publication type that also uses another publication type within four years. The percentages are related to the numbers (N) in Table 2. Based on data set A.

	Humanities N	*Humanities %*	*Soc Sci N*	*Soc Sci %*
Books	265	89.2 %	250	91.6 %
Articles in books	891	75.1 %	1,275	76.1 %
Articles in journals or series	930	60.5 %	1,291	46.5 %

So far, we can conclude that book publishing and journal publishing seem to supplement each other rather than represent alternatives in the SSH. We will return to a possible explanation for this in the discussion at the end.

We now turn to another dimension in the publication patterns of the SSH – the language dimension. In non-English speaking countries, the use of the native language in scholarly

publications is an indication that the publication is mainly oriented at a national or regional audience of readers in which not only peers, but also students, policy makers, professionals, media and a wider public may be reached as well. Since scholarly publications in the native languages are relatively frequent in the SSH, publishing in an international language is, on the other hand, not the normal situation, as in the sciences, but a clear expression of an ambition to reach an international audience of experts in the field.

We proceed as with the publication types and start with an overview of the use of language in publications in Table 4. In both the humanities and the social sciences, the majority of scholarly publications are in the international languages. However, publications in the native language are much more frequent than in the sciences, indicating that such publications have a specific role in the SSH.

Table 4. Number and percentage publications per language type. Based on data set A.

	Humanities N	*Humanities %*	*Soc Sci N*	*Soc Sci %*
International language	4,368	61.1 %	8,666	71.7 %
Norwegian language	2,777	38.9 %	3,418	28.3 %
Total	7,145	100.0 %	11,817	100.0 %

Again, the question may be raised: Are the native and international languages supplementing each other, or are they competing as alternatives? By going down to the level of individual researchers, we can observe in Table 5 that high proportions of the researchers combine both types of languages in their publication practice. While a majority of researchers publish in the international languages, there is *no minority of researchers* publishing in the native language only. Researchers in the SSH are *normally bilingual* in their publication practice (if their native language is not English).

Table 5. Number and percentage of the researchers using international and native languages in their scholarly publications within four years. Based on data set A.

	Humanities N	*Humanities %*	*Soc Sci N*	*Soc Sci %*
International language	1,482	78.2 %	2,687	83.2 %
Norwegian language	1,228	64.8 %	1,725	53.4 %
Total (unique researchers)	1,895		3,229	

A more general conclusion from the results so far, is that although the *majority of publications* in the SSH are published in journals and in international languages, *the majority of researchers* are publishing in books and in the native language as well. Is this picture changing?

Results, Part II: Developments in the Publication Patterns in the SSH

To study the developments, we use data set B, by which it is possible to cover a longer period of time. The general picture is that the publication patterns in the SSH are quite stable, both with regard to publication types (Figure 1) and the use of international versus native languages (Figure 2). In relative shares, the uses of international languages and of journals are increasing, but not by a high rate. In absolute numbers, there is no in reduction book publishing or the use of the native language, since in data set B, which we are using here, there was an increase in the total number of publications by more than 50 per cent between 2005 and 2011.

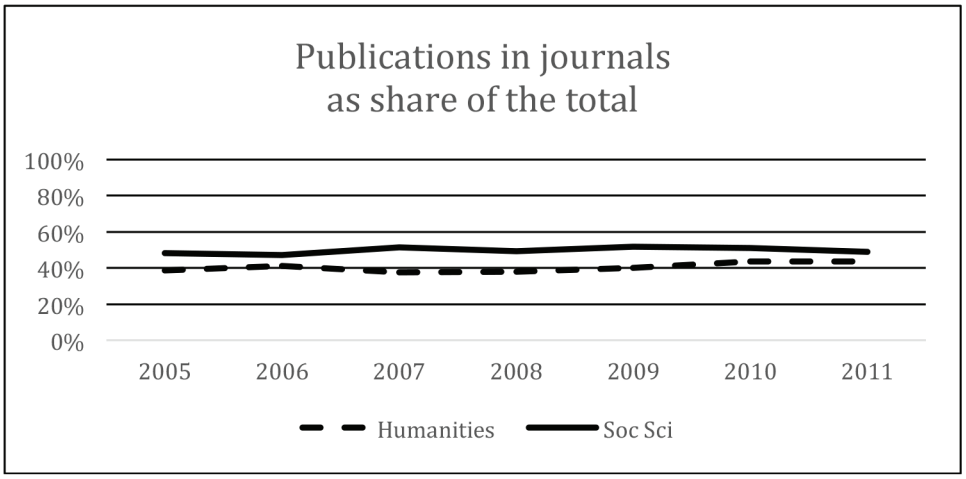

Figure 1. Scholarly publications in journals as a percentage of the total, which also includes articles in books and books. Based on data set B.

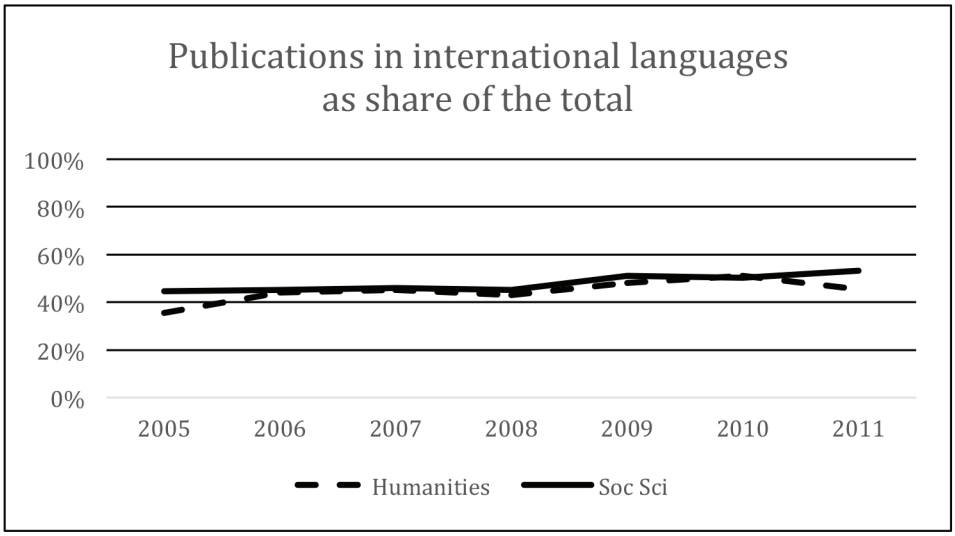

Figure 2. Scholarly publications in international languages as a percentage of the total, which also includes publications in the native language. Based on data set B.

Discussion and Conclusions

The normal publication practice in the SSH, in which both types of languages, and books as well as journals, are used for scholarly publishing by the majority of researchers, seems to prevail during a period of internationalization. The stability of the publication patterns, as well as their differences *within* the SSH (Sivertsen & Larsen, 2012; Ossenblok, Engels & Sivertsen, 2012), indicate that the choice of language and publication type is not just a question of new trends versus old traditions. Publication patterns are more deeply rooted in scholarly norms, methods and practices. The monograph, the edited book and the journal article represent different methodologies that may all need to be used at different times. The choice of language depends on the international scholarly relevance of the research versus the societal relevance for the culture and society being studied. One and the same research project may well contribute with different parts to both dimensions. The SSH would lose their *raison d'être* and societal impact by disconnecting from the surrounding culture and society and mainly communicating in international journals that are only read by peers abroad. At the same time, publishing in those specialized journals on the international level is necessary in

order to be confronted with and inspired by the scholarly standards, critical discussions and new developments among other experts in the field.

In the context of criteria for research evaluation in the SSH, there is a need to accept that none of the alternatives in the two dimensions of the scholarly publication patterns that have been described here – language and publication type - can be regarded as more valuable alternatives. All of them contribute – with different roles and connected to different methodologies, audiences and feedbacks – to research excellence and societal relevance of the SSH. The coverage in Scopus or the Web of Science of the scholarly publishing pattern in the SSH is far from complete (Sivertsen, 2014). Hence, *coverage in a commercial indexing service* should not be used as a criterion for research quality or an indicator of internationalization in the SSH.

Abstract
As science policy shifts towards an increasing emphasis in societal problems or grand challenges, new scientometric tools are required to inform decision-makers. However, while traditional bibliometrics could focus on the knowledge production side (the science supply), grand challenges also demand to investigate the articulation of societal needs. In this paper, we present an exploratory investigation of the grand challenge of obesity -an emerging health problem with enormous social costs. We illustrate a potential approach, showing: (a) how scientific publication can be used to describe existing science supply by using topic modelling based on publication abstracts; (b) how question records in the French parliaments can be used as an instance of social demand; and (c) how the comparison between the two may show (mis)alignments between societal concerns and scientific outputs.

Conference Topic
Science policy and research assessment

Introduction
Tackling complex global problems or grand challenges – such as climate change, food security, poverty reduction, risk of global pandemics – requires not only to increase R&D expenditure, but also the exploration and eventually the coordination of a variety of stakeholders with different areas of expertise and pursuing diverse research avenues. Typically these challenges benefit from the understanding of the physical and biological phenomena underlying a challenge (e.g. the virus and its genes), but also demand an understanding of the environmental and social contexts in which they occur, and the policy networks and instruments available in those contexts (Ely, Van Zwanenberg & Stirling, 2014).
Science policy funding schemes for societal problems or grand challenges seek to align science supply with social problems or needs. Although science is conducted in conditions of incomplete knowledge, it is well documented that certain particular research options are much

better aligned to certain outcomes (Sarewitz, 1996, pp. 31–49). It is, for example, very unlikely that astrophysics be useful for improving health care in malaria. Historically, several lines of inquiry in science policy have explored the alignment between research options and social outcomes, namely related to priority-setting and evaluation of research, but also to broader considerations related to the "supply" and "demand" of policy-relevant science. For this reason, a suitable interpretation of the alignment issue should be based on our understanding of the current state of the science (the *supply*) and what is required to achieve social goals (the *demand*) (Sarewitz & Pielke, 2007). The "demand" side must therefore consider not only the plurality of outcomes, but also various ways of articulating specific science or technology -driven pathways for achieving them. This in turn can refer to a process of public deliberation whereby different outcome preferences or divergent underlying values are made explicit by stakeholders. Similarly, the "supply" side is not just about how much "high-risk, high-return" research should be undertaken, but also about what type of outcomes are more or less *likely* to result from a given line of research. In this article, one the one hand, we apply the concept of *research landscape* (Wallace & Rafols, 2014) in order to map the scientific research on obesity.

On the other hand, we symmetrically map one of the interpretations (representations) of social needs (demand) on obesity. The supply-demand schema can be represented as in Figure 1. Here societal demand and scientific supply are not related directly in one single way. Instead they can relate via a variety of interpretation/representations of the "obesity" social needs. These representations shape science policy and affect actions that may reconcile supply and demand.

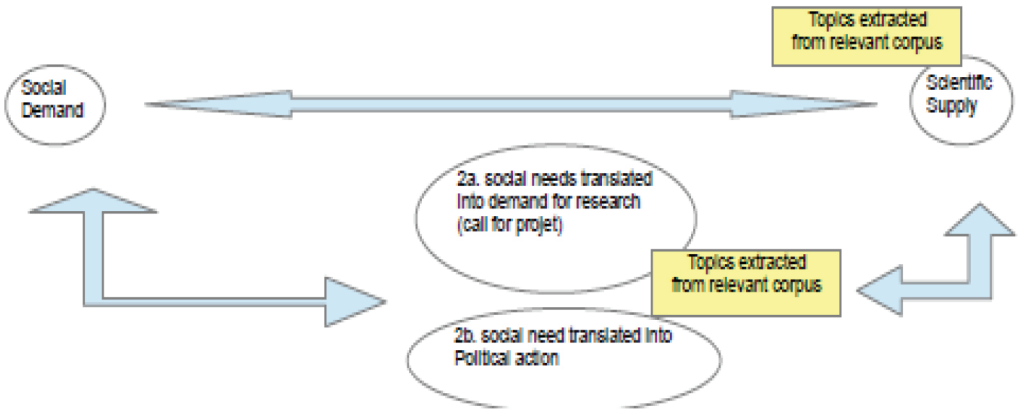

Figure 1. Social demand – scientific supply and political discourse as an example of intermediary representation.

In this paper we investigate the alignment (or lack thereof) between science supply and social demand by mapping, first, the scientific supply via the research landscape of obesity as defined by topic modelling of publication abstracts, and, second, social demand according to political discourse in the French parliaments. These maps of both supply and demand are specific and partial representations used in this preliminary and exploratory study -- other, complementary representations would be possible. For example, supply could be represented by a topic modelling of grants abstracts (as Talley et al., 2011 did for the US National Institutes of Health). And demand could be mapped using newspaper articles, among many other sources.

Data and Methods

Data

In order to define the relevant corpus for obesity, we follow a two-step method. First, we retrieve all publications with indexed MeSH term matching the search *obes** in MEDLINE/PubMed during the 2002-2013 period. This search was performed on October 16, 2014 and it returned 87,315 records.

Then, we launched *medlineR*, a routine based on the R language that allows the user to match data from Medline/PubMed with records indexed in the ISI Web of Science (WoS) database (Rotolo & Leydesdorff, 2015). The routine identified 71,055 WoS records (WoS core collections), with 'article' or 'review' as document types.

Second, we used Leiden's classification system to identify clusters of publications related to obesity. The classification system is constructed at the level of individual publications and clustering is based on direct citations (Waltman & van Eck, 2012) for the period 2000-2013. Obesity publications appear in 4,718 micro-clusters (in which at least one publication is tagged obesity), out of 32,466 micro-clusters for the whole WoS corpus. All the publications from clusters with at least 25% of publications tagged as 'obesity' were considered to be relevant for the study. This threshold of 25% is arbitrary and exploratory. Further explorations will use a lower threshold to test the robustness of this choice. The obesity corpus thus obtained contains 54,424 publications.

Topic modelling

Topic modelling provides a suite of algorithms to discover hidden thematic structure in large collections of texts. A topic model takes a collection of texts as input and it discovers a set of topics (recurring themes that are discussed in the collection) and the degree to which each document exhibits those topics.

Latent Dirichlet Allocation (LDA) is the simplest topic model. The intuition behind LDA is that documents exhibit multiple topics. LDA is a statistical model of document collections that tries to capture this intuition. It is most easily described by its generative process, the assumed random process. A topic is defined as a distribution over a pre-defined vocabulary. Moreover, it is assumed that the topics are specified before data have been generated (technically, the model assumes that the topics are generated first, before the documents). Now for each document in the collection, we generate the words in a two-stage process:

1. Randomly choose a distribution over topics.
2. For each word in the document
   (a) Randomly choose a topic from the distribution over topics in step #1.
   (b) Randomly choose a word from the corresponding distribution over the vocabulary.

This statistical model reflects the idea that each document contains multiple topics. Each document exhibits the topics with different proportion (step #1); each word in each document is drawn from one of the topics (step#2b), where the selected topic is chosen from the per-document distribution over topics (step #2a).

The goal of topic modelling is to automatically identify the topics from a collection of documents. The documents themselves are observed, while the topic structure (the topics, per-document topic distributions and the per-document per-word topic assignments) is a hidden structure.

Results on Science Supply

For this study, we fitted a 100-topic model to the 54,424 publications of the obesity corpus. We perform LDA with the R package “topicmodels” and visualize the output using LDAvis.

Figure 2 shows a map of these 100 topics. Topics are located close to one another if they are similar in terms of distributions of the words belonging to the selected dictionary. The measure of topic similarity is the matrix of Jensen-Shannon divergences between topics, considered as distributions over words, into two-dimensional coordinates and is represented in a 2d space through multi-dimensional scaling (i.e., principal coordinates analysis).
In addition, a clustering technique is used to cluster topics into research areas. We applied k-means clustering to the topics as a function of their two-dimensional locations in the global topic view with k=10. Labels are assigned to clusters. These labels are obtained by extracting the most relevant terms for each cluster of topics, where the term distribution of a cluster of topics is defined as the weighted average of the term distributions of the individual topics in the cluster.

Figure 2. Map of topics of publications on obesity (2003-2013).

Results on the Societal Demand

The same approach has been used to map the social demand. In order to define one possible interpretation, we refer to the questions that the members of the French Parliament (i.e. Assemblée Nationale or Senate) can ask to the government. Deputies and senators publicly question the members of the Government in different ways. The question can be asked during a Parliament session to the government or be written and a Parliament session is not necessary and addressed to one of the ministers. We retrieved this information and built up two datasets.

First, we selected all the questions asked by the Senators where the word *obes** was reported in the public database - with records from 1985 on - which is now available. We got 242 questions from 1992 - year of the first occurrence of 'obesity' in these questions - to 2014. Second, we collected oral and written questions asked by members of the Assemblée Nationale in the last three legislatures, getting: 422 questions (2002-2007), 870 (2007-2012) and 380 (2012 – 2014). The output of the 10-topic model is shown below for the Senate questions.

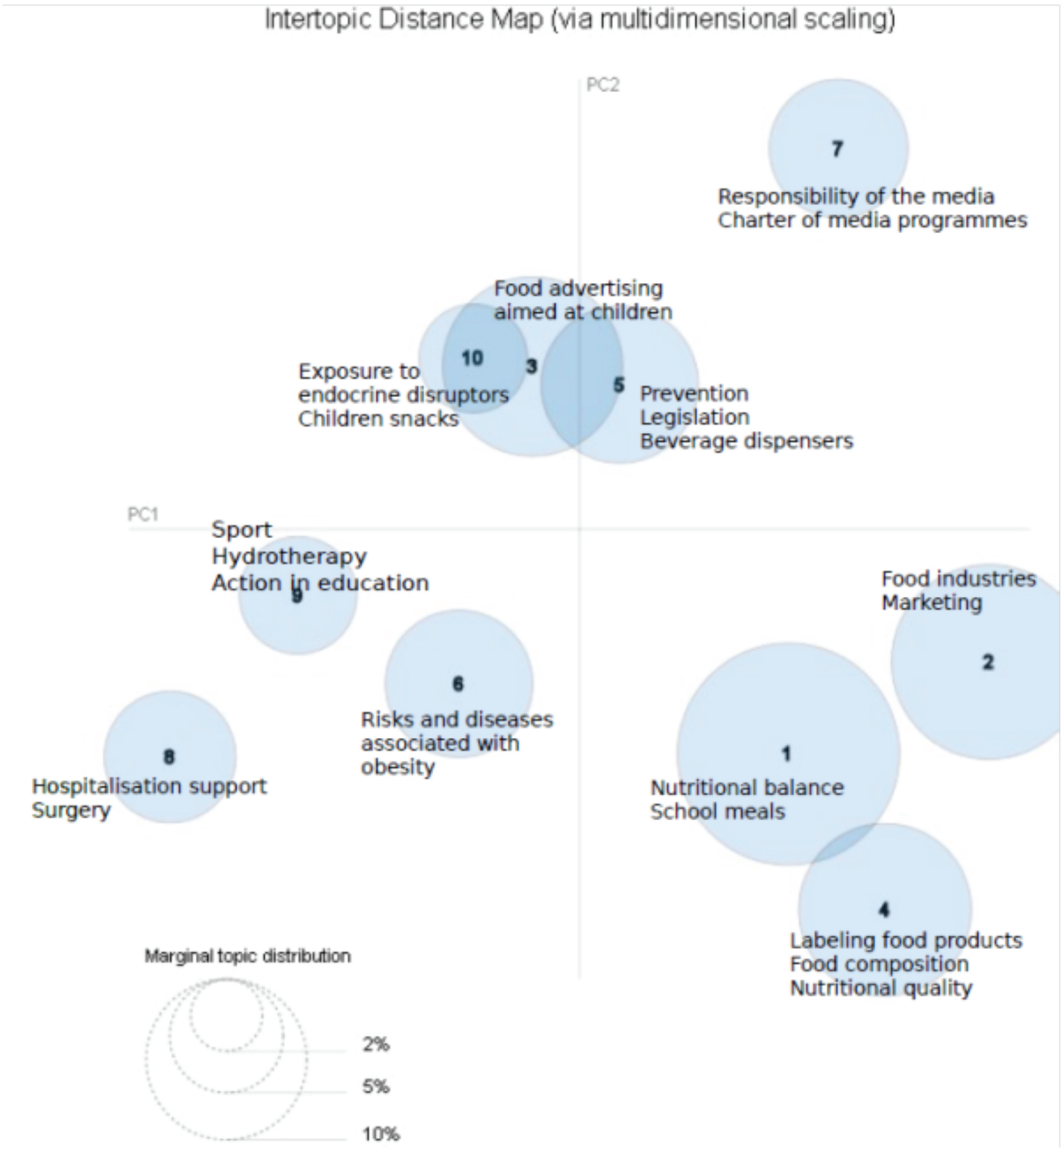

Figure 3. Map of topics for questions in the French Senate (1992-2014).

Discussion

In the centre of the Figure 2, we have a cluster of topics concerning *Physical activity, psychology and quality of life*, then turning around clockwise we find *Food consumption and diet* and then two clusters concerning mainly topics linked to biology research and further four clusters related to medical and surgery issues. The clusters of topics identified in the research landscape are mainly concerning medical and biological issues and only two clusters seem to deal with social and behavioural determinants of obesity, respectively *Obesity & ethnicity* and *Food consumption and diet*. The political discourse (Figure 3) seems to be organised around topics different from the research landscape. Among *the ten topics defined*

three main groups are reasonably identified. The first one, on the top part of the graph (i.e., topics number 3, 5, 7 and 10), is concerned mainly with children nutrition and the role of media as in advertising. A second group of topics, on the bottom right of the graph (i.e., topics number 1, 2 and 4), deals with food industry, marketing, and labelling issues. Finally, a third group, at the bottom left (i.e., topics number 6, 8 and 9) is concerned by medical and surgery issues. Only three out of ten topics of political discourse seem to find a counterpart in the research landscape. A preliminary analysis therefore suggests that, while research is concerned about the biophysical mechanisms that lead to obesity, many of the political questions are about the social mechanisms that favour obesity, such as advertisement, beverages, marketing, etc. This may suggest insufficient research regarding the social origin of obesity.

Acknowledgments

We would like to thank Tommaso Ciarli for suggesting to us the use of Parliament database as one of the possible representations of social needs. We thank Ludo Waltman for sharing the article level classification system.

Abstract
Do highly productive researchers have significantly higher probability to produce top cited papers? Or does the increased productivity in science only result in a sea of irrelevant papers as a perverse effect of competition and the increased use of indicators for research evaluation and accountability focus? We use a Swedish author disambiguated dataset consisting of 48,000 researchers and their WoS-listed publications during the period of 2008-2011 with citations until 2014 to investigate the relation between productivity and production of highly cited papers. As the analysis shows, quantity does make a difference.

Conference Topic
Indicators; Science policy; Research assessment

Introduction
One astonishing feature of the scientific enterprise is the role of a few extremely prolific researchers (Price, 1963). Thomson Reuters call them *Highly Cited Researchers* and they are listed and recognized per area. Based on another dataset, Scopus publications, Klavans & Boyack (2015) call them "superstars" and use them for large-scale studies of publication behaviour, thereby showing that superstars publishes less in isolated areas (retrieved using a clustering procedure), in dying areas, or in areas without an inherent dynamics. Highly productive and cited researchers tend to look for the new opportunities. Obviously, the highly productive researchers have to be taken into consideration for many reasons, both for science policy and for scholarly understanding of how the science system works.
Within bibliometrics there is a discussion on how to measure and to identify the superstars. Many current papers discuss the correlation between the various indicators developed for performance measurement. One of the stable outcomes is that there is a high correlation between the numbers of papers a researcher has published and the number of citations received (Bosquet & Combes, 2013). From that perspective, both indicators tend to measure the same attribute of researchers, as is actually materialized in the introduction of the H-index (Hirsch, 2005). Parallel, the discussion about impact has shifted from counting (field normalized) numbers of citations to more qualified types of citations and publications. As the progress of science rests on the huge amount of effort and publications, the number of real discoveries and path breaking new ideas is rather small. This has led to a different focus. Instead of counting publications and citations, the decisive difference is whether a researcher contributes to the small set of very highly cited papers. Different thresholds are deployed, from the top 1% or 10% of the highly cited papers or with the CCS method proposed by Schubert & Glänzel (1988). Only when reaching into these select set of papers that qualifies for citations above the x% level one can be considered as really having distinctive result that contributes to scientific progress. Increasingly, performance measures take this selectivity into account, and when calculating overall productivity and impact figures for researchers, papers (productivity) and citations (impact) are weighted differently depending on the impact percentile the paper belongs to (Sandström & Wold, 2015).
Of course, the question now comes up what a good publication strategy is – given this way of performance evaluation. Is publishing a lot the best way – or does that generally lead to normal

science, with low impact papers? The total number of citations received may still be large, but no top papers may have been produced. This is also the underlying idea of emerging movements in favour of 'slow science' like e.g., in the Netherlands; there the 'science in transition' movement (Dijstelbloem et al., 2014) was able to convince the minister of science and the big academic institutions to remove productivity as a criterion from the guidelines for the national research assessment (SEP). The underlying idea is that quality and not quantity should dominate – and that with all the emphasis on publications this has become corrupted.

However, others seem to see this differently. In his important work on scientific creativity, Simonton (2004) has extensively argued that (i) having a breakthrough idea is a low probability event that happens by chance, and therefore that (ii) the more often one tries, the higher the probability to have a 'hit' so now and then. There are also other contextual factors that may improve the chance for important results, but overall, the number of tries (publications) is the decisive variable. This also explains why Nobel laureates have so many more publications than normal researchers (Zuckerman, 1967; Sandström & Van den Besselaar, forthcoming). The more often you try (publish), the higher the probability that there is something very new and relevant, and atypical for the scientific community (Uzzi et al., 2013).

This brings us to the question whether there is a strong positive, or a negative relation between overall output (number of publications) and high impact papers. The answer of this question may inform our understanding of knowledge production and scientific creativity, but is also practically relevant for selection processes, and as explained above for research evaluation procedures: is high productivity a good thing, or a perverse effect and detrimental to the progress of science?

Methods and Data

In order to investigate this, we use the 74,000 WoS-publications 2008-2011 (with citations until 2014) of all researchers with a Swedish address using the following document types in databases SCI-E, SSCI and A&HCI: articles, letters, proceeding papers and reviews.

For identifying authors and keeping them separate we use a combination of automatic and manual *disambiguation* methods. An algorithm for disambiguating unique individuals was developed by Sandström & Sandström (2009), based on Soler (2007) and Gurney, Holdings & van den Besselaar (2012) and was found to proceed fast, although with minor manual cleaning methods. The deployed method takes into account surnames and first-name initials, the words that occur in article headings, and the journals, addresses, references and journal categories used by each researcher. There is also weighting for the normal publication frequency of the various fields.

As indicated, the data covers 74,000 articles and 195,000 author shares that have been judged to belong to Swedish universities or other Swedish organisations. In a few cases, articles from people who have worked both in Sweden and in one or more Nordic countries have been kept together, and articles have thus been included even if they came into being outside Sweden (the process of distinguishing names is thus carried out at Nordic level).

All articles by each researcher are ranked, based on received citations and according to the about 260 subject categories as specified in the Web of Science, and the articles are divided into CSS (Characteristic Scores and Scales) classes (0, 1, 2, 3). While measures based on percentile groups (e.g. top1% etc.) are arbitrarily constructed, CSS have some advantages concerning the identification of outstanding citation rates (Glänzel & Schubert, 1988). The CSS method is a procedure for truncating a sample (e.g., a subfield citation distribution) according to mean values from the low-end up to the high-end. Every group created using this procedure helps to identify papers that fulfil the requirements for being cited above the respective thresholds. In this paper we will use two levels, level CSS1 and CSS3, which in the

former case cover the 20%-25% most cited papers, and in the latter case the about 2%-3% of most cited papers: the "outstandingly cited papers" (Glänzel, 2011).
In this paper we will investigate the relation between quality and quantity in several different ways. We proceed in this way, as from a methodological perspective different options are open, without a convincing argument which one would be the better. By using a variety of methods, we avoid to produce results as artefacts of the method deployed.
(i) Firstly, we calculate the probability to have one, two or three and more top cited papers, given the productivity level. We calculate this for the health, i.e. medical sciences (about 15,000 researchers), where we classify these authors in several productivity classes. Class 1 has one publication in the four years period under study, class 2 has two, class 3 has three to four, class 4 has five to eight, class 5 has nine to sixteen, class 6 has seventeen to 31 publications, and finally class 7 covers researchers with 32 or more publications. Publications are integer counted, but citations are field normalized.
(ii) Secondly, we do a simple regression with the total number of (integer counted, IC) publications as the independent variable, and the (also integer counted) number of top cited publications in terms of one of the definitions as discussed above. Also, here citations are field normalized. We have here all researchers, without normalizing for field based productivity figures. As the total set of researchers is dominated by life and medical sciences and by natural sciences, and as these groups have comparable average publications and citations, we assume that this does not really influence the results. Under point four below, we introduce a way of taking field differences in productivity into account.
(iii) Thirdly, we do the same analysis as described above, but use fractional instead of full counting. This helps to investigate the effect of different ways of counting on the relations under study.
(iv) Fourthly, we move to the field-normalized (fractional counted) productivity, and calculate the relation between in this way defined productivity and having at least one publication in CSS1 respectively in CSS3. In the last analysis, we can provide an integrated analysis of all researchers across all fields, as we produced field normalized output counts. This is done with a method – Field Adjusted Production (FAP) based on Waring estimations – as initially developed by Glänzel and his colleagues (Braun, Glänzel & Schubert, 1990; Koski, Sandström & Sandström, 2011) during the 1980s. FAP is further explained and tested in Sandström & Sandström (2009). Basically, the method is used in order to compensate for differences between research areas concerning the normal rate of scholarly production. For this all journals in the Web of Science have been classified according to five categories (applied sciences, natural sciences, health sciences, economic & social sciences, and arts & humanities). Categorisation of journals into macro fields is based on Science Metrix classification of research into five major domains. Note that in some of the following analysis we will refrain from applying the Waring method, consequently, instead the analysis will be performed per scientific macro fields (for further information, see < http://science-metrix.com/en/classification>).

Results

(i) Does the probability of highly cited papers increase with productivity?

We calculated the number of top cited papers (CSS3) for each of the seven productivity classes. From this, Figure 1 was created. Clearly, the probability increases with productivity, and this is the case for 1, 2 and 3 or more papers in the CSS3 class. In fact, the relation is slightly different for the three criteria. The higher the criterion, the larger the effect is at the high end of the productivity distribution.

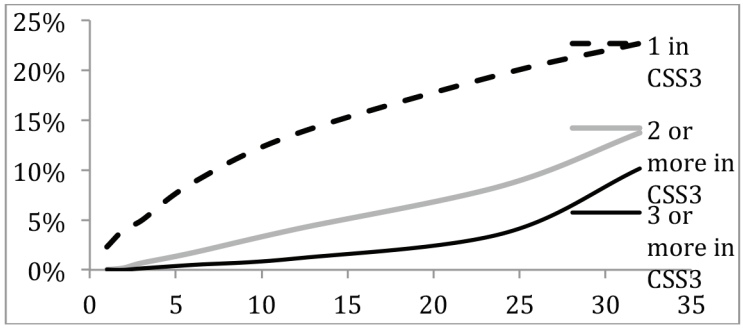

Figure 1. Share of papers in the CSS3 top cited class by productivity class.

(ii) What is the effect of productivity on the number of highly cited papers?

We have done a regression analysis with highly cited papers as dependent variable, and productivity as independent variable. We did the analysis for the various top cited classes. In the three figures below, we show the regression results. For papers in the top 1% of the cited papers (Figure 1) the correlation is about 0.5. For the CSS3, the top 10% of the cited papers, and the CSS1 classes, the correlations are 0.58, 0.78 and 0.88. The correlations are fairly high.

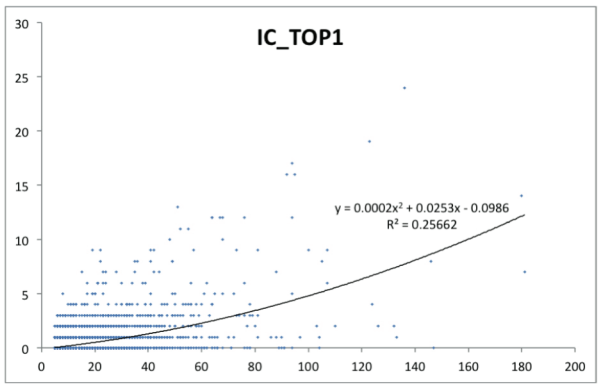

Figure 2. Top 1% of cited papers by total number of papers.

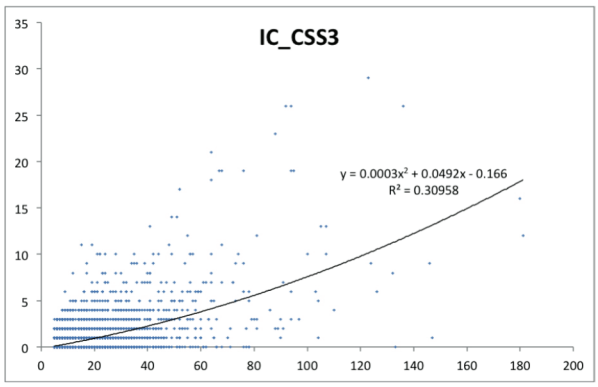

Figure 3. CSS3 cited papers by total number of papers.

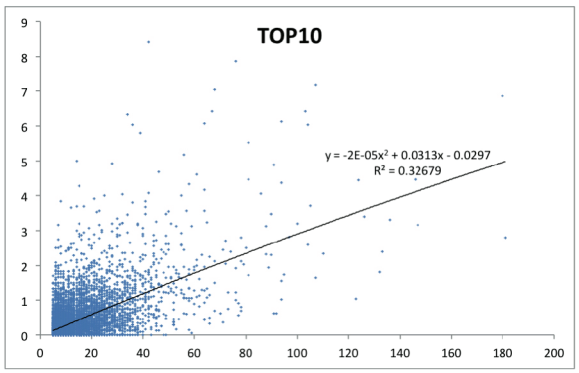

Figure 4. Top 10% of cited papers by total number of papers.

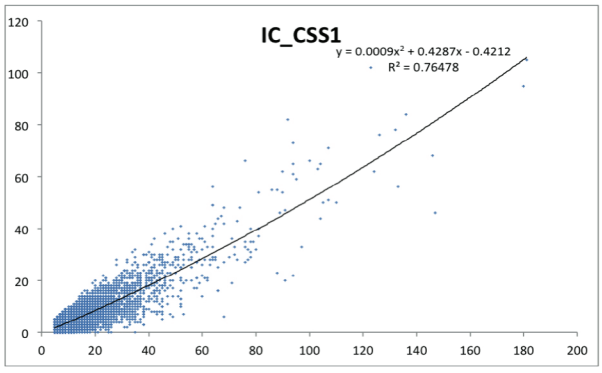

Figure 5. CSS1 cited papers by total number of papers.

Interestingly, the correlation becomes higher the lower the citation threshold. Why this is the case is not yet investigated. A possibility is that high productive researchers with top papers always have co-authors of these high cited papers who themselves are not highly productive. In that sense one also expects top cited authors in the lower productivity segments, reducing the explained variance. So probably, one should only include PIs in the analysis to avoid this effect. This could be the topic for a subsequent study.

One should realize that a small share of all authors produces most of the papers and of the highly cited papers. The 6.3% of most productive researchers (everybody above eleven publications in four years) are responsible for 37% of all papers and for 53% of the top 1% of the cited papers. Also this supports the idea that quantity makes a difference.

(iii) And the effect of fractional counted productivity on the number of highly cited papers?

We did the above analysis also using fractional counting of productivity. The patterns are the same, but the correlations are about .15 to .20 lower than in the full counted model. How this can be explained will be addressed in a coming paper. But also here, the 6.3% of the most productive authors are decisive: they have 46.8% of the fractional counted top 1% of the cited papers.

(iv) What is the effect of field adjusted production counting?

The relation between having at least one paper in CSS1 and total field normalized output is plotted in Figure 6, and as becomes obvious, the correlation is fairly high (r = 0.79), and not much smaller than in the above four where we did not use the field adjusted production (0.90, see Figure 5). The results here suggest that indeed the more papers someone publishes, the higher the probability of having a paper in the group of fairly good papers cited above the threshold of CSS1.

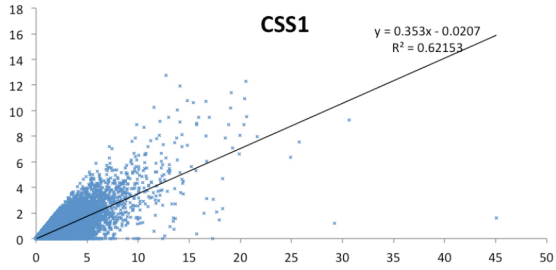

Figure 6. Fractionalized CSS1 by field adjusted production (all areas of science).

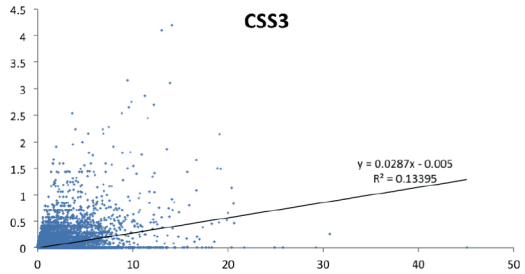

Figure 7. Fractionalized CSS3 by field adjusted production (all areas of science).

We also plot the relation between having at least one paper in the CCS3 (Figure 7), so in a much more narrow defined top, and field-normalized productivity, and although correlation is lower here, it is still considerable (r = 0.37). However, in the CSS3 case, the correlation when applying FAP is lower than the correlation without applying FAP (Figure 3), namely is 0.58. These differences need some further exploration.

The underlying distribution for the fields of Natural sciences and Medical and Life sciences are given in Table 1, which shows for seven distinct productivity categories the percentage of Swedish researchers in that category, the average number of papers published in a four-year period, the average fraction of paper production, and of course the percentage of researchers with at least one paper in CCS3.

As 'field adjusted' production (FAP) might be a rather abstract concept, we have translated it below for the various disciplines into 'normal papers'. So, what is the relation between the number of papers produced (in a period of four years) and the probability of having a 'top cited paper' (in the top 2%-3% cited papers CSS3 class) during the period 2008-2014? This is a more sophisticated version of the analysis presented in section (i) above. As we clearly see in Table 2, the higher the number of papers, the more likely that one has a paper that ends up to be an outstandingly cited paper. Actually, the increase is rather steep and one may say that in most disciplines only with some ten papers in the period under consideration, there is a good chance of having a top paper. The humanities have a different pattern, as with a production of five papers one has the highest chance of reaching the top.

Table 1. CSS3 papers by production levels, Health sciences and Natural sciences

	Medical and life sciences				Natural sciences			
Category	researchers	Mean P	Frac P	CSS3	researchers	Mean P	Frac P	CSS3
1 (1 paper)	40.8%	1	0.2	0.03	9,0%	1	0.2	0.02
2 (2 papers)	16.92%	2	0.4	0.06	16,3%	2	0.5	0.05
3 (>2-4)	17.08%	3.4	0.7	0.10	17,4%	3.4	0.9	0.10
4 (>4-8)	13.36%	6.1	1.3	0.21	13,7%	6.1	1.6	0.21
5 (>8-16)	7.23%	11.6	2.4	0.44	8,3%	11.5	2.8	0.40
6 (>16-32)	3.36%	22.3	4.4	1.05	4,1%	22.0	4.7	0.87
7 (>32)	1.18%	50.5	8.8	3.45	1,2%	47.6	9.8	2.68
Average		4.3	0.9	0.17		4.6	1.1	0.17

Data for this table is built on publications from 37,114 researchers.

Table 2: Probability of one outstanding paper (CSS3) at different levels of production.

Average # of		Discipline				
publications	Class	Natural	Health	Applied	Ec &Soc	Hum
1	1	5%	7%	7%	6%	9%
2	2	11%	13%	13%	13%	8%
3	3	20%	21%	21%	24%	25%
6	4	31%	34%	33%	34%	33%
11	5	49%	54%	53%	55%	33%
20	6 / 7	61%	80%	66%	83%	
38	7			88%		
46	7	83%				
49	7		93%			

Note: Data for this table consist of ≈190,000 article shares with <40 authors per paper. The numbers of publication are the field-specific averages per productivity class (for more information, see Table 1).

Conclusions

As the above results show, there is not only a strong correlation between productivity (number of papers) and impact (number of citations), that also holds for the production of high impact papers: the more papers, the more high impact papers. In that sense, increased productivity of the research system is not a perverse effect of output oriented evaluation systems, but a positive development, as it strongly increases the occurrence of breakthroughs and important inventions (c.f. Uzzi et al., 2013). The currently upcoming discussion that we are confusing quality with quantity therefore lacks empirical support. As we deployed a series of methods, with results all pointing in the same direction, the findings are not an artefact of the selected method.

The analysis also gives an indication of the output levels that one may strive at when selecting researchers for grants or jobs.

We also plan some future work: Firstly, we plan to extend the analysis to some other countries, which of course requires large-scale disambiguation of author names. Secondly, we will in a next version control for number of co-authors, and for gender. The former relates to the discussion about team size and excellence, the latter to the ongoing debate on gender bias and gendered differences in productivity. Thirdly, the aim is to concentrate on principle investigators, and remove the incidental co-authors with low numbers of publications, as they may seem to be high impact authors at the lower side of the performance distribution. This all should lead to a better insight in the relation between productivity and impact in the science system.

Abstract
In most countries, basic research is supported through governmental research councils that select, after peer review, the individuals or teams what will receive funding. Unfortunately, the number of grants these research councils can allocate is not infinite, and many researchers (45% in Quebec) are not able to obtain any funding. A small minority of those who do get funded account for the majority of the available funds. However, it is unknown whether or not this is an optimal way of distributing available funds. The purpose of this study is to measure the relation between the amount of funds given to 14,103 individual Quebec's researchers over a fifteen year period (1998-2012) and the total outcome of their research in terms of output and impact from 2000 to 2012. Our results show that both in terms of the quantity of papers produced and of their scientific impact, the concentration of research funding in the hands of a so-called 'elite' of researchers generally produces diminishing returns.

Conference Topic
Science policy and research assessment

Introduction
In most countries, basic research is supported through governmental research councils that select, after peer review, the individuals or teams that will receive funding. Unfortunately, the number of grants these research councils can allocate is not infinite. For example 20% to 45% of Quebec's researchers, depending on the discipline, had no external funding between 1999 and 2006 (Larivière et al., 2010). National scientific agencies, including the National Science Foundation (NSF – United States) and Natural Science and Engineering Research Council (NSERC – Canada), also tend to give fewer grants of a higher value, which leads to high rejection rates (Joós, 2012; NSERC, 2012; NSF, 2013). In Canada, 10% of the researchers funded by the Social Sciences and Humanities Research Council (SSHRC) accumulate 80% of available funds, 10% of those funded by the Canadian Institutes of Health Research (CIHR) obtain 50% of the funds, and 10% of those funded by the NSERC accumulate 57% of the funds.[1] The situation is similar in Quebec where we combine funding from the national

[1] Data compiled by the Observatoire des Sciences et Technologies (OST) using results of competition for each of the councils, and the *Almanac of Post-Secondary Education in Canada, of the Canadian Association of University Teachers*.

and provincial agencies: 20% of the researchers getting 80% of the funds in social sciences and humanities (SSH), 50% of the funds in health, and 57% of the funds in natural sciences and engineering (NSE) (Larivière et al., 2010). With a few researchers receiving most of the funds available and many not receiving any, it seems legitimate to ask whether this concentration of funds leads to better collective gains than funding policies that promote a more even distribution of funding. The aim of this study is to provide a partial answer to this question, by linking the amount of funding obtained by Quebec's scientists with their research productivity and impact.

Even though the funding of science theoretically plays a substantial role in scientific discoveries, its relation to outcomes has not been extensively researched. McAllister and Wagner (1981) observed a linear relationship between funding and output at the institution level. A few years later, Moed et al. (1998) found that departments of Flemish universities with the most funding actually had a decrease in publications. Other studies (e.g., Heale et al., 2004 and Nag et al., 2013) investigated the relation between the amount of funding and the research output of individual researchers. They reported that one of the strongest determinants of the number of publications was the amount of funding, although an increase in funds did not yield a proportional increase in the number of articles. Thus, there are decreasing returns to scale. Others have found that productivity is only weakly related to funding (Fortin & Currie, 2013), and that publications do not increase linearly with the amount of funding but rather appears to reach a plateau (Berg 2010). On the whole, while most studies—unsurprisingly—found a positive relationship between inputs and outputs, very few have looked at decreasing returns to scale associated with the concentration of research funding. Nicholson and Ioannidis (2012) found that only a minority (about 40%) of all researchers eligible to NIH funding who published highly cited articles (1000 citations or more) actually received such funding. Previous studies found that funded researchers publish more (Gulbrandsen & Smeby, 2005) and are more cited (Zhao, 2010; Jowkar, 2011; Campbell et al., 2010; van Leeuwen et al., 2012) than those who do not receive any funding.

This study aims to contribute to this debate, by analyzing the research output and impact of all of Quebec's researchers from all disciplines over a period of 15 year. More specifically, it aims at answering two questions: 1) how does the research productivity and scientific impact of individual researchers vary with the amount of funding they receive? 2) Is this variation similar in the three general fields of science that are health, natural sciences and engineering, and social science and humanities?

Methods

Data on funding for all Quebec's academic researchers from 1998 to 2012 were obtained from the Information System on University Research, an administrative database from the Quebec provincial government that covers all funded research in Quebec's universities. Researchers were divided in three broad research disciplines: Social Sciences and Humanities (SSH), Natural Sciences and Engineering (NSE) and Health according to the discipline of their university department. Some were put in two different disciplines (N=169), and those for whom the discipline was not known and not found were excluded (N=263). The number of researchers in each field is shown in table 1. For each researcher, we calculated the total amount of funding received from the three main funding agencies in Quebec (FRQSC [SSH], FRQNT [NSE] and FRQS [health]) and Canada (SSHRC [SSH], NSERC [NSE] and CIHR [Health]). The total funds attributed for each projects were divided equally by the number of researchers on the application, each of them receiving an equal share. Other sources of funding were not taken into account. Publication data for each researcher from 2000 to 2012 were obtained from Thomson Reuters' Web of Science. Since citations take time to accumulate, they were counted up to the end of 2013.

Table 1. Number of Quebec's researchers by field

Field	*Number of researchers*	*Funded*		*Not funded*	
		N	*%*	*N*	*%*
SSH	6,229	3,869	62.1%	2,360	37.9%
NSE	3,244	2,647	81.6%	597	18.4%
Health	4,630	2,666	57.6%	1,964	42.4%
Total	14,103	9,182	65.1%	4,921	34.9%

Similarly to Berg (2010), we divided researchers in bins of equal size (50 researchers per bin), except for the bin regrouping researchers who did not receive any funding (see table 1 for the number of researcher in each field who did not receive funding). For each bin, we calculated the average and median amount of funding received. Then we calculated the average and median of four indicators used to measure the research outcome: the total count of articles, the fractional number of articles, the total number of citations and the average relative citations (ARC).

Results

Figure 1 and Figure 2 provide the mean and median number of papers of researchers, using both full (Figure 1) and fractional counting (Figure 2), as a function of total funding received. For each bin for each discipline and each indicator, the average is higher than the median, implying a skewed distribution of the data. The high values of R^2 in both figures indicate that the number of publications is strongly linked to the amount of funding received by researchers. The best fit line for each domain is a quadratic equation which suggests diminishing returns. For example, the median number of publications of researchers in NSE who received about \$5 million is about 72 (and 19 for fractional count), while those who receive \$2.5 million published a median number of 47 articles (13 for fractional count). Thus, doubling the funding does not seem to double the output. In Health, the most funded bin received almost three times more funding than the second most funded one, but published only two times more articles. Furthermore, in health, the apex is reached within the data range, which shows that a decline in production could be associated with higher levels of funding. On the whole, the correlation between funding and publications appears to be strong in all fields with values of R^2 higher than 0.91, but for each domain and calculation method, a rapid growth in the number of publications is observed for smaller amounts received and is followed by a slower growth as funding increases. However, this effect is less apparent for the total number of publications in SSH.

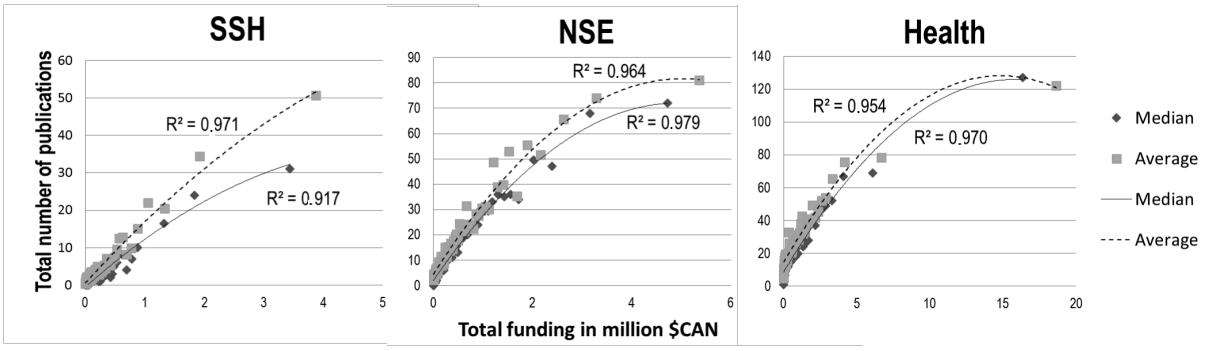

Figure 1. Full number of publications as a function of the amount of funding received.

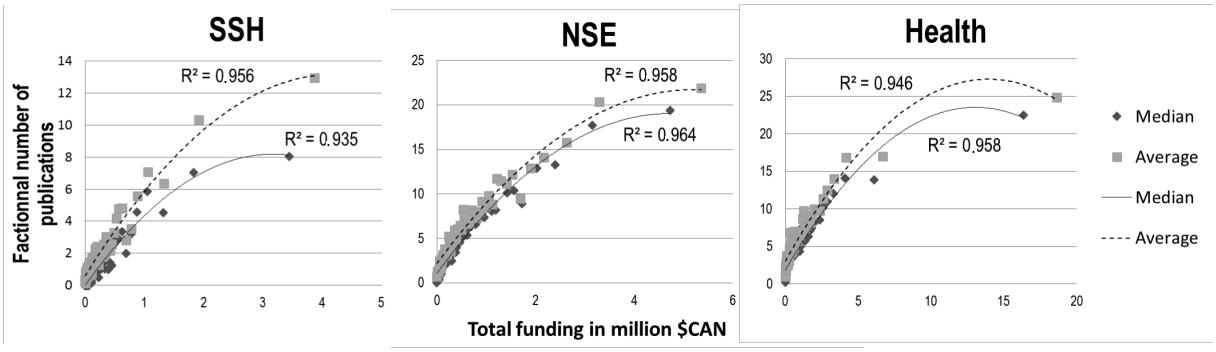

Figure 2. Fractional number of publications as a function of the amount of funding received.

Figure 3 shows the relationship between raw citations and funding received; the best-fit line is also a quadratic equation suggesting decreasing returns to scale in scientific impact. Similar to publications, the relation between the average of relative citations and the amount of funding (Figure 4) is weaker than for the previous indicators, with R^2 between 0.4 and 0.9. The nature of the relation is also different, the best-fit line being a power function, except for the median in SSH and the average in NSE, which are quadratic function. The power function indicates decreasing returns: the average relative of citations keeps increasing when increasing the total of funding, but not proportionally. For both impact indicators, we observe a trend similar to that observed for the number of publications. While the impact of papers published increase rapidly for funding of less than approximately $2 million in NSE and $5 million in health, the total number citations increase at a much slower pace once this threshold is met. Here, SSH are the exception, with the total number of citation seemingly increasing more rapidly for highly funded researchers. For field-normalized citations, the impact remains almost the same for all fields after a threshold of approximately $1 million is met.

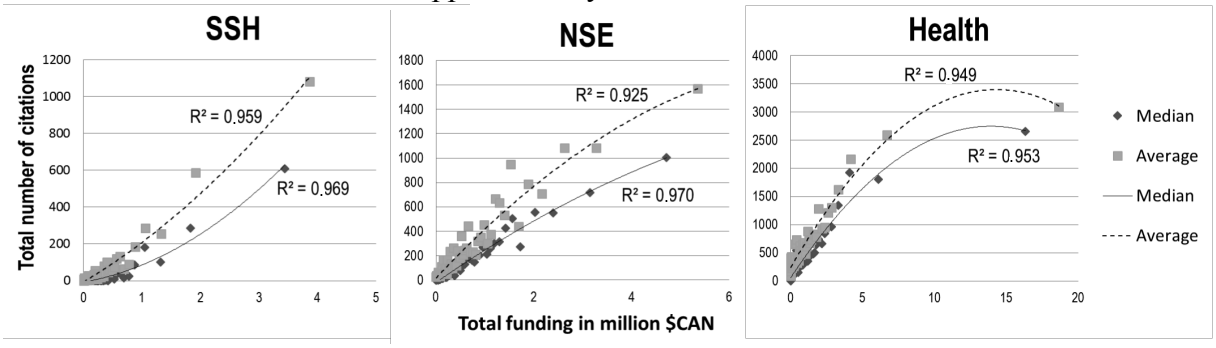

Figure 3. Total number of citations as a function of the amount of funding received.

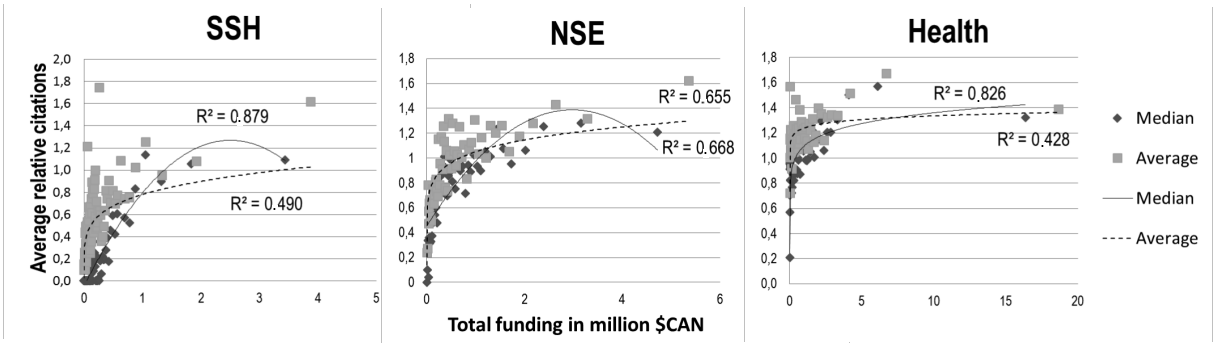

Figure 4. Average relative citations as a function of the amount of funding received

Discussion and conclusion

Based on our observations, funding is strongly linked to productivity and impact of individual researchers, but there are decreasing returns to scale for all of the indicators measured, except for the total citation count in SSH. This suggests that, even though more funding does in general lead to a higher number of publications, giving bigger grants to fewer individuals may not be optimal. If maximum output is the objective, then giving smaller grants to more researchers seems to be a better policy. In terms of scientific impact, the quickly reached plateau indicates that increasing funding has a very small impact on relative citations. Again, if the goal of research funding is to generate research that has a greater impact, giving grants to more researchers seems to be a better decision.

According to our results, SSH seem to be an exception, showing very little decreasing returns to scale. However, this could be explained by the fact that some research specialties in SSH (e.g., psychology and geography) have publication practices that are similar to those in NSE or Health. A closer look at the data shows that some researchers in psychology and geography tend to be both more funded – since they are often funded by the health and natural sciences funding agencies respectively – and more prolific than those in other field. Twenty-three (23) of the 50 most funded researchers and 33 of the 50 most prolific researchers are in those two fields, while they were 10 out of 50 in a randomly selected bin of researchers with less funding. Thus, the lower decrease in return of research funding in SSH could potentially be explained by an overrepresentation psychology and geography researchers in the highly funded bins, and their underrepresentation in less funded ones.

One of the many potential explanations for these decreasing returns is the high cost of equipment and infrastructures. Some research projects may simply not be possible without these initial investments, which do not necessarily lead to more output. Furthermore, while receiving funding does provide researchers with the means to carry on their research projects, it does not guarantee that they will succeed at achieving publishable results. Research grants are sometimes used as a performance indicator, which encourages researchers to apply for more grants (Hornbostel, 2001) that they might not necessarily need. This could lead to an inefficient use of the funds received (Sousa, 2008). Another explanation could be that researchers receiving larger grants may not participate directly on all the work funded with those grants (Boyack & Jordan 2011)

Some limitations of this study should be acknowledged. We did not control for other factors that can have an impact on a researcher's productivity (e.g., team size, academic age or gender), so further research may want to take into account such factors, as well as sources of funding other than government grants. Also, some of the potential outcome of funding and research cannot be measured with bibliometric indicators (e.g., the number of students trained and social outcomes). The funding received is sometimes linked to a particular project, and further research could aim at comparing outcomes of funded projects specifically. Another limit might be the lower coverage of SSH publications in the Web of Science, since researchers in SSH tend to publish in local journals or to publish books. Finally, as discussed above, the division of researchers in three broad disciplines might be problematic, especially for SSH. A more precise clustering of researchers based on research topic could provide better results and a clearer understanding of the phenomenon of decreasing returns of research funding.

In sum, both in terms of the quantity of papers produced and of their scientific impact, the concentration of research funding in the hands of a so-called 'elite' of researchers generally produces diminishing returns. In a context where financial resources devoted to research are declining in constant dollars, it is important to ask whether the way funding is allocated is optimal. Our numbers show that it is not the case: a more egalitarian distribution of funds would yield greater collective gains. It should be understood that the main determinant of

scientific production is not so much the money invested, but, rather the number of researchers' at work and, by funding a greater number of researchers, we increase the overall research productivity. Research policies that concentrate financial resources also seem to forget that there is a certain degree of serendipity associated with scientific discoveries, and by funding the work of many researchers as possible, we increase the likelihood that some of them make major discoveries.

Abstract
Over the last few decades, the massification of quantitative evaluations of science and their institutionalisation in several countries has led many researchers to aim at publishing as much as possible. This paper assesses the potential adverse effects of this behaviour by analysing the relationship between individual researchers' productivity and their proportion of highly cited papers. In other words, does the share of an author's top 1% most cited papers increase, decrease or remain stable, as her number of total papers increase? Using a large dataset of disambiguated researchers (N= 25,994,021) over the 1980-2012 period, this paper shows that the higher the number of papers a researcher publishes, the more likely they are amongst the most cited in their domain. This relationship was stronger for older cohorts of researchers, while decreasing returns to scale were observed in some domains for more recent cohorts. On the whole, these results suggest that at the macro-level, the culture of publishing as many papers as possible did not yield to adverse effects in terms of impact, especially for older researchers. For such researchers, who have had a long period of time to accumulate scientific capital, there can never be too many papers.

Conference Topic
Science Policy and Research Assessment

Introduction
In the second half of the 20th Century, but even more so over the last few decades, evaluations have become widespread in various spheres of society (Dalher-Larsen, 2011). Although scientific research has long been exempt from external evaluations thanks to Vannevar Bush and post WWII non-interventionist science policy, it has always been assessed internally through peer review. These means of evaluating research and researchers have, however, slowly changed since the 1980s, when researchers and administrators became aware of the roles that bibliometric analyses could play in such evaluations. Quantitative publication and citation analyses gained even more importance in the 2000s (Cameron, 2005), when tools for assessing individual researchers' output and impact became widespread. While in some cases, these methods have been developed to complement peer review in the allocation of research funding—such as the BOF-key in Flanders (Belgium) (Debackere & Glänzel, 2004), the Research Assessment Exercise/Framework in the UK—in other settings, these quantitative evaluations of research have become the main mean through which research is assessed and funded (Sörlin, 2007). Various publication-based and citation-based funding models can be found in Australia, Norway, Denmark, Sweden and Finland—and translates as the currency through which academic exchanges of tenure, promotion and salary raises are made (e.g. Fuyono & Cyranoski, 2006).
While there has always been subliminal bibliometrics performed through peer evaluation—as reviewers were skimming through reviewees' CVs through the process—the massification of

evaluations and their institutionalisation led many researchers and institutions to put large emphasis on the number of papers they published. This has led to adverse effects (Binswanger, 2015; Frey & Osterloh, 2006; Haustein and Larivière, 2014; Weingart, 2005). Indeed, like any social group, researchers are prone to change their behaviour once the rules of the games become explicit or what is expected from them; phenomenon that could be referred to as the Hawthorne effect (Gillespie, 1993), or to Goodhart (1975) or Campbell's laws (1979). As most evaluations and rankings are first based on numbers of published papers, this has created incentives for researchers to *author as many papers as possible.* In Australia (Butler, 2004), where publications counts were used without differentiating between publication venue or citations received, researchers have been found to increase their numbers of publications in journals with high acceptance rates and lower impact. Along these lines, the h-index, which together with the Impact Factor, is likely the most popular bibliometric indicator in the scientific community, is largely determined by numbers of papers published than on citations (Waltman & van Eck, 2012).

Within this context, researchers have adopted many publication strategies. While some researchers focus on publishing few, high-quality papers—e.g. 'selective' (Costas & Bordons, 2007) or 'perfectionists' (Cole & Cole, 1973)—others publish as many papers as possible, without not all of them necessarily being of high quality—e.g. 'prolific scientists' (Cole & Cole, 1973) or 'big producers' (Costas & Bordons, 2008)). However, little is known on the publication strategy that yields the highest results in terms of impact. In order to better understand the relationship between productivity and impact, this paper compares, for a large dataset of disambiguated researchers (N= 25,994,021), their total number of papers with the proportion of these papers that made it to the top 1% most cited of their field. Thus, this paper aims at answering the following key question: Does an authors' share of top papers start to decrease with a certain number of papers published? Or is it stable, as production and impact are two distinct dimensions of scientific activity. In other words, *how many is too many?* What is the probability for an author to publish top cited papers relate to the number of papers published? A good analogy for this is archery: if an archer throws one arrow, what is the probability that it hits the center of the target? Does an increase in the number of arrows thrown leads to an increase in the proportion of arrows hitting the center of the target?

Two opposite hypotheses could be made. The first one would be that authors with just 'average' production—rather than low or high production— are the ones more likely to publish top cited papers, as these authors, perhaps, focus more on the 'quality' of their output than just on quantity (i.e. selective scholars). The second hypothesis would be that, it is the authors with very high number of papers who, on average, publish the highest proportion of top cited papers. This hypothesis would be on agreement with the theory of Merton's cumulative advantages (Merton, 1968), and supported by empirical work in the sociology of science (Cole & Cole, 1973). Similarly, in a Bourdieusian framework, the main goal of a researcher is to increase its rank in the scientific hierarchy and gain more scientific capital (Bourdieu, 2004). If publishing a high number of scientific papers and being abundantly cited are the ways through which researchers can reach this goal, then they will adapt their behaviour to reach these evaluation criteria.

This focus on publishing as many papers as possible—often referred to as 'salami slicing'—has been long discussed (e.g. Abraham, 2000; Jefferson, 1998). However, only a few authors have analysed the effect of 'salami slicing' on papers' citations. For instance, Bornmann and Daniel (2007) have shown, for a small sample of PhD research projects in biomedicine (N=96), that an increase in the number of papers associated with a project lead to an increase in the total citation counts of papers associated with the projects. However, they do not show whether the impact of each paper taken individually increases with the number of papers published. Similar to this study, Hanssen and Jørgensen (2015) analysed the effect of

'experience' on papers' citations; experience being defined as the author's previous number of publications. Drawing a sample of papers in transportation research (N=779) they show that experience is a statistically significant determinant of individual papers' citations, although this increase becomes marginal once a certain threshold is met in terms of previous papers published.

Methods

This paper uses Thomson Reuters' Web of Science (WoS) for the period 1980-2012. Only journal articles are included. Given that the units analysed in this paper are individual researchers, we used the disambiguation algorithm developed by Caron & van Eck (2014) to identify the papers of individual researchers. On the whole, the algorithm managed to attribute papers to 25,994,021 individuals, which were divided into seven cohorts based on the year of their first publication (Table 1).

Table 1. Number of disambiguated researchers per cohort

Year of first publication	Number of researchers
<=1985	3,574,667
1986-1990	2,733,002
1991-1995	3,282,421
1996-2000	3,810,652
2001-2005	4,310,886
2006-2011	6,930,289
>=2012	1,352,104

As we want to assess researchers' contribution to research that has the highest impact, we isolated for each discipline the top 1% most cited papers published each year (normalized by WoS subject categories). Citations are counted until the end of 2013, and exclude self-citations. The broad disciplines used are those of the 2013 Leiden ranking which are based on the assignment of WoS Subject Categories to five main domains (CWTS, 2013). Figures in the paper presents classes of numbers of papers in which there are at least 100 researchers.

Results

Figure 1 presents, for the oldest cohort studied—researchers who have published their first paper before 1985—the relationship between the number of papers throughout their career and the proportion of those papers that made it to the top 1% most cited. For any specific number of papers, the expected value of top 1% papers is, as one might expect, 1%. Researchers for all five domains have one thing in common: authors with very few papers are, on average, much less likely to publish high shares of top 1% most cited papers. For *Biomedical and health sciences* and for *Social sciences and humanities* we observe a continuous increase in authors' proportion of top papers as their overall number of papers increases. For *Life and earth sciences* the share of papers does increase with the number of papers, until about 10 papers where they starts to oscillate, although in general an increasing pattern is still observed, especially after 40 papers. Perhaps the most deviant pattern is found in *Mathematics and computer science* where for just for the very low levels of production there is an increase in the share of highly cited publications, but this share decreases between

4 and 20 papers. It then starts to increase again for higher numbers of papers, despite important fluctuations. Natural sciences and engineering follow a similar pattern, with a decrease in the share of top papers between 6 and 30 papers, followed, in this case, by a clear increase until very high levels of productivity.

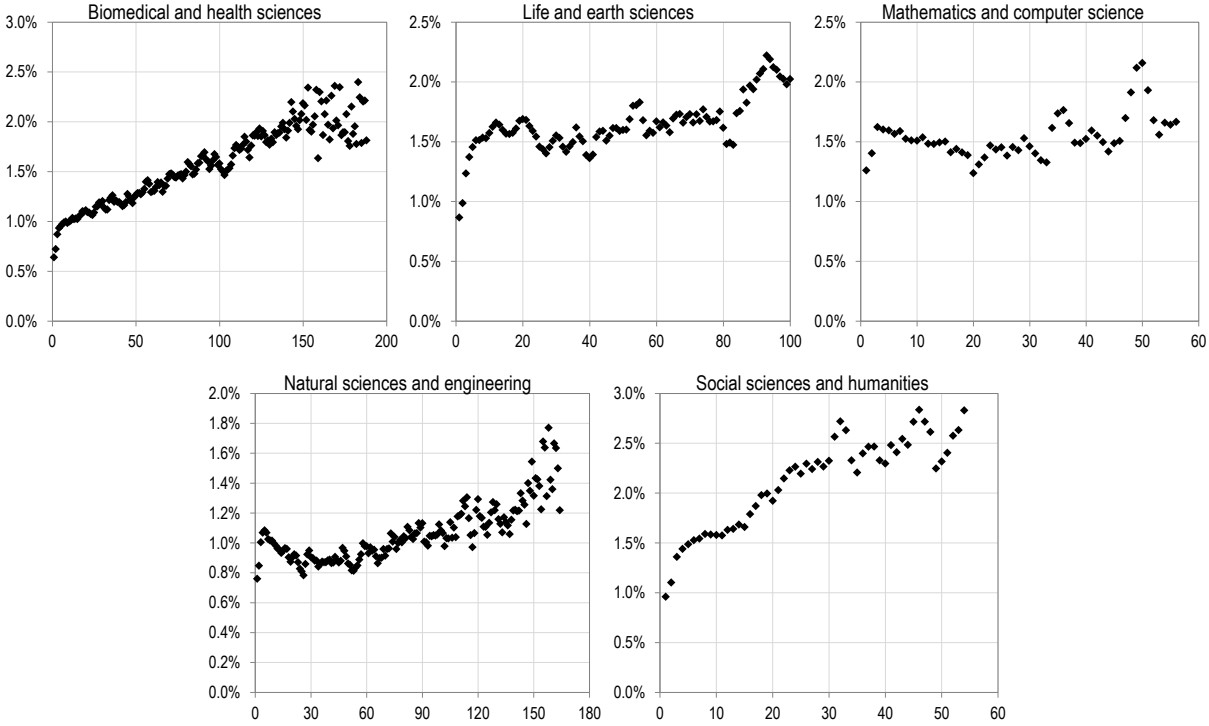

Figure 1. Proportion of top 1% most cited papers (*y* axis), as a function of the number of papers published (*x* axis), for the cohort of researchers who have published their first paper before 1985, by domain. Only classes of numbers of papers with 100 researchers or more are shown.

When researchers who have published their first paper between 2006 and 2011 are considered, different pattern are observed (Figure 2). For *Biomedical and health sciences* there is an increase in the share of highly cited publications up to around 15 publications, when some important fluctuations—or certain decreasing returns to scale—start to appear. A similar pattern is observed for the *Life and earth sciences* with the variability starting from levels of production of around 10 publications although, in this case, a decrease is clearly observed. For the other domains the pattern tends to be clearly increasing, although oscillations are also observed for the higher levels of production, which could also be seen as decreasing returns to scale. For the other three domains, there is clearly an increase in the share of top papers as the number of papers increases. However, we also observe for these three fields a decrease at very high levels of productivity.

An important characteristic of this cohort is that it got socialized to research recently—when the evaluation culture was more present—which might explain why they might be more prone to try to publish as much as possible. However, the drop in the share of top papers observed in each domain—although at different levels of productivity—suggests that these academically-younger scholars struggle to keep impact high once a certain threshold is met. This might be due to the fact that these scholars have not yet secured permanent or tenure positions and, thus, might feel that they cannot be as selective as older scholars who might choose their collaborators more easily.

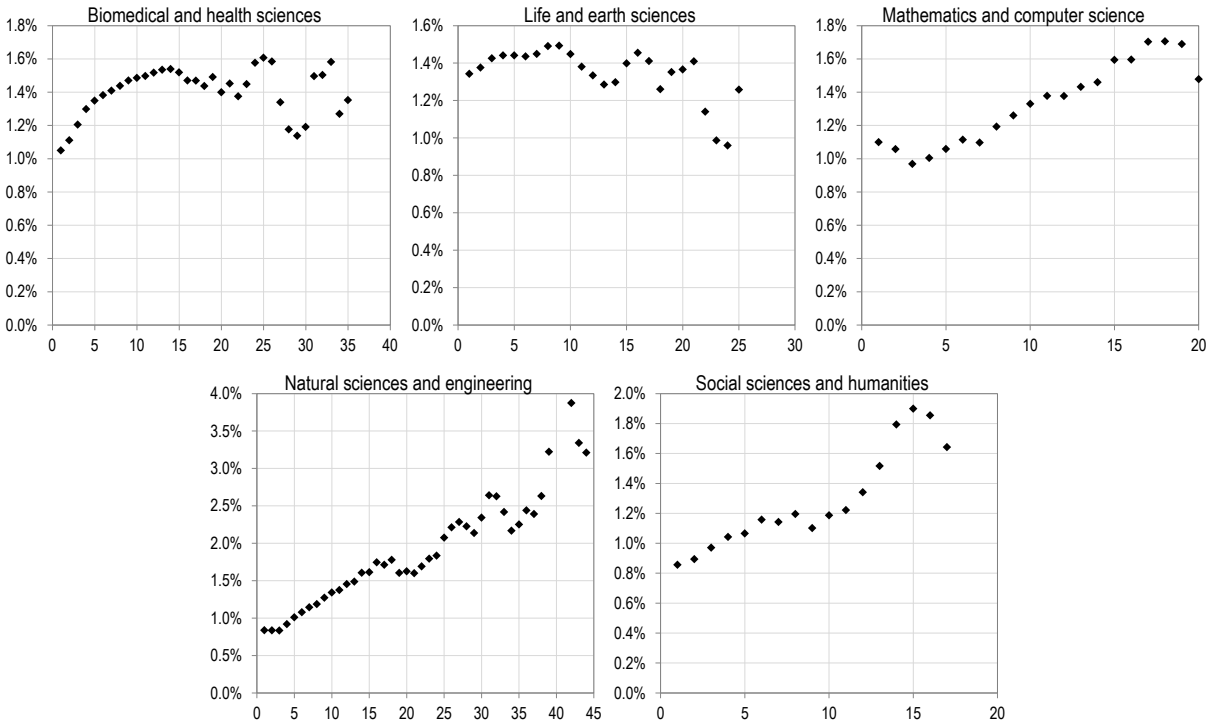

Figure 2. Proportion of top 1% most cited papers, as a function of the number of papers published, for the cohort of researchers who have published their first paper between 2006 and 2011, by domain. Only classes of numbers of papers with 100 researchers or more are shown.

Discussion and Conclusion

Previous research has shown that, in many contexts, the focus on indicators in research evaluation has had adverse effects, especially in terms of papers published (e.g. Binswanger, 2015). This paper aimed to provide an original analysis of one of these adverse effects, which is to aim to *publish as much as possible*. Our results have shown that, especially for older researchers, the higher the number of papers published throughout their careers, the higher the share of these papers ends up being amongst the top cited papers of their fields. This effect was higher for *Biomedical and health sciences* and for *Social sciences and humanities*, but in all fields the most active group of researcher was also having a higher share of top cited papers. A general exception to this trend was found in academically-younger researchers working in the field of *Life and earth sciences*, where higher scientific output was associated with lower impact than low-to-mid scientific output. Decreasing returns to scale were also more common for more junior researchers than senior ones.

These results conform to the Mertonian theory of cumulative advantages (Merton, 1968): the higher the number of papers an author contributes to, the more he or she gets known and, hence, is likely to attract citations. In Bourdieusian terms, the more an author publishes and accumulates citations in a domain, the more this capital will yield additional papers and citations. The relationship could also be in the other direction, as highly cited authors might have more opportunities to contribute to papers, given the scientific capital they have accumulated. Still, the results show that top cited authors do not only contribute on average to more papers, but also to more *highly cited* papers. On the whole, these results suggest that, at the macro-level, the culture of publishing *as many papers as possible* did not yield to adverse effects in terms of impact, especially for senior researchers. For such researchers, who have had a long period of time to accumulate scientific capital, there can never be *too many papers*.

Research Assessment and Bibliometrics: Bringing Quality Back in

Michael Ochsner[1] and Sven E. Hug[2]

Introduction

Bibliometric indicators are used to compare research performances and also to assess and evaluate research performance (see, e.g. Gimenez-Toledo et al., 2007; Lane, 2010). However, recently scholars voice protest against bibliometric assessments (see, e.g., Lawrence, 2002; Molinie & Bodenhausen, 2010; Drubin, 2014). The arguments put forward are manifold. For example, the application of the impact factor, which is often used, but not meant, to evaluate individual researchers, is criticized (DORA, 2013). Then, there are myriads of perverse or unintended effects, like focus on high impact journals and mainstream topics, focus on review articles and short communications, strategic behavior, or lack of replication because of the low reputation of replication studies (e.g., Butler, 2007; Lawrence, 2003; Mooneshinghe et al., 2007). Furthermore, scholars from the social sciences and humanities (SSH) criticize that that bibliometric indicators cannot capture quality (e.g., Plumpe, 2009).

The authors of this paper were involved in a project to develop quality criteria and indicators for humanities research (see http://www.psh.ethz.ch/crus). Here, we argue that while bibliometric indicators and methods are powerful tools to describe research practices and, to some extent, scientific impact, there are some problems when they are readily used as quality indicators in research assessments. We feel that also other disciplines can learn from the critique of humanities scholars on simplistic quantitative assessments and from the findings of the research on quality in the humanities.

Notions of quality

The aim of the project "Developing and Testing Research Quality Criteria in the Humanities" was to find quality criteria and indicators that were at the same time accepted by the humanities scholars and implementable in different linguistic, cultural, and disciplinary settings. Analyzing the humanities scholars' critique, we found that the development of criteria must take into account the disciplinary research practices, that the measurement must be transparent and consensual, and that the notions of quality must be made explicit (Hug et al., 2014). We used the Repertory Grid technique to make the notions of quality explicit and base the development of quality criteria on the actual research practices. We found that there are two different conceptions of quality, a more traditional one, which can be described with individual, ground-breaking research that opens up new paradigms, and a more modern conception that can be described as interdisciplinary, project-focused, and public-oriented. Both kind of research can be good as well as bad (Ochsner et al., 2013). Hence, interdisciplinarity, for example, differentiates between two different ways of doing research but is not an indicator of quality (interdisciplinarity can point to good research, when it merges different theories and methods, but it can equally point to bad research that uses interdisciplinarity only for getting funding or for the career). Therefore, notions of quality should be taken into account in research evaluations. They might shed light on gaming strategies as well as on problems with indicators that are not linked to research practices or research quality.

Catalogue of quality criteria

Using the notions of quality, we developed a catalogue of quality criteria that are linked to the research practices in the humanities. Humanities scholars then rated these criteria as well as indicators measuring those criteria. We found that a broad range of quality criteria and aspects must be taken into account to adequately assess research quality (Hug et al., 2013) and that only about 3% to 32% of the scholars' notions of quality can be quantified adequately, depending on the discipline. Furthermore, we found that there is a mismatch between the quality criteria put forward by the scholars and the quality criteria used in evaluation procedures (Ochsner et al., 2012). Hence, current evaluation procedures do not measure research quality in the humanities adequately. This does not mean that the existing evaluation procedures and criteria are useless (e.g., societal impact is not necessarily linked to research quality but is a legitimate criterion in evaluations), but it shows that

a very important dimension of research assessment is not reflected adequately: quality of research.

The humanities, so what?!

Our research bases on the humanities. What is the relevance of this research to the rest of academia? First, we argue that humanities scholars, while not specialised in quantification, are experts in critical thinking. Hence, their critique of evaluation procedures often points to the consequences of the instruments on research practices. This is what increasingly also happens in the natural sciences (e.g., DORA, 2013; Drubin, 2014) because some perverse effects start to become apparent. Hence, a focus on research practices in assessments could help minimise negative impact of indicators. Second, when we presented the criteria at conferences and workshops, also natural scientists were present. They surprisingly often said that the criteria we presented made also sense to them with a few exceptions. Hence, what could be learned from the case of the humanities would be the following: base evaluation procedures on research practices; be aware that the indicators used will affect the research practices; formulate quality criteria in a way that makes sense to the scholars; involve as many stakeholders as possible in the definition of quality criteria.

Bringing quality back in

While the bibliometric community is well aware of the possible drawbacks of bibliometric indicators, the most common reaction by the research evaluation community is to look for other sources of the same kind of indicators and altmetrics. We think that the problem is not a technical one but a conceptual. At the beginning of any research evaluation and science policy should be a reflection on the goals. Do we want scholars to use most of their time to feed Twitter, comment on Research Gate, or 'pimp' their statistics in Google Scholar?
We think that research evaluation should bring quality back in. Evaluation and assessments should not solely *judge* the merits of scholars but help them to *enhance* their impact by fostering research quality. Hence, bibliometrics and altmetrics are powerful instruments to describe certain impacts, visibility, networks etc. But research assessments should also make clear statements about other aspects of research quality. Therefore, the disciplinary community should have a say in what criteria are applied in their assessments. New ideas of research evaluation based on research practices should lead scientific discussion much more than technical issues vaguely related to research quality.

Introduction

There is an increasing demand for science to help in addressing grand challenges or societal problems, such as tackling obesity, climate change or pandemics. In this context, it becomes important to understand what different sciences can offer to tackle these problems, and towards which directions scientific research should be developed. A useful starting point is to investigate what is the existing science supply, and which research options are better aligned to address grand challenges and societal demands (Sarewitz & Pielke, 2007). In order to map the science supply, we need a representation of the knowledge on research topics relevant for a problem.

Bibliometrics can provide very helpful tools for developing knowledge representations. However, these representations are highly dependent on the data and methods used. As a result, bibliometric tools or indicators often reproduce the biases in the data collection and treatment. For example, it has been shown that conventional bibliometric analyses are biased against non-English languages (Van Leeuwen et al., 2001), developing countries (Velho & Krige, 1986), applied science (Van Eck et al., 2013), the social sciences and humanities (Martin et al., 2010) and interdisciplinary research (Rafols et al., 2012). The aim of this paper is to investigate the biases introduced by available databases in the representation of research topics.

In a previous study on rice research, we showed that the bibliographic database CAB Abstracts (CABI) – which is focussed on agriculture and global health – has a larger coverage of rice research for most low income countries than Web of Science (WoS) or Scopus (Ciarli, Rafols & Llopis, 2014). For example, India has twice the number of publications in CABI on rice compared to Scopus and about 4 times those in WoS. In this study, we present evidence that shows that this unequal coverage distorts significantly the knowledge representation of rice research, globally and for different countries. Such bias may have policy effects, in particular for a societal issue such as rice production.

As shown in Figure 1, we find that the journal coverage of the bibliometric databases WoS and Scopus under-represent some of the more application oriented topics (namely: i) production, productivity and plant nutrition (top left); ii) plant characteristics (top center); and iii) diseases, pests and plant protection (center).

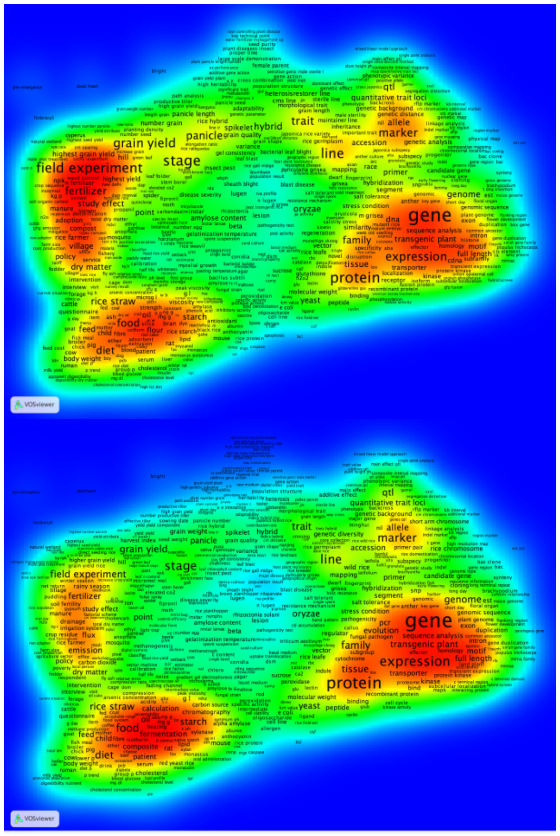

Figure 1. Publication density for rice research in CABI (top) and in WoS (bottom). The top left and top right areas under-report in WoS are related to production and seed characteristics.

Given that these are issues relevant to small farmers, producing for the local market, and with no access to the seeds developed with molecular biology techniques (GM – bottom left), we pose the

question whether the inadvertent effect of the biases in the dominant database is to under-represent, the type of research that has most chances of being relevant for improving their wellbeing, without introducing the use of the highly contested GM seeds.

Figure 2 illustrates that under-representation of research on production, pest and seed characteristics is particularly acute in some countries with molecular biology research (related to GM), but with a focus on research to address food security and local farming needs (in this case Iran). Rice research in these countries tends to be more focused on increasing crop yield, precisely the topic under-represented in WoS and Scopus.

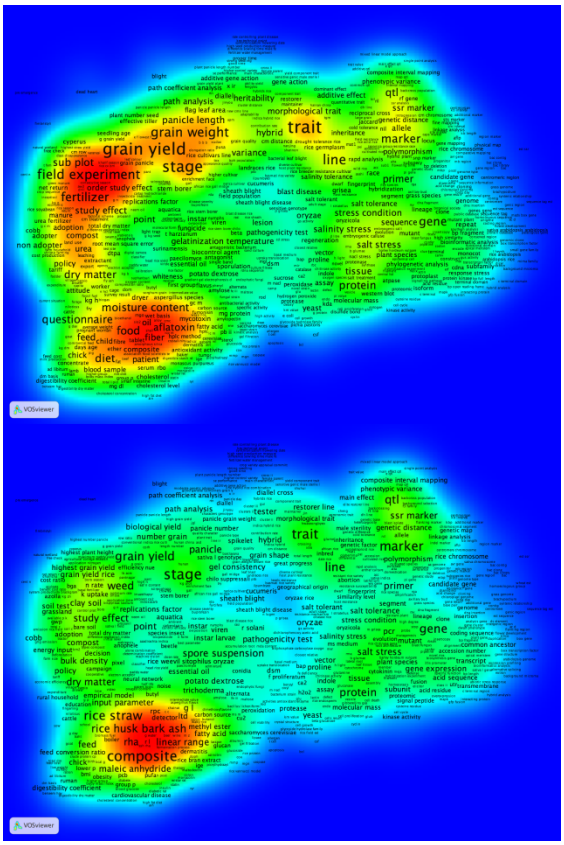

Figure 2. Publication density for rice research in Iran for CABI (top) and WoS (bottom).

Conclusions

Since knowledge representation can play a significant role in framing research strategies, policy and technological development, in this ignite talk we want to draw attention to the topic bias in the dominant bibliometric databases. From a technical point of view, few bibliometric and science policy experts will be surprised to hear that WoS and Scopus, are under-representing low income countries and more applied research. Given these results, we pose the question whether such conceptual biases may result in strategies that do not take into account knowledge and techniques which may be developed in closer connection to farmers and consumers local needs. This study does not answer this question, but it shows that it is a meaningful and important issue for bibliometrics to address: bibliometric exercise that use dominant databases may have a negative effect on policies relevant to important social issues, particularly in developing countries.

Information on methods and data

Publications on rice for the period 2003-2012 were downloaded from the WoS (including SCI-Expanded, SSCI, A&HCI, CPCI-S i CPCI-SSH) searching “rice” or “oryza” in the field “topic”. Scopus records were downloaded searching in title, abstract or keywords, i.e. TIT-ABS-KEY ("rice" OR "oryza"). Similarly, documents with “rice” or “oryza” were searched in title and abstract of the database CAB Abstracts. The records of the different databases were matched with multiple matching algorithms. The analysis was carried out using Vantage Point, the statistical package R and the visualisation programme VOSviewer.

Introduction

Collaborative innovation is a trans-disciplinary approach for developing the wholeness synergy to improve the competitiveness of an organization through holistic, competitive and complementary interactions between and among innovation participants in a specific environment (Bommert, 2010; Swink, 2006). The collaborative innovation system essentially consists of three sectors: industry, universities, and the government, with each sector interacting with the others, while at the same time playing its own role. Collaborative innovation system is a complex conglomerate of interacting independent parties. The network of institutional relations among universities, industries, and governmental agencies has been considered as a Triple Helix (TH). Collaborative innovation system (CIS) is based on a multi-input, multi-output transformation relation. It is an important issue to investigate the performance related to the transformation process of limited innovation resources for improving collaborative innovative outputs. Previous studies have been done to evaluate the performance of collaborative innovation. However, those studies failed to consider the complexity of the collaborative innovation system. Data envelopment analysis (DEA) is a method for measuring the efficiency of peer decision making units (DMUs). Recently network DEA models been developed to examine the efficiency of DMUs with internal structures. The internal network structures range from a simple two-stage process to a complex system where multiple divisions are linked together with intermediate measures. In this study, we propose a network DEA with parallel production systems to measure the efficiency of University-Industry Collaborative Innovation. The purpose of the present study is to construct a complete measurement framework characterizing the CIS' production framework from original S&T investment to final outputs, and measure the CIS' process-oriented technical efficiency, which is implemented in China's context. It is hoped that this study will benefit China's collaborative innovation policy-making.

Network DEA model

We propose a network DEA with parallel production systems in this section. Assume that there are n DMUs, and each DMU has two *sub-DMUs*. Figure 1 depicts the visual structure of the DEA model.

The part of inputs is consumed by SDMU1 and SDMU2 together, and part of DMU output is co-produced by SDMU1 and SDMU2. Besides, some inputs and outputs are consumed or produced by SDMU1 or SDMU2 alone. Variables are defined as follows: $X_1 = (x_{1j}^1, \mathrm{K}\ , x_{mj}^1)$ represent m separate inputs which are consumed by SDMU1; $X_2 = (x_{1j}^2, \mathrm{K}\ , x_{hj}^2)$ represent h separate inputs which are consumed by SDMU2; $X_s = (x_{1j}^s, \mathrm{K}\ , x_{lj}^s)$ represent l inputs consumed by SDMU1 and SDMU2 together. The vector of $Y_1 = (y_{1j}^1, \mathrm{K}\ , y_{sj}^1)$ are s outputs produced by SDMU1; the vector of $Y_2 = (y_{1j}^2, \mathrm{K}\ , y_{tj}^2)$ are t outputs produced by SDMU2; the vector of $Y_s = (y_{1j}^s, \mathrm{K}\ , y_{uj}^s)$ are u outputs produced by SDMU1 and SDMU2 together.

For analytical tractability, we use $X_{s1} = (x_{1j}^{s1}, \mathrm{K}\ , x_{lj}^{s1})$, $X_{s2} = (x_{1j}^{s2}, \mathrm{K}\ , x_{lj}^{s2})$, $Y_{s1} = (y_{1j}^{s1}, \mathrm{K}\ , y_{uj}^{s1})$ and $Y_{s2} = (y_{1j}^{s2}, \mathrm{K}\ , y_{uj}^{s2})$ to represent the shared inputs and outputs of SDMU1 and SDMU2 in each subsystem, and $X_s = X_j^{s1} + X_j^{s2}, Y_s = Y_j^{s1} + Y_j^{s2}$.

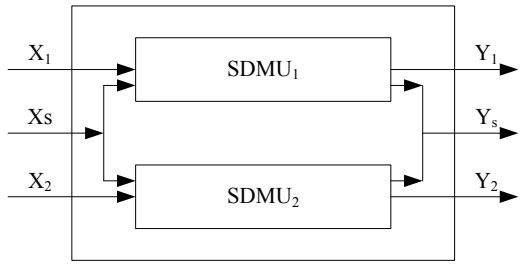

Figure 1. Parallel system structure.

In this study, we choose new product sales as independent output in Industry sub-system, the number of universities' published papers as independent output in universities sub-system. Patent applications in IU collaboration innovation system mainly come from both industry and universities subsystems; therefore the number of patent applications is seen as a shared output in the system.

According to DEA parallel production system efficiency evaluation model proposed by Kao (2009), parallel production system efficiency of the DMU under constant returns to scale (CRS) can be represented as follows:

$$\overline{\theta}^*_{CRS} = \min \quad \theta$$

$$s.t.$$

$$\sum_{k=1}^{2}\sum_{j=1}^{n} \lambda_j^k y_{rj}^{sk} \geq y_{ro}^s \quad r = 1,\mathrm{K}\ ,u$$

$$\sum_{j=1}^{n} \lambda_j^1 y_{rj}^1 \geq y_{ro}^1 \quad r = 1,\mathrm{K}\ ,s$$

$$\sum_{j=1}^{n} \lambda_j^2 y_{rj}^2 \geq y_{ro}^2 \quad r = 1,\mathrm{K}\ ,t$$

$$\sum_{k=1}^{2}\sum_{j=1}^{n} \lambda_j^k x_{ij}^{sk} \leq \theta x_{io}^s \quad i = 1,\mathrm{K}\ ,l$$

$$\sum_{j=1}^{n} \lambda_j^1 x_{ij}^1 \leq \theta x_{io}^1 \quad i = 1,\mathrm{K}\ ,m$$

$$\sum_{j=1}^{n} \lambda_j^2 x_{ij}^2 \leq \theta x_{io}^2 \quad i = 1,\mathrm{K}\ ,h$$

$$\sum_{j=1}^{n} \lambda_j^1 = \sum_{j=1}^{n} \lambda_j^2$$

$$\lambda_j^k \geq 0 \quad k = 1,2;\ j = 1,\mathrm{K}\ ,n$$

The main data in this paper are all selected in the "*China Statistical Yearbook of Science and Technology*". Considering the time lag in innovation activities, we select the data in 2009 as input data and the data in 2010 as output data in this paper. This study excludes all provinces that have missing data. Finally, this study evaluates 30 observations of Chinese provinces.

Table 1 summarizes three efficiency scores under constant returns to scale (CRS), variable returns to scale (VRS) and non-increasing returns to scale (NIRS).

Table 1. Three Efficiencies of Chinese provinces.

Province	$\overline{\theta}^*_{CRS}$	$\overline{\theta}^*_{NIRS}$	$\overline{\theta}^*_{VRS}$

Guizhou	0.6488	0.6488	0.6661
Yunnan	0.5810	0.5810	0.6081
Shaanxi	0.6860	0.6860	0.6861
Gansu	0.8782	0.8782	0.8828
Qinghai	0.3233	0.3233	0.8972
Ningxia	0.5769	0.5769	0.6545
Xinjiang	0.7036	0.7036	0.7416

Results

The average efficiency under constant returns to scale of University- Industry collaborative innovation in China is 0.7642. However, the efficiencies of some provinces are less than the average efficiency. By the view of economic region, the efficiencies of UI collaborative innovation in eastern, northern and southern coastal China are higher than other areas in China.

Introduction

Bibliometric indicators became a common tool for evaluating universities (Geuna & Martin, 2003). Furthermore, individual academics and researchers are also evaluated, promoted, and tenured based on their productivity, particularly the one visible in international databases such as the Web of Science (WoS). This methodology is widely accepted even in non-English speaking countries (Pajić, 2014).

Growing emphasis on bibliometric indicators is followed by a continuing debate on their suitability for the evaluation in social sciences and humanities (SS&H) (Nederhof, 2006). Secondary importance of journals and the prevalence of monographs are usually identified as the key features of "publication behaviour" in SS&H (Hicks, 2012). Economics and psychology are often considered to be more similar to sciences (Engels, Ossenblok, & Spruyt, 2012).

This paper presents initial results on the scientific productivity of professors promoted and tenured at the University of Novi Sad (UNS). The main goal was to analyse publication patterns in SS&H and their implications for the evaluation of individuals.

Data and method

UNS is the second largest state university in Serbia. It consists of 14 faculties and 2 research institutes. Presented analysis was focused on the production of professors promoted or tenured in 2009-2013 at 6 UNS faculties in SS&H. Data were taken from the reports publicly available on the UNS website[1]. Each report contained bibliography provided by the candidate and was verified by the corresponding committee of at least three members.

The sample included 297 professors in language and literature (99), education (62), economics (32), psychology (27), law (26), history (19), sociology (12), philosophy (10), and science (e.g. professors of chemistry at teachers colleges) (10). The total of 9007 publications were extracted and categorized according to the origin (national, international), and type (books, journal articles, proceedings, other). In order to balance the differences in the publication counts among the researchers of different academic rank, only publications from the last promotion period of 5 years were taken into account.

[1] http://www.uns.ac.rs/sr/izborZvanje/bilteni.html Reports were removed during the preparation of this paper and are no longer available online, but are available from the authors.

Since this is a preliminary analysis, it was mostly based on descriptive statistics. Because of skewed distributions, non-parametric tests were used to test the basic differences among disciplines.

Results and discussion

Kruskal-Wallis test indicates significant differences in scientific productivity among researchers from different fields: $H(8, 297) = 22.99$, $p < .01$ (Figure 1). It is difficult to draw a solid conclusion, mainly because of highly skewed distributions and large individual differences, but clearly psychology and sciences have the highest median values, while the lowest scientific activity is that of the researchers in the field of law. The most pronounced individual differences were observed in the fields of language and literature, and educational sciences.

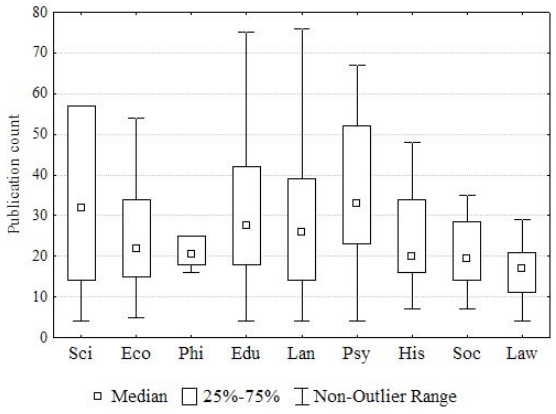

Figure 1. Differences in scientific productivity among researchers in nine scientific fields.

Distributions of the major types of publications among scientific fields differ significantly: χ^2 (16, 8492), $p < .01$ (Figure 2). The share of articles is somewhat unusually high in humanities, and ranges around 40% in all fields. Contrary to usual beliefs, psychology and sciences have the lowest proportion of journal articles within the total number of publications. On the other hand, the highest proportion was detected in the field of law where journal articles account for almost 2/3 of all publications. However, the list of the most frequent journal titles revealed that more than half of the articles were from a journal published by the same faculty where the candidates were promoted or tenured.

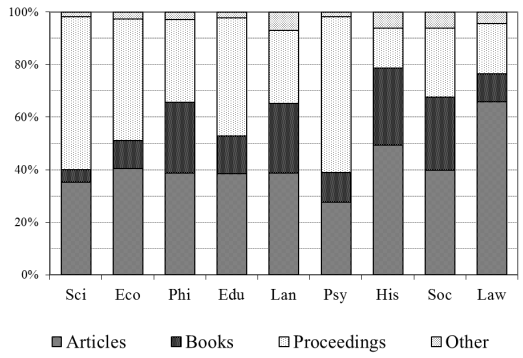

Figure 2. Proportions of different types of publications in nine scientific fields.

Our results have confirmed the importance of book chapters and monographs in humanities, although this type of publication is not predominant in any of the fields. Conference abstracts and proceedings are the most frequent type of publication in four out of nine analyzed fields.

Figure 3 shows the proportions of (inter)national publications across scientific fields. The strongest focus on international sources is noticeable in the sciences, and the lowest in history, sociology, and law. The results that are not in line with the usual beliefs are rather nationally oriented publication behavior of Serbian psychologists, and a relatively high ratio of international sources in philosophy.

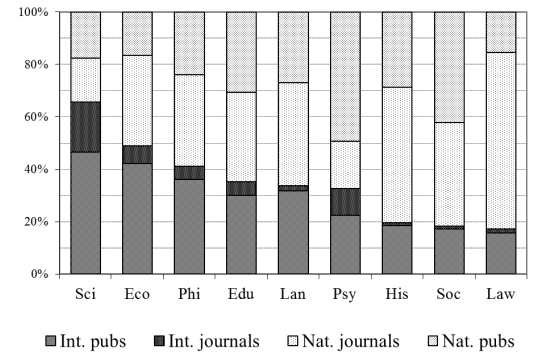

Figure 3. Proportions of national and international publications in nine scientific fields.

Professors at the faculties in Serbia are required to have one to three papers published in WoS journals prior to promotion or tenure. Table 1 shows the list of the 15 most common (allegedly) WoS journals reported in 297 reports. The majority of journals are actually national or regional WoS journals with the rather low impact factor values (IF). The disturbing fact is that several professors were promoted based on their articles published in journals of dubious quality, those that were dropped from WoS because of academic malpractice (e.g. *HealthMED*, *TTEM*, *Metalurgia Int*) or were never indexed by WoS nor any major international bibliographic database (e.g. *Brit Amer Stud*). In addition, 12 other journals were falsely reported as top ranked WoS titles.

Table 1. Most common (allegedly) WoS journals listed in 297 promotion and tenure reports.

Journal title	%	Country	IF
Psihologija	17.50	SRB	0.188
TTEM	5.83	B&H	drop.
HeathMED	5.13	B&H	drop.
Croat J Educ	3.03	CRO	0.034
Roman J Eng Stud	2.30	ROM	-
Med Sport	2.30	ITA	0.125
Vojnosan pregl	2.10	SRB	0.269
New Edu Rev	1.63	POL	drop.
Filoz istraživanja	1.63	CRO	AHCI
Brit Amer Stud	1.40	ROM	-
Panoeconomicus	1.16	SRB	0.778
Riječ	1.16	CRO	-
Didactica Slov	0.93	SLO	drop.
ICCCC	0.93	ROM	0.694
Metalurgia Int	0.93	ROM	drop.

drop. - dropped from WoS

Conclusion

Our results have shown that SS&H are clearly more nationally oriented compared to sciences. However, journals as knowledge dissemination channels seem to be equally important across all fields. Apart from the conference proceedings, journal articles are the most common type of publications. It's obvious that the current promotion and tenure rules affect the professors' publication behaviour. Such patterns are not determined simply by the characteristics of a discipline, but in some cases by the ease of access to particular sources, e.g. journals having a rather lenient editorial policy.

Science policy institutions should be aware that the evaluation is a dynamic process that must combine both the rules and the means to assess the effects of those rules and to monitor their implementation.

The Serbian Citation Index: Contest and Collapse

Dejan Pajić

dpajic@ff.uns.ac.rs
University of Novi Sad, Faculty of Philosophy, Department of Psychology,
Dr Zorana Đinđića 2, 21000 Novi Sad (Serbia)

The Past

Ten years ago, a poster titled *The Serbian Citation Index: context and content* was presented at the ISSI conference held in Stockholm (Šipka, 2005). *Serbian Citation Index (SCIndeks)* was at the time a pioneering effort to build a comprehensive, open access citation index of Serbian scientific journals with three missions: local *dissemination* of research findings in the open access mode, global *promotion* of the Serbian science, and objective *evaluation* of national journals, institutions, and researchers.

Started as an ambitious project of the group of enthusiasts and volunteers in 1990s, SCIndeks has become truly embraced nationally during the 2000s. In the period when Serbia was represented in the Web of Science (WoS) with only three journals, SCIndeks was recognized as a tool to enhance the public accountability, visibility, and quality of local journals. *Centre for Evaluation in Education and Science (CEES),* SCIndeks developer and publisher, started receiving full financial support from the Serbian Ministry of Science (SMS), both for the maintenance of SCIndeks and for publishing the *Journal Bibliometric Report (JBR)*. The report is published annually and contains the national impact factor and almost 20 other bibliometric indicators for over 300 journals covered by SCIndeks. JBR is used for journal rankings and, indirectly, as a data source for the evaluation of individual researchers, their promotions, and tenures.

The Contest

The role and importance of a national citation index cannot be evaluated outside the global scientific information market. The first test for SCIndeks was the recognition and perception of Serbian journals by the major international database providers. After Elsevier's Scopus and Google's Scholar appeared in 2004, Thomson Reuters' indexing policy has also changed radically. The question was whether the CEES efforts to improve the visibility and quality of local journals would result in increased number of titles accepted for indexing in WoS and Scopus. Figure 1 shows the number of journals published in Serbia and three neighbouring countries indexed in WoS and Scopus. All countries have managed to improve their visibility in international databases, but the Serbian progress is only slightly ahead of Bulgarian and far behind Romanian and Croatian. Neither Bulgaria nor Romania has national citation index or a repository of national journals. On the other hand, Croatian journals are presented in the *Portal of Scientific Journals of Croatia* and the *Croatian Scientific Bibliography*, both funded by the government, but having limited functionality compared to SCIndeks, especially regarding the support for journal editors, evaluators, and science policy institutions. It seems that the mission to promote journals through SCIndeks has failed or at least has not succeeded in lowering a potential bias in inclusion policies of the major database providers.

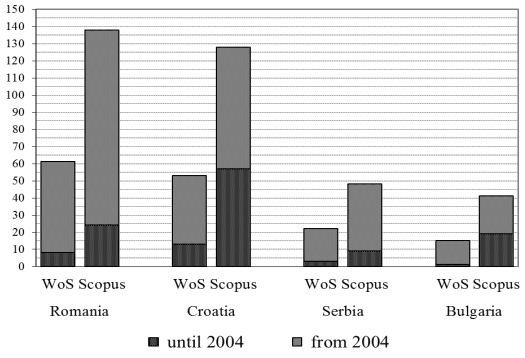

Figure 1. Growth in the number of WoS and Scopus journals published in Serbia and three neighbouring countries.

Another, and perhaps the more important contest, was carried out at the local (political) level. Every assessment brings the risk of conflict of interest. If such an assessment influences the allocation of funds and promotion and tenure decisions, the risk is even higher. Although the government supported CEES financially, it did not fully uphold the practical implementation of CEES reports on the quality of national journals (Šipka, 2014). Journal rankings based on impact measures and SCIndeks data were often altered by the ministerial committees in order to favour the very journals whose editors were members of those committees. In some cases, worst ranked national journals were given the status of international ones. At the level of individuals, it would mean that a candidate for promotion would earn points sufficient for a position of assistant professor by publishing two articles in a bottom-ranked local journal or a journal that was not even accepted for indexing in the national citation index.

The Collapse

In 2014, SMS has ceased to finance both the JBR and SCIndeks. In 2015, the effects of that decision have become visible in the form of significantly reduced SCIndeks coverage. A large amount of data were taken offline and became inaccessible to the users of SCIndeks and other web services, such as Google Scholar. Table 1 shows the amount of this "information market disturbance".

Table 1. SCIndeks data available online before and after the cut of funding.

No. of	*Apr. 2008*	*Apr. 2014*	*Apr. 2015*
journals	357	411	56
abstracts	82.876	151.027	19.900
full texts	23.421	58.068	12.172
references	917.567	2.078.642	335.344

As a response to the CEES' "strategic move", SMS has decided to continue using SCIndeks data for evaluation purposes and to finance JBR after all. However, all journals are now required to pay the indexing fees, including some additional costs for options like the full-text availability, cited reference search and cross-linking within SCIndeks. In short, a communication failure between CEES and SMS anticipates the start of a "natural selection" process for the majority of Serbian academic journals and the collapse of the open science idea in Serbia.

One aspect of this collapse is the fact that tens of thousands of papers written by the authors from Serbia are no longer available online and that additional costs are required for them to reappear. Another equally relevant issue is the profile of journals currently accessible through (what was) the national citation index. All of those journals are willing (or able) to pay the indexing fees, but just a few of them were previously classified as leading national journals. An example of this obvious compromise is the fact that although the diversity of affiliations within journal issues was strongly encouraged by both the national regulations and earlier SCIndeks inclusion guidelines, CEES indexes several journals with the majority of papers written by the authors affiliated with the journal's publishing institution.

The Future

Under the current circumstances, SCIndeks can no longer be considered to be the national citation index. The question is who should be concerned with the fact that it has become a mere commercial product with the special status at SMS. The state is surely a loser in this scenario being unable to claim and protect at least the metadata whose production it financed for several years. As for the Serbian scientific community, its future reactions are maybe not that hard to predict. A certain segment of this community has already expressed their opinion on this matter through the acts of various interest groups opposing the implementation of evaluation methodology based on SCIndeks data. On the other hand, an increasing number of researchers from Serbia are shifting the focus towards international journals, both when publishing and citing journal articles (Pajić & Jevremov, 2014). The evaluation of national science is hence being either spurned or entrusted to the international publishers and their reviewers. In this context, national citation index is becoming a costly repository whose functionalities will not be missed much by researchers or journal editors. More than 300 Serbian journals are now available online and none of them relies solely on SCIndeks when it comes to the visibility. Although some editors are satisfied with the combination of journal's personal website and free Google Scholar services, the growing number of Serbian journals are also being available through other databases and repositories, such as the *Directory of Open Access Journals*, *ERIH PLUS* or *EBSCO* databases. What was conceived as a joint effort to truly promote Serbian science has turned into an "every man for himself" strategy ten years after.

Conclusion

The basic idea of a national citation index was fully justified in the period of domination of Thomson Reuters' citation indices. But this domination is not nearly as strong as it was before, mainly due to the emergence of Scopus and Scholar. We can consider *SciELO* (now hosted by WoS) as an example of a successfully realized "peripheral" citation index. If this was achieved by covering some 1,200 journals from 12 different countries, then SCIndeks and its 400+ journals tell us how justified is the idea of a national citation index and how ambitious it should be. SCIndeks and its fate is the fate of any self-sufficient and rigid science policy institution, but also the fate of any scientific community that is simply too confined and too small. Too small to neglect the inevitable globalization of science, too small to rely on the integrity of its own members to ensure the quality control, and finally too small to satisfy its own ambitions.

Selecting Researchers with a Not Very Long Career - The Role of Bibliometrics

Elizabeth S. Vieira[1] and José A. N.F. Gomes[2]

Introduction

The scientific community has developed many institutionalized forms of evaluation where peer review has an important role, but recently, bibliometric methods have been gaining some acceptability to assess the scientific performance.

The two techniques have been related to one another in different ways: 1) bibliometric methods have been used to analyze the peer review processes (Moed, 2005, chapters 19 and 20); 2) the peer review process uses bibliometric parameters as an auxiliary instrument (Moed, 2005 chapter 18, p. 233-234); and 3) peer reviewers are called in to validate and correct the results of some bibliometric process (e.g. Norris & Oppenheim, 2003; Rinia, van Leeuwen, van Vuren, & van Raan, 1998). There are some national scientific systems that use bibliometric techniques or a mix of bibliometric techniques and peer review to decide the allocation of funding (e.g. Excellence in Research for Australia (ERA); *Valutazione della Qualità della Ricerca* (VQR)). Taking into account the advantages and limitations of bibliometric techniques and the intensive use, recently, there is a growing interest in its potential in helping peers to prepare the final decisions and therefore several studies have been made on the subject (e.g. Vieira, Cabral, & Gomes, 2014a, 2014b, Bornmann & Leydesdorff, 2013). In this study, we exploit the usability of bibliometrics as support tool this time in selecting candidates that had been awarded their PhD's more than 6 and less than 12 years ago and had worked as independent researchers for less than 6 years. We deem this study important as: (1) there is a growing use of bibliometric indicators and it is important to know their caveats and strong points at the different levels; and (2) the use of bibliometric indicators is more controversial when applied to individual researchers, especially at initial steps of their careers.

Methodology

This study considers the applicants to the development grants of the opening *Investigador FCT* carried out in Portugal since 2012. The publications indexed in the Web of Science Core Collection of the 120 applicants from the Engineering and Technology (28), Natural Sciences (23), Exact Sciences (48) and Medical and Health Sciences (21) were used to calculate a set of bibliometric indicators that are intended to describe the scientific performance. Bibliometric techniques are not used in a formal way in the opening. However, we are looking for indicators that may be implicit in peer judgments. A set of 17 indicators was determined: *TD* (number of documents); *TDC* (number of cited documents); *NDF* (number of documents after fractionation by the total number of authors); *PA* (% of articles); *PP* (% of proceedings papers); *PR* (% of reviews); *PAP* (% of documents as articles and proceedings papers simultaneously); *PDAC* (% of documents as corresponding author); *h* index, h_{nf} index (Vieira & Gomes, 2011); $SNIP_m$ (median of all the *SNIP*s of the journals where the applicant has published, Moed, 2010); SJR_m (median value as in the $SNIP_m$, Gonzalez-Pereira, Guerrero-Bote, & Moya-Anegon, 2010); *PTDIF* (% of documents published in journals with Impact Factor- *IF*); *PQ1* (% of documents published in journals in the first quartile in its scientific domain, according to the *IF*); *HCD* (% of documents highly cited in the top 10%); *NI* (average number of citations per document after normalization); *DIC* (% of documents with international collaboration). There is a huge number of bibliometric indicators and we tried to select those that describe the several dimensions of the scientific production. Nevertheless other indicators could be used.

Using as dependent variable the decision of the peers panel (selected-1; not selected–0) and the bibliometric indicators as independent variables we applied binary logistic regression aimed at determining those indicators that can be used to predict the final decisions made by the peers.

Results

The model

The application of the binary logistic regression lead to the following model:

$$P_i = \frac{e^{-1.88+1.116SJR_m+0.064HCD}}{1+e^{-1.88+1.116SJR_m+0.064HCD}}$$

where P_i is the probability of the applicant i to be selected by the peers for funding. The SJR_m and the *HCD* are the indicators that were found to be able to represent the decisions made by the peers panel.
The sensitivity determined for this model was 73.2%, the percentage of false positives obtained was 35% and 70% of the cases are predicted correctly by the model. The probability of the forecasted probability by the model for a selected applicant to be higher than that of a non-selected one is 75.3% (ROC curve).

Forecasts

The predictions given by the model are useful in preparing the decisions to be taken by the peers, but the use can be increased if complemented with some type of uncertainty measure. Here, this is shown using the margins concept. Margins are being used in bibliometrics at the individual level for the first time as far as we know.
In Figure 1 is shown the probability of a given applicant to be selected for funding as we increase the value of the *HCD* and SJR_m, respectively, and maintaining the average value of the other variable. For each predicted value is also shown the confidence interval at 95%, working as the uncertainty measure. All this information can be used by the peers to improve the decision making process.

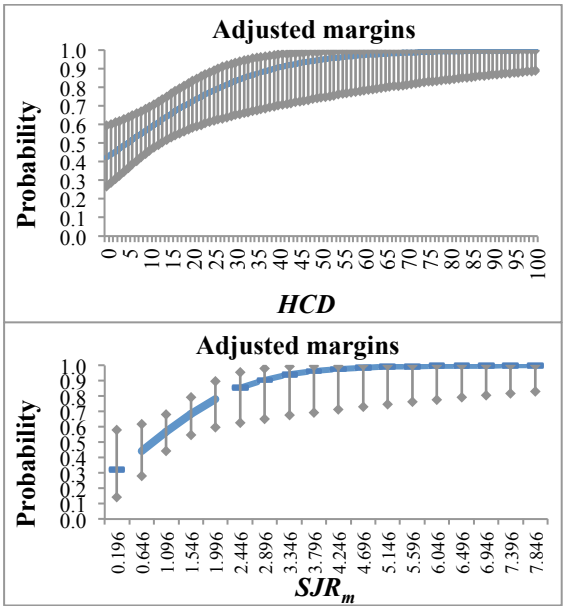

Figure 1. Predicted probabilities complemented with confidence intervals (95%). The dashed zone represents values with a few observations.

Conclusions

From this study some findings can be drawn:

- ✓ The bibliometric indicators are useful in describing the performance of applicants with PhD's earned 6 to 12 years ago.
- ✓ A composite indicator (*HCD* and *SJRm*) when used by the peers will have a positive impact on the final decision.
- ✓ Bibliometric indicators can be used, for example, as input tool helping peers panel in their decision making process as the indicators can give consistent and objective information.
- ✓ The *HCD* is a serious candidate as tool in support decisions of peer evaluations as it was also found to be useful in describing the final decisions in other types of openings (Vieira et al., 2014a, 2014b).

Introduction

In recent years, there has been a growth in the number of papers that synthesize empirical research studies on gender and sex inequalities in academic statements. Furthermore, these studies can comply with European requirements of equalities since the Treaty of Amsterdam of 1999 enacted that equality between men and women should be included in all policies (Fernández Álvarez, 2014).

Theses are the research papers by excellence and a good indicator to elucidate the lines and research trends in a field of science, since this work must be original and specialized and are subject to a rigorous academic assessment (Delgado López Cózar et al., 2006).

Our objective is to analyse the differences in gender representation in the Spanish sociological theses focusing on three actors involved in the process: PhD students, supervisors and academic assessment boards.

Method

Records were obtained from TESEO, the governmental database of the Spanish Ministry of Education, Culture and Sport, which includes the Spanish theses defended and approved after evaluation. The search was limited to theses indexed by UNESCO codes related to Sociology (code 63) and to theses from the departments of Sociology of Spanish universities. A relational database was created to analyse and compare results.

Results

The total number of theses defended was 3,413. In the role of the PhD student, men presented 253 more theses than women did, while in the role of supervisor and academic assessment board, the differences were much greater: 1,004 and 1,159, respectively (Table 1).

Table 1. Number of PhD theses by gender and role.

Role	Male	Female	Total
PhD student	1,833	1,580	3,413
Supervisor	1,593	589	2,182
Assessment board	1,824	665	2,489

The percentage difference between males and females for PhD students is of 7 points, while for supervisors is of 47 points in favour of males, and for academic assessment boards this difference is of 47 points (Figure 1). The highest percentage of difference occurs in the role of academic assessment board, where 73.3% of board members were of males (Figure 1).

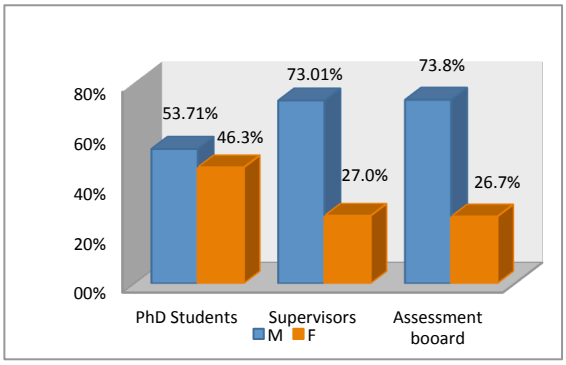

Figure 1. Percentage differences in PhD theses by gender and role

In the annual evolution of the percentages in the roles of supervisor and academic assessment board, men remain between 70% and 80% and women between 20% and 30%. On the contrary, from 2006-2010 period, women-PhD students reach parity (50%) and even surpass men in conducting thesis, ranking 57.8% in the last five-year period analysed (2011-2013) (Figure 2).

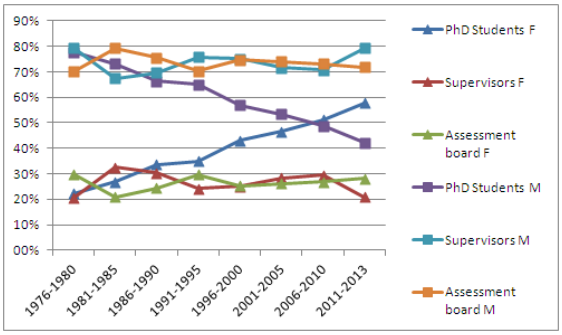

Figure 2. Five-year evolution of PhD theses by gender and role (1976-2013).

Discussion and Conclusions

Although a century has elapsed since the first woman enrolled in a Spanish university and its presence in several strata of the university has greatly improved, the percentage of women compared to men remain far from achieving parity in some roles.

The participation of women at the Spanish universities has increased steadily and its consolidation as PhD students today is a reality (Bermudez et al., 2011). However, from this stage, the academic careers of women slow down and the number of women who leave after doctorate is large (Bordons et al., 2003; Villarroya et al., 2008). Consequently, the percentage of female lecturers in Spain is between 30% and 35%, and the female professors between 14% and 20%. Therefore, it is noteworthy the existing great inequality in the Spanish universities as a professional field and that even though women are more numerous and better prepared than men at all levels of education, this is not reflected in prestigious academic positions (González Alcaide et al., 2009).

In conclusion, the promotion of women to positions of great academic responsibility is slow and is not in line with the number of women who obtained his doctorate in Sociology in Spain. Future research could explore other variables and behaviours, for example, if students of one gender tend to have supervisors from other different gender, as well as these trends in other fields and countries.

Introduction

The global number of papers published in different areas has increased over the years (King, 2004). Moreover, the science has experimented changes in academic production scenarios, such as decreased number of solo and increased team authors over the years (Nabout et al., 2015). For many a researcher the number of authors is one measure of collaborations (Price, 1958).

In fact the collaboration has promoted strong changes in science, and there are different reasons for collaboration: increased publication quality (Padial et al., 2010), and sharing costs and ideas (Vermeulen, Parker & Penders, 2013). For Ecology, complex questions such as global climate change, conservation plans of biodiversity among others, have promoted collaboration between scientists (Nabout et al., 2015). Moreover, there are different possible levels of colaboration and an important paper of Katz & Martin (1997) addresses this issue. For these authors, collaboration is: "Thus, a 'research collaboration' could be defined as the working together of researchers to achieve the common goal of producing new scientific knowledge." (Katz & Martin, 1997)

In general, the collaboration can be inter- or intra- at different spatial scales (e.g. national or international; intra or interinstitutional). This variation indicates levels of collaboration. Therefore, collaborations can occur between researchers from the same institution, between institutions of the same country and between different countries (Katz & Martin, 1997). Several methods have been proposed to measure the collaboration and using different units (researchers, institutes).

The aim of this study is to investigate the temporal trends of number of authors in Ecology journals between 1945 until 2014. Moreover, we will investigate the influence of level of collaboration (intra-institution - II; between-institutions - BI and between-countries - BC) in scientific quality (i.e. number of citation of paper). Our hypothesis is that collaborative papers (BC) generate more citations.

Data

To assess the number of authors and level of collaboration in Ecology papers, we selected all journals listed in category "Ecology" in Web of Science (www.isiknowledge.com, searched in February of 2015). We selected for this study only original articles (type of document), excluding notes, reviews, errata and others. We adopted this strategy to control the influence of type of document in the number of authors (Padial et al., 2010). The selection of papers considered all periods available in the Web of Science database (1945-2014). For collaboration analysis we consider only recent papers (2012-2014). For each paper, the following data were obtained: i) number of authors, ii) number of citations, iii) year of publication, and iv) the level of collaboration. For this last variable, papers were categorized according to the number of institutions of the authors and co-authors and their location. Therefore, authors affiliated with the same

institution were classified as intra-institutional collaboration (II); between-institutional in same country (BI) or between institution in different countries (BC).

Temporal Trends of Number of Authors

We found a total of 333,214 articles published in journals in the Ecology of Thomson-ISI between the years 1945 and 2014. The investigation of the number of authors per paper demonstrated a strong decay in the numbers of single-authored papers. In the early years, about 80% of papers in Ecology were single-authored. In 2014 this value is 4.8%. Statistical models suggest that in 2030 only 0.01% of papers will be single-authored (see Nabout et al., 2015). In addition, the number of papers with two authors have also declined from the beginning of the '90s. Therefore, recently there has been observed the increment in the number of papers with four and five authors, which enhances the tendency of multi-authored papers in Ecology. This trend has been observed in many other areas of science (Abt, 2007).

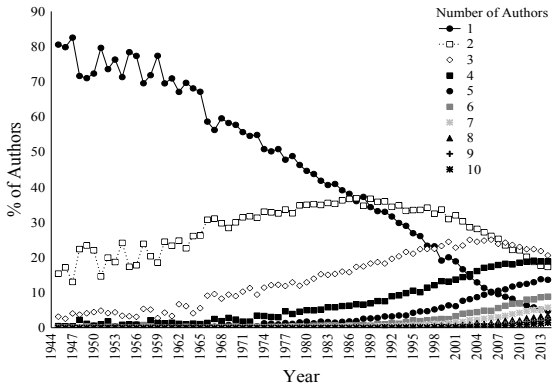

Figure 1. Temporal trends of the proportion of number of authors in Ecology Papers.

Levels of Collaboration

The papers of the years 2011, 2012 and 2013 exclusively of Ecology, totaling 10,457, were classified according to the level of collaboration (II, BI or BC). The Kruskal-Wallis (H) one-way analysis of variance by ranks was performed to assess if the number of citations is affected by the level of collaboration. We found a strong statistically significant difference ($P<0.01$), suggesting that collaborative papers written by authors from different countries received more citations Figure 2). This result reinforces the importance (and a recent trend) of international collaboration.

Using the same analysis we observed that the number of authors differs significantly between the levels of collaboration. In other words, BC papers have higher number of authors than those of SI and BI papers ($H = 1868$, $P < 0.001$). Therefore, the number of authors can also be an indication of the level of collaboration.

Finally, our work shows an increase in the number of multi-authored papers in Ecology. This is probably due to the complexity of questions in ecology which promotes collaboration between researchers. In addition, international collaborations have promoted papers with more citations (see Glänzel, 2001). Thus, the reduction of travel costs and the internet has allowed greater exchange between countries. In addition, governmental strategies can help in the exchange of researchers, such as the Program Science Without Border in Brazil. Thus, we encourage collaboration between researchers seeking to improve the ecological research of countries.

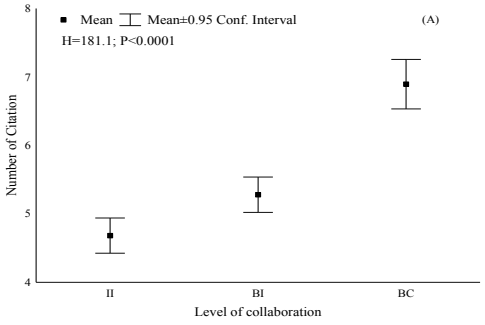

Figure 2. Number of citations for each one of level of collaboration.

A Bootstrapping Method to Assess Software Impact in Full-text Papers

Erjia Yan[1] and Xuelian Pan[2]

[1] *ey86@drexel.edu*
Drexel University, College of Computing and Informatics, 3141 Chestnut Street, Philadelphia, PA 19104 (U.S.A.)

Introduction and Motivation

There is a concerted effort to study science of science in multiple spheres. However, a clear gap exists in how to incorporate digital outputs, such as software, as an integral component in scholarly communication. This tension has become aggravated in recent years because software can be the end products in many scientific inquiries. Therefore, there is the need to build a framework to assess the impact of software in science. One cornerstone in the framework is the design of text-based methods to identify software entities in full-text corpora because these entities are largely mentioned in the text rather than formally cited in the way as their publications counterpart. This research-in-progress paper will serve this purpose by the development and evaluation of a bootstrapping method to automatically extract software entities from a full-text data set.

Despite the effort of indexing digital outputs such as Thomson Reuters' Data Citation Index or SageCite by University of Bath, U.K., the use of full-text data is necessary to identify patterns of software references because these digital outputs are referenced in unsystematical ways in scientific literature. They can be embedded in documents by digital object identifiers (DOIs), hyperlinks, and featured on dedicated websites or simply be mentioned in paragraphs, footnotes, endnotes, acknowledgements, or supplementary materials. A 2014 citation study on three oceanographic data sets showed that these digital outputs are more likely to be mentioned in the text than formally cited (Belter, 2014). Intuitively, one would think of curating a list of software names; however, it will not be feasible due to the velocity, variety, and volume of software that has been developed and applied constantly. Thus, merely using metadata or static listings is incapable of capturing the full extent of the impact of software. Instead, full-text publication data provide the crucial context for this purpose.

This study will use a bootstrapping method to identify software uses in a full-text data set. It will allow us to expand the impact and attribution mechanism by assessing the impact of software.

Methods

The bootstrapping method is used to extract software entities from full-text papers. It is a self-sustaining technique used to iteratively improve a classifier's performance through seed terms (Riloff & Jones, 1999; Riloff, Wiebe, & Wilson, 2003). The bootstrapping process contains the following steps: (1) Label seed terms or learned entities in the text. Seed terms are used in the first iteration, and learned entities are used in other iterations. (2) Generate contextual patterns of seed terms in the first iteration, and create contextual patterns of learned entities in other iterations. (3) Score these contextual patterns and select top ranked N patterns as candidate patterns. (4) Score entities extracted by candidate patterns and select top ranked M entities as learned entities. (5) Go back to the first step until the system cannot learn any new positive entities.

The calculation of pattern scores and entity scores determine the effectiveness of the bootstrapping method. If a pattern gets a higher score, then it is selected into the candidate pattern pool. Entities extracted by these candidate patterns are considered as candidate entities. To boost the performance, we incorporated three heuristic rules to the calculation of pattern scores. The first feature is an unlabeled entity containing at least one uppercase letter. An entity with this feature gets a score of 1 if it contains one or more uppercase alphabetic letters; otherwise, it gets a score less than 1. The second feature focuses on version numbers. An entity with this feature gets a score of 1 if a version number is collocated. The third and fourth features deal with the presence of trigger words: a score of 1 if the left context (third feature) or right context (fourth feature) of an entity contains trigger words.

Preliminary Results

To construct a corpus that has a good balance between sentences having software entity that mentions and does not mention, we selected 427 sentences that a particular software entity is mentioned from papers published between January 6 and December 29, 2013 in the data set. 573 sentences that do not contain software entities were also included in the corpus. We use this data collection method to attain a balanced experiment set to evaluate several entity extraction methods.

Experiments that use randomly sampled sentences will be pursued as future work. We used nine frequently occurring seed terms in the proposed bootstrapping method, including SAS, SPSS, MotIV, PAML, rGADEM, Limma, PICS, PHYLIP, and Minitab. To prepare the gold standard, we manually labeled software entities in the experiment data set and in total annotated 292 unique entities. The annotations are considered as the gold standard.

Table 1 displays the experimental results of the RlogF metric entity extraction system (Thelen & Riloff, 2002), Stanford Pattern-based Information Extraction and Diagnostics (SPIED), and our software extraction system. All methods in Table 1 used the same sets of seed terms, stop word list, and common word list.

Table 1. Experimental results of software extraction.

System	*Prec*	*Recall*	*F*
RlogF	91%	7%	0.12
SPIED	40%	28%	0.33
OurSystem	80%	62%	0.70

Table 1 shows that our system performed better than RlogF and SPIED based on the F score. Although RlogF has the highest precision, it missed a great number of software entities and resulted in the lowest recall. By comparing the software entities extracted by our system and the gold standard, we found seven of the one-time occurring entities were not identified by our system thus reducing the recall. We speculate that the recall may be improved when more sentences that contain low frequently occurring software entities are added to the data set such that the bootstrapping method will be able to learn their contexts.

Table 2. Popular software use in science.

Freq	*Software entities*
2	Prism, PASW, Vienna RNAfold, survival, Stata, SeqMan, rtracklayer, R2WinBUGS, Quantity One, PyPop, Origin, Microsoft Office Excel, JMP, GeneSpring GX, genefilter, FlowJo, Effective T3, Cytoscape, COMSTAT, CellquestPro, APE, ADE4, MetaMorph Imaging System
3	SigmaPlot, WinBUGS, T3SEpre, Statistica, MetaMorph, TiMAT2, stats, Statistical Package for the Social Sciences, STADEN, limma Bioconductor
4	HyPhy, IRanges, ImageJ, Affy, Vienna RNA
5	SigmaStat, MEGA, Vegan, Geneious
≥6	R, SAS, SPSS, MotIV, Bioconductor, Weka, PAML, rGADEM, Limma, PICS, PHYLIP, Minitab, Cellquest, RNAfold, Image J, GraphPad Prism

Table 2 shows 59 popular software entities in science which occurred more than once in the test corpus based on our extraction method. Statistical software packages are well presented in Table 2; however, we also see some domain-specific open access software tools—future impact assessment may primarily focus on these.

Conclusion and Future Work

The contemporary research landscape is changing: software has increasingly been developed and applied in many data-driven projects. Therefore, there is the need to assess its impact on science and to incorporate software in scientific evaluations. This paper is part of a larger effort to build a scientific assessment framework for digital outputs that include software and data. It has proposed a bootstrapping method to extract software entities in a full-text corpus. Results show that it has successfully extracted software entities with the F score at the 0.7 level which is an improvement over the baseline methods RlogF and SPIED. Future work will involve using the whole *PLOS ONE* full-text set and introducing more advanced features to further enhance the performance of the method. Research will also benefit from integrating the number of full-text software entity mentions with citation- and usage-based metrics to complement the impact assessment of software.

Article and Journal-Level Metrics in Massive Research Evaluation Exercises: The Italian Case

Marco Malgarini[1], Carmela Anna Nappi[1] and Roberto Torrini[1]

{marco.malgarini, carmelaanna.nappi, roberto.torrini}@anvur.it
ANVUR, Via Ippolito Nievo 35, 00153, Rome. (Italy)

Introduction

Article level metrics are usually the preferred choice for research evaluation. However, for recent articles they may be integrated or substituted considering some measure of journal impact (Abramo et al., 2012). The use of journal level metrics is also often considered as particularly appealing for administrative purposes, because of their readily availability, easiness to use and comprehensibility (Bordons et al., 2002). On the other hand, the IF is often criticized on the grounds of its possible biases and lack of methodological consistency (Vanclay, 2012). The aim of our paper is to provide evidence about the effects of the use of journal level metrics on the results of a massive research evaluation exercise like the one that has been performed in Italy with reference to the period 2004-2010 (VQR 2004-2010, see Ancaiani et al., 2015). More specifically, in the following we evaluate the effects of the use of the impact factor (IF) on the ranking of Italian Universities at the aggregate level, at the area level and for individual researchers.

Effect of the use of the Impact Factor at the University level

In order to assess the impact of the use of IF, we calculate two different indicators of research quality, denoted as R_VQR and R_IF. The former is based on the rules used for the VQR, and the latter uses only the Impact Factor in order to evaluate the articles; the analysis is limited to the research products evaluated only with bibliometrics. We then rank the 93 Italian Universities on the basis of those indicators, finding that the Spearman correlation index among the two rankings is equal to 0.92; moreover, the R^2 of a regression of R_VQR over R_IF and a constant is equal to 0.85. Hence, the analysis at the aggregate level shows that the final ranking of Italian Universities based on journal metric alone is very close to that obtained with the VQR algorithm (see also Figure 1).

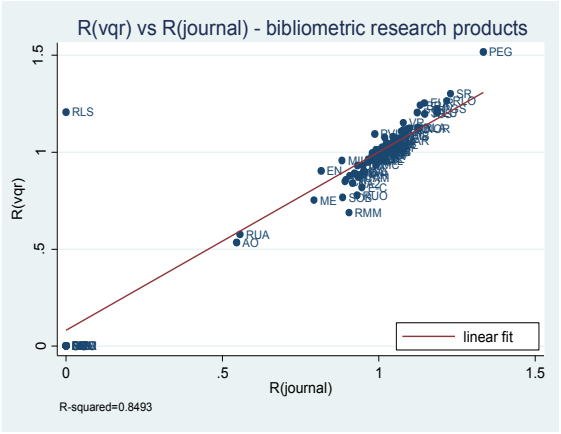

Figure 1 – The relationship among University evaluation performed with different metric.

Effect of the use of the Impact Factor at the Area level

However, it is well possible that the relationship is weaker when we are interested in ranking Universities in each scientific area. In order to shed light on this issue, we repeat the analysis for the 14 areas considered in the VQR (Table 1). Correlation between the two rankings is still above 0.8 in all the Research Areas except for Chemistry. The Spearman correlations among rankings are significant at 5% level in all the research areas.
Table 2 reports the coefficients of the regressions of R_VQR on R_IF (beta) and a constant (alpha); the table also reports the R^2 of the regression (column 3) and the standard deviation (column 4) normalized with respect to the average value of R_{iVQR} in each Area. Standard deviation is pretty low if compared to the average value of R (around 7%) in the Areas of Mathematics, Physics and Industrial Engineering, while in Earth Science, Medicine and Biology the normalized standard deviations grow to 17% of the average level of R in those areas. Similarly, the areas with a low normalized standard deviation are also whose with a higher R^2 and vice-versa. Hence, results confirm that the two evaluation methods bring very similar results also at the area level.

Table 1. Spearman Correlation between Rankings obtained with VQR bibliometric rules and Journal metric (* indicates statistical significance at 5%).

Research Area	Spearman	# Univ.
Mathematics	0.926*	64
Physics	0.825*	65
Chemistry	0.654*	60
Earth Science	0.724*	46
Biology	0.861*	66
Medicine	0.701*	58
Veterinary Sciences	0.876*	50
Construction engineering	0.720*	54
Industrial engineering	0.769*	67
Psychology	0.764*	61

Table 2. Sensitivity of research evaluation to the use of the Journal Impact Factor at the area level.

	(1)	(2)	(3)	(4)
Research Area	α	β	R^2	St. dv.
Mathematics	-0.055	1.039***	0.921	0.058
Physics	-0.13**	1.124***	0.847	0.060
Chemistry	-0.029	0.998***	0.706	0.100
Earth Science	0.180	0.815***	0.478	0.170
Biology	-0.142	1.132***	0.720	0.168
Medicine	0.083	0.894***	0.340	0.167
Veterinary Sciences	-0.004	1.016***	0.787	0.125
Construction engineering	0.186*	0.813***	0.532	0.100
Industrial engineering	-0.014	1.004***	0.675	0.070
Psychology	0.0778	0.916***	0.744	0.155

Effect of the use of the Impact Factor at the individual level

We finally look at how the use of the IF influences evaluation results for each h individual researcher. In this case, we regress individual scores obtained using either citations or the Impact Factor. Results of the estimation are reported in Table 3.

The relationship among the results obtained with the two different metrics is now rather weak: the R^2 of the regression is equal to 0.18 for the whole sample, varying between 0.20 and 1.156 in each year. The constant of the regression is rather high, while the beta coefficient associated with the IF is much lower than in previous estimates. Hence, at the individual level using alternatively only the citations or only the impact factor would imply a rather different outcome.

Table 3. Citations vs Journal Metric scores at individual level.

	Coefficient							
	Whole sample	*2004*	*2005*	*2006*	*2007*	*2008*	*2009*	*2010*
IF	0.488***	0.525***	0.531***	0.521***	0.507***	0.487***	0.507***	0.383***
Constant	0.280***	0.247***	0.232***	0.254***	0.282***	0.301***	0.233***	0.374***
#obs.	76,15	9,23	9,77	10,24	10,88	11,56	12,15	12,31
R^2	0.184	0.201	0.197	0.202	0.197	0.194	0.186	0.156

Conclusions

Overall, results may be considered as supportive of the idea of using two different bibliometric indicators for assessing research quality: on one hand, the use of the IF is not found to bias in a significant way University rankings, both at the aggregate and at the Area level; on the other hand, at the individual level, citations and IF evaluation are found to be rather different, pointing to the need of integrating the two different information in order to obtain a more robust measure of research quality for each individual researcher.

Accounting for Compositional Effects in Measuring Inter-Country Research Productivity Differences: The Case of Economics Departments in Four European Countries

Giannis Karagiannis[1] and Stelios Katranidis[2]

[1] *karagian@uom.edu.gr*, [2] *katranid@uom.edu.gr*
University of Macedonia, Department of Economics, Egnatia str. 156, 546 36Thessaloniki (Greece)

Introduction

Most of cross country studies on research productivity differences do not take into account compositional differences in academic staff force, such as sex, years of experience, origin of PhD studies, even though there are well documented evidence that (a) males tend to publish more than females (Gupta et al., 1999); (b) junior academic staff tend to publish more and in better outlets than senior stuff (Ben-David, 2010); and (c) academic staff with PhD studies in North America tend to be more productive (Katranidis et al., 2014). These aspects of observed faculty heterogeneity affect research productivity and are expected to have an impact on country average performance (Combes et al., 2003)[1].

Methodology and Data

In this paper we use the pure output or the single constant input DEA model, which is also known in the literature as the Benefit-of-the-doubt (BoD) model, to construct in the first stage a composite indicator of research productivity based on publication and citation counts at the faculty staff level. In particular, the BoD model in its multiplier form is given as (Cherchye et al., 2007):

$$\begin{aligned} I^k = \max_{s_i^k} & \sum_{i=1}^{N} s_i^k I_i^k \\ \text{st} & \sum_{i=1}^{N} s_i^k I_i^j \le 1^j \quad \forall j = 1, \dots, K \\ & s_i^k \ge 0 \qquad \forall i = 1, \dots, N \end{aligned} \tag{1}$$

where I_i^k is the i^{th} sub-indicator of the k^{th} unit, s_i^k are the weights to be estimated, j is used to index units and i to index sub-indicators which in our case correspond to different research outcomes (i.e., publication and citation counts). The BoD model is equivalent to the multiplier form of the input-oriented, constant returns to scale (CRS) DEA model when there is a single constant input that takes the value of one for all evaluated units. Based on this, the dual formulation of the BoD model is given as:

$$\begin{aligned} I^k = \min_{\lambda_j^k} & \sum_{j=1}^{K} \lambda_j^k 1^j \\ \text{st} & \sum_{j=1}^{K} \lambda_j^k I_i^j \ge I_i^k \quad \forall i = 1, \dots, N \\ & \lambda_j^k \ge 0 \qquad \forall j = 1, \dots, K \end{aligned} \tag{2}$$

where λ refers to intensity variables. Then the results at the country level are obtained by using the aggregation rule suggested by Karagiannis (2013), namely:

$$I = \frac{1}{K} \sum_{k=1}^{K} I^k \tag{3}$$

Thus, the aggregate composite performance indicator equals the simple (un-weighted) arithmetic average of the estimated individual composite indicators.

At the second stage we use Ray (1991) regression model to account for several contextual variables such as country dummies, a sex dummy, years of experience, and origin of PhD studies (i.e., overseas, Europe, home country and inbreeding), i.e.:

$$I^k = h\left(z_r^k\right) + e^k, \tag{4}$$

where r is used to index contextual variables and is $e^k < 0$ represents managerial inefficiency pure of (favorable and unfavorable) contextual variables. After taking into account the impact of contextual variables through (4) we re-calculate faculty level research performance scores and country averages. Our interest is to examine if and by how much these country averages differ from the unadjusted ones obtained via (1) or (2), and which countries are affected the most by the contextual variables.

We apply the above methodology to European faculty members in selected departments of Economics. In particular our sample consists of four countries, i.e., Belgium, Denmark, Greece and Portugal and a total of 383 faculty members and 15 departments. The analysis covers the period 1996-

[1] This research is implemented through the Operational Program "Education and Lifelong Learning" and is co-financed by the EU (European Social Fund) and Greek national funds.

2012 and the publication and citation count data come from Scopus database.

Empirical Results

Our main empirical results are summarized in the following tables:

Table 1. Unadjusted Composite indicator vs. efficient and unproductive faculty members.

	Unadjusted Composite indicator	Number of efficient faculty members	Number of unproductive faculty members
Belgium	0.144	1	6
Denmark	0.105	0	10
Greece	0.084	0	9
Portugal	0.062	1	18

Table 2. Number of unproductive faculty members vs. Adjusted Composite Indicator.

	Number of unproductive faculty members	Max value	Standard deviation	Adjusted Composite Indicator
Belgium	6	1	0.18	0.120
Denmark	10	0.588	0.11	0.100
Greece	9	0.667	0.10	0.086
Portugal	18	1	0.13	0.062

According to the unadjusted composite indicator, Belgian faculty members are found to be the more efficient and Portuguese the less efficient. In addition, in these two countries we can find the two fully efficient faculty members we have identified. At the same time these two countries are the ones with the relatively higher heterogeneity in terms of research productivity as indicated by the standard deviation of the unadjusted composite indicator.

When the composite indicator scores are adjusted for the potential impact of the aforementioned contextual variables by means of (4), the resulting efficiency scores change but not as much. They tend to improve a little bit for Belgium, Denmark and Portugal because these countries have a relatively higher percentage of inbred faculty members who in turn perform better compared to other faculty members. On the other hand, Portugal performance is adversely affected by the relatively larger percentage of females (31%) who though publish less than males and this counteract with the positive effect of inbred faculty, resulting in an unchanged national average.

Concluding Remarks

The empirical results indicate that the overall effect of the contextual variables considered is positive for the two northern European countries, i.e. Belgium and Denmark, and negligible for the two southern European countries, i.e., Greece and Portugal. Nevertheless, the two northern European countries perform better than the two southern European countries, regardless of environmental differences.

Metrics 2.0 for Science 2.0

Isidro F. Aguillo

isidro.aguillo@csic.es
Cybermetrics Lab. IPP-CSIC. Albasanz, 26-28. Despacho 3E14. Madrid 28037 (Spain)

Science 2.0

The concept Science 2.0 is a recent development designed to take advantage of the new sharing technologies and social networks of the Web 2.0 and that it is now strongly linked to the current and future research policies of the European Commission.

According to ideas developed by Ben Shneiderman this Science in Transition can be described according to two groups of actions,

Integrating the whole research cycle and its stakeholders, including all and both activities and people involved in them, far beyond that focusing only on the authors of papers, and

Opening the whole set of data; tools, results and metrics derived from the cited research (and communication) cycle from the very first moment the information is generated.

The urgent need to adapt the current set of quantitative indicators to this new concept is the reason for this poster. We intend to provide a critical analysis of the current status of the bibliometrics y related quantitative techniques for science evaluation and to introduce a new umbrella term, Metrics 2.0, for describing future scenarios for the discipline.

Current Metrics situation

A SWOT analysis is introduced for describing major issues related to bibliometrics and the attitude of bibliometricians and the rest of scientists' attitude regarding the discipline.

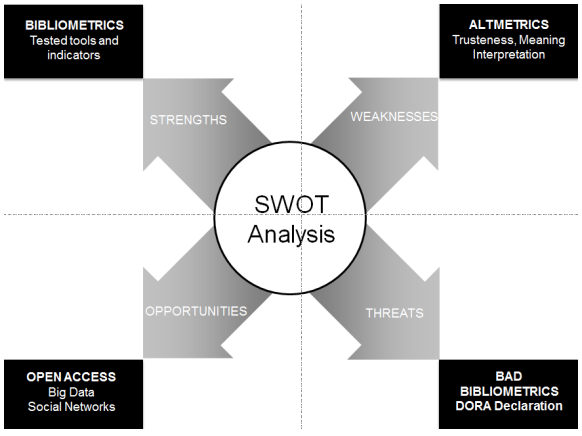

Figure 1. SWOT analysis of bibliometrics.

In recent years the term Informetrics become popular for describing an extended set of disciplines that are closely related to bibliometrics, including patentometrics or webometrics. However the fast development of the Internet, especially regarding the social networks, make this term become obsolete for describing a increasingly complex situation.

Specifically, there are two current developments that are having an impact on the discipline:

Altmetrics 'revolution'. The Web 2.0 tools have used as sources for extracting quantitative data when they are proxies for scholarly communication. Thousands of papers are exploring the capabilities of the different social networks using citation analysis for comparative purposes with mentions, readings or visits to bibliographic units.

Moving beyond Journal-level Metrics. After decades of criticism, and with the recent publication of the Declaration of San Francisco (DORA) the level of analysis is moving from Journal-level to Article-level metrics.

Proposals for Metrics 2.0

Regarding bibliometrics

The most serious problem is related to the way the contribution of each author (and the institution/s to whom is affiliated) is measured in a co-authored document. Traditionally two options were used: Full count (100% of merit for each author) and fractional counting (dividing full merit by the number of authors equally). As the number of authors per paper is growing exponentially, the last option is being discarded in most of the cases. Other alternatives, like identifying in the signature the relative contribution of each author, are still not a feasible option.

Traditionally full count is supported as it favours collaboration, especially international one. But this option is masking relevant phenomena for policy decisions. For example asymmetric collaboration with developing countries provides to their scientists and institutions with output/impact values that are not correlated with their low R&D investment prompting funders to not increase their budgets. Even with symmetric collaboration the full count based results are not able to discover the impact of the current economic crises that reduced

considerably the money invested in scientific research.
Taking into account that is a temporary proposal that intends not to reduce the level of scientific collaboration we suggest using a variant of the full count giving 50% of the merit instead of 100% to each author in papers with two or more authors.
In the case of organizations (and countries) where it is possible to identify the leading institutional author this should be granted the 100% authorship.
Although not a perfect or definitive solution this proposal should be especially useful for solving the problem of 'bad bibliometrics' that spoiled the major university rankings.

Regarding altmetrics

Apart of an ugly name, altmetrics is a confusing tangled set of mixed value tools. A first proposal could be to segregate the field in different subfields according to the tool that is involved. So, twittermetrics is different in both methodology and results interpretation to wikimetrics, for example. But there are two actions that are perhaps far more justified. It is highly recommended to set up a new discipline called Usagemetrics for the analysis of visits, visitors and their behaviour to academic and scientific websites. This is a very rich environment with dozens of candidate variables to build indicators independent from the standard citation motivations. The second moving is related to the tools where mention motivations are close to the citation ones, the most obvious one is Mendeley. In similar cases the proposal is to transfer these tools from altmetrics to the traditional bibliometrics arena.

Regarding Open Data y Big Data

The scientific community is strongly pushing for making openly available the data obtained from the experiments that is used later for preparing papers. Beyond the usefulness of this Open Data for replicating the results or for comparative purposes, the success of the initiative can make available huge amounts of information that could be considered, regarding the size-related challenges they pose, at the same level of the Big Data produced by the so-called Big Science. This is call for the scientific authorities for considering offering Big Data facilities and services for an extended group of scientists.

$$\text{Big Data} = \sum \text{Open Data}$$

Regarding Author Profiles

Until very recently the author-level metrics were technically a complex work when huge numbers of researchers were involved. Now the profiling services offered by several services (ResearcherID, Google Scholar Citations) or the major interests by the own research organizations (CRIS) and supported by disambiguation identifiers (ORCID) are changing completely the situation. In this new scenario, inspired by the results of the EU Project ACUMEN, we propose to set up author profiles with the following characteristics:
Bibliometric indicators from several sources, Non-bibliometric indicators, like those from altmetrics sources; context information like academic age, academic status, gender, levels of funding, networks membership and role, geographical or discipline biases, among others.
Rankings are a valuable tool if context is appropriately included in their elaboration. Relative indicators (percentages, quartiles) are being shown as far more trusted for this kind of classifications. However the use of composite indicators is still an open unresolved question that is still strongly criticised by the experts.

Conclusion

Metrics 2.0 should open and transparent, with data and indicators provided in a rich metadata environment.
Multiple sources and indicators are required, reflecting the diversity of the research activities, counting correctly and exhaustively the results and evaluating the different levels and magnitudes of the visibility and impacts of these results for all the communities, academic or not.
Presentation of the indicators, including friendly visualization of data is also relevant, but it is probably secondary to offer to end-users unrestricted customisation (including exporting in several formats) capabilities.
Summarising, bibliometricians can no longer been accountants able to extract, standardize, group and visualize the records from the Web of Science, but experts in several fields, with strong knowledge of different information sources and professionals capable of understanding specific needs and contexts ready to customise procedures according to the specific situation. Data, methodology, results and reports should be open to third parties in a mandatory way.

Evolution of Research Assessment in Lithuania 2005–2015

Saulius Maskeliūnas[1], Ulf Sandström[2] and Eleonora Dagienė[3]

saulius.maskeliunas@mii.vu.lt, ulf.sandstrom@indek.kth.se, eleonora.dagiene@vgtu.lt

Lindstedtsvägen 30, 10044 Stockholm (Sweden)
[3]Vilnius Gediminas Technical University, Sauletekio al. 11, LT-10223 Vilnius (Lithuania)

Introduction

Traditionally, governmental funding of scientific research has been based on input factors (e.g. student numbers), however since the end of the 1980s most developed countries have introduced assessment systems based on scientific output. Numerous examples of research quality assessment can be named as products of innovation and incremental change (Barker, 2007; Hicks, 2012; RDI Council, 2013). An overview of assessment methods applied in Eastern European countries in the field of Social Sciences and Humanities has recently been presented (Pajic, 2015), but information about Lithuanian assessment of research is lacking. Here, we analyse seven sequential Lithuanian methods of research assessment in the period 2005–2015, their influence and consequences.

Evolution of Lithuanian research assessment methodologies

The methodologies of research assessment in Lithuania have changed very often over the period 2005–2015. There is quite a great difference between assessment of papers in Social Sciences & Humanities (SSH) and papers in Science & Technology (S&T). While SSH researchers should have publications in any peer-reviewed journals (Table 1), S&T papers have higher requirements: to gain scores, they have to be published in journals included in *Thomson Reuters Web of Science Core Collection* (WoS) (Table 2).

The value of each research article published in a journal indexed by WoS in SSH was calculated by the following formula in 2006 only:

$$AIV = PVV\frac{N_{IA}}{N_A}\left(1+\frac{IF_j}{IF_{AIF}}\right) \qquad (1)$$

here: AIV – contribution of institution authors; PVV – [primary] value of unit in points; N_{IA} – number of authors from the institution; N_A – total number of authors, IF_j – journal Impact Factor (Thomson Reuters Journal Citation Reports), IF_{AIF} – Aggregated Impact Factor of the subject category in which this journal is listed or average of Aggregated Impact Factors of all subject categories in case the journal is listed in more than one category in Thomson Reuters Journal Citation Reports.

The value of each research article published in a journal indexed by WoS in S&T (2003–2015) and SSH (2008 and 2015) is calculated by the similar formula:

$$AIV = PVV\frac{N_{IA}\sqrt{N_{IP}}}{N_A}\left(1+k\frac{IF_J}{IF_{AIF}}\right) \qquad (2)$$

here: N_{IP} – number of different foreign affiliations (but, if $N_{IP} > N_A$, then there is considered that $N_{IP} = N_A$); $k = 1$ for evaluation until 2007, and $k = 2$ for evaluation of 2008 and later years;

Significant and frequent changes in the evaluation criteria were caused by the search for most fair distribution of governmental funding for Lithuanian research by the Ministry of Science and Education, in order to encourage the highest-level academic research.

All systems of research assessment since 2006 have encouraged S&T researchers to publish their papers in high impact journals and have urged Lithuanian journals to improve their quality as well as actively seek to be indexed in international databases and especially in Thomson Reuters Web of Science. When Thomson Reuters started the expansion of the Web of Science in 2007–2009, many Lithuanian (LT) journals were included into its databases. But, the methodologies used in 2010 and 2011 were disadvantageous to most LT journals as they didn't fulfil the requirements asking *only* for papers in journals which had more than 20 % of citations from journals (citing side) with an impact factor (IF) higher than the aggregate impact factor (AIF) of the respective subject field. This requirement was probably not field neutral but, instead it seemed to be disadvantageous to some fields of science and created funding for other fields. Consequently, some subject fields were downgraded by this requirement and received no score or low scores. However, this citation requirement was not used for evaluation starting from 2012 and will formally withdrawn in 2015.

Since 2009 for SSH and from 2010 for S&T, expert evaluations (by national experts) of papers and monographs presented by institutions is used in addition to previous bibliometric evaluation. Since 2010 the number of 1st level papers and monographs presented by academic and research institutions for expert evaluation is proportional to number of full time equivalent of PhD researchers in both S&T and SSH (i.e., it could be presented not more than one 1st level publication per 5 full time researchers in a research area, and if the unit has doctoral studies in a research area – it can present 1st level publication not depending on number of researchers).

From 2011 the assessment system is carried out every third year (not annually as before). That helps aca-

demic and research institutions to minimize the drawbacks of productivity fluctuations. The last assessment period was 2009–2011. In 2015, there will be an evaluation of 2012–2014; which will determine the allocation of budgets for 2016–2018 for all universities and governmental research institutions. However it is rather complicated to evaluate the dynamics because of rather frequent changes in evaluation criteria. The benchmarking of Lithuanian research 2009–2013 was run on April 2014 – April 2015 by the Research and Higher Education Monitoring and Analysis Centre (MOSTA), following the methodology prepared by Technopolis Group and involving only international European experts. Here the experts have noticed the need for greater internationalization of Lithuanian Social Science research.

Conclusions

The shift in methodologies for formal assessment of scientific publications produced by Lithuanian higher education and research institutions has urged researchers to communicate their results in international scientific journals, and for the Lithuanian scientific journals to seek inclusion in international databases (especially Thomson Reuters Web of Science, Journal Citation Reports) and to improve their quality. The effect of changes in journals' indicators up until 2012 is the focus of a parallel poster presentation (Dagiene & Sandström, 2015). Whether the introduction of national expert evaluation will change this overall pattern or not is yet to be investigated.
