In this paper we investigate the problem of university classification and its relation to ranking practices in the policy context of an official evaluation of Romanian higher education institutions and their study programs. We first discuss the importance of research in the government-endorsed assessment process and analyze the evaluation methodology and the results it produced. Based on official documents and data we show that the Romanian classification of universities was implicitly hierarchical in its conception and therefore also produced hierarchical results due to its close association with the ranking of study programs and its heavy reliance on research outputs. Then, using a distinct data set on research performance we further explore the differences between university categories. We find that our alternative assessment of research productivity – measured with the aid of Egghe's *g*-index – only provides empirical support for a dichotomous classification of institutions.

Conference Topic
University Policy and Institutional Rankings

Introduction
Since the beginning of the 1980s nationally relevant university research coupled with the pressure for accountability have increasingly shaped the policies and priorities of individual universities (Geuna, 2001). Since then, the growing importance of research has been continually underscored by transnational policy documents such as the EU 2020 Strategy, by implementation of performance-based research funding mechanisms which create new competitive pressures within national university systems (Hicks, 2012) and, perhaps most visibly and controversially, by national and international university rankings which fuel debates surrounding 'world-class universities' (Sadlak & Liu, 2007; Salmi, 2009; Shin & Kehm, 2013). It is now well established that "international rankings of universities have become both popular with the public and increasingly important for academic institutions" (Buela-Casal et al., 2007, p. 351). At the same time rankings have also become "successful as an agenda-setting device for both politicians and for the higher education sector" (Stensaker & Gornitzka, 2009, p. 132).

In this paper we present an empirical exploration of the research-driven ranking and classification processes directed toward the Romanian higher education institutions (henceforth "HEIs") in the policy context of a new Law on National Education. In accordance with the new law a comprehensive process of evaluation was conducted in Romania in 2011 with the dual aim of (1) classifying HEIs (at the global, institutional level) and (2) ranking their constituent study programs. The ranking and classification were conducted using a common methodology that heavily emphasized the research productivity of university staff. Our primary objective is to contribute to a better understanding of the relation between the classification and ranking processes by discussing the methodological outline of the official evaluation and by analyzing its results. To achieve this goal we rely on official documents and on data collected with regard to the actual results of the classification and ranking processes. A secondary objective of our paper is to investigate the consistency of the institutional classification categories used in the official evaluation. To do this we employ an alternative data set on research performance, measured using the *g*-index which – for the set of papers of an individual researcher – represents "the largest rank (where papers are arranged in

decreasing order of the number of citations they received) such that the first *g* papers have (together) at least g^2 citations" (Egghe, 2006, p. 144). Our goal is to investigate whether an alternative assessment of research based on this index confirms the official classification of institutions, which was largely determined by research performance.

Background

Theoretical considerations

Higher education in recent years has witnessed the emergence of numerous university rankings, which have been the focus of comprehensive studies that aimed to investigate their methodological underpinnings, theoretical outlook and practical consequences (e.g., Dill & Soo, 2005; Salmi & Saroyan, 2007; Usher & Medow, 2009; Rauhvargers, 2011). In a more recent study Hazelkorn (2013) noted no less than 10 global rankings and at least 60 countries that have introduced national rankings. All these studies highlight (among other aspects) the fundamental importance that ranking systems generally attach to research performance, the deleterious consequences that rankings may have for institutional diversity and quality and, perhaps most importantly, the methodological caution which should be exercised when undertaking and interpreting rankings.

As more and more rankings have been developed over the years and as concerns have mounted regarding their implications and methodological problems (e.g.: van Raan, 2005; Billaut, Bouyssou & Vincke, 2010; Longden, 2011), the adjacent subject of university classification has also received increased attention (see for example Shin, 2009). This has been the case especially at the broader European level where the international ranking impetus has been critically received by scholars and policymakers and carried forward in a new direction with the introduction of the U-Map and U-Multirank initiatives, which, unlike pre-existing commercial rankings, focus on a user-driven approach and emphasize multidimensionality in evaluation.

Classification of universities has tended to be a much less debated subject than rankings, but these two distinct processes are nonetheless naturally interwoven with each other. On the one hand, due to strictures of comparability "classification is a prerequisite for sensible rankings" (van der Wende, 2008, p. 49). On the other hand, classifications are often interpreted as rankings even though this is clearly against the intentions of the classifying agency. Shulman (2005) and McCormick (2008) provide several examples of how the Carnegie Classification of US HEIs is actually understood as a form of ranking by several types of stakeholders.

A useful analytical distinction made between classifications and rankings involves conceptualizing them in the context of the broader notion of institutional diversity which itself may be divided into vertical diversity and horizontal diversity. According to van Vught (2009), the former refers to differences between higher education institutions owing to prestige and reputation while the latter stems from differences in institutional missions and profiles. In light of this distinction, classifications are "eminently suited to address horizontal diversity" (van Vught & Ziegele, 2011, p. 25) while rankings "are instruments to display vertical diversity in terms of performance by using quantitative indicators" (Kaiser, Faber & Jongbloed, 2012, p. 888).

The Romanian policy of classification and ranking

In 2011, following the provisions of the new law on national education a comprehensive national evaluation was conducted for the first time by the Romanian Ministry of Education with the aim of classifying all accredited HEIs and, additionally, of ranking all accredited study programs offered by the universities. This process was by far the most elaborate evaluation of the Romanian system of higher education and the first one to explicitly

undertake an official classification of HEIs and an official ranking of their study programs on the basis of quantitative indicators.

With regard to the classification process the law stipulated that all universities must be classified as belonging to one of the following three classes: *A – universities focused on education*; *B – universities focused on education and research*; and *C – universities focused on advanced research and education*. This would point toward a functional differentiation with regard to research capacity but the law also stipulated that the allocation of public funding was to be a function of the results of the classification process: universities from class A could only receive public funding for study programs at the bachelor level, those from class B could receive funding for programs at both bachelor and master level, while those from class C were the only ones to receive public funding for all types of programs (including PhD). With regard to the ranking of study programs, the law on education did not contain any detailed provisions. However, a subsequent government decision (789/03.08.2011) established five distinct hierarchical classes A (high quality), B, C, D and E (poor quality). These program ranking classes should not be confused with the university classes.

A detailed methodology for the classification and ranking processes was made public through Ministry of Education Order 5212/ 26.08.2012. This methodology outlined a complex system of criteria, performance indicators, variables and weights. Table 1 provides a simplified account of the evaluation methodology for the particular case of social sciences. At the most general level, four common criteria were used for both classification and ranking purposes: (1) research; (2) teaching; (3) relation to the external environment; and (4) institutional capacity. The most important aspect in the evaluation process was the research performance of the staff working in the universities and/or the study programs under assessment. This is especially significant for our later use of the *g*-index.

Table 1. Criteria, indicators and weights used in the evaluation process for university classification and study program ranking (social sciences).

Criteria and global weights	*Performance indicators and weights within criterion*	*Variables within indicator*
I. Research (weight: 0.50)	Results of scientific research - 0.75	11
	Research funding - 0.10	5
	International recognition - 0.02	2
	PhD programs - 0.13	2
II. Teaching (weight: 0.25)	/	6
III. Relation to external environment (weight: 0.20)	Relation to economic environment - 0.20	2
	Relation to social environment - 0.05	3
	Community development - 0.45	3
	Internationalization - 0.30	9
IV. Institutional capacity (weight: 0.05)	Indicator 1 - 0.34	3
	Indicator 2 - 0.11	3
	Indicator 3 - 0.11	4
	Indicator 4 - 0.11	4
	Indicator 5 - 0.11	4
	Indicator 6 - 0.11	1
	Indicator 7 - 0.11	5

Source: Ministry of Education Order 5212/ 26.08.2012

Within the research criterion four distinct performance indicators were defined but the most important of these four was an indicator dealing with the research output of the staff members employed by the universities. This indicator had a weight of 0.75 while the other three indicators (research funding, international recognition, and PhD programs) had much lower weights (0.10, 0.02, and 0.13). This indicator of research output was itself further broken down into 11 different variables such as the relative influence score of articles, the number of publications in journals indexed in the ISI Web of Knowledge, books, book chapters, etc.

For the ranking of study programs each university reported specific data for all of the distinct programs it operated; then, global indicators were calculated at the level of the study program for the first three criteria listed in Table 1. A separate global indicator was calculated at the university level for the institutional capacity criterion. A further step then entailed the calculation of an overall *aggregated index of ranking* (AIR) based on the four global performance indicators and their attached weights. As a final step in the ranking of a study program, its AIR was compared to the highest one obtained among all the similar study programs and, based on certain predefined intervals, it was finally designated as belonging to one of the five ranking classes.

For purposes of classification a separate *aggregated index of classification* (AIC) was calculated at the global level of each university. The AICs were calculated following a formula which incorporated three factors: (1) the absolute value of the research score obtained at the global level of the HEI; (2) a more complex factor calculated as a sum of the global indicators obtained by each of the study programs organized by the HEIs; and (3) an indicator based on the confidence level given to the HEIs by the Romanian Agency of Quality Assurance in Higher Education (ARACIS) following its periodic evaluations.

Upon calculation of the AICs of all universities the class of a particular HEI could finally be determined. Similar to the process used to establish the ranking classes of study programs, in order to determine a university's class its AIC was compared to the highest one obtained within its category (comprehensive universities were compared to other comprehensive institutions, specialized HEIs were only compared to their counterparts). First, universities were sorted in descending order of their AIC scores. Then, again following predefined intervals, universities were classified in one of the three categories A, B or C.

Without going into further details, it is apparent from even a brief analysis of the methodological outline that the evaluation conducted for purposes of classification actually had the general underpinning of a ranking. This is primarily a consequence of the fact that the classification was based on the composite scores of university performance (the AICs), which were sorted in descending order and clustered in accordance with predefined thresholds. Moreover, the classification relied on the research scores obtained by the constituent study programs of the universities and, therefore, on the partial results of the ranking process of these programs. In effect, research was the object of double counting, once at the individual level of the study programs and once more at the aggregated level of the HEIs. Based only on the analysis of the methodology used in 2011, we may argue that the entire classification process was actually hierarchical in nature and that vertical, not horizontal differentiation was a foreseeable consequence not only at the level of study programs (where ranking was explicit) but also with regard to the more general level of universities (where ranking was disavowed in favour of the more neutral label of 'classification'). However, no empirical analysis has so far been undertaken with regard to the relation between the actual results of the classification and the results of the program rankings. In addition, no independent empirical test of the three classification categories has been conducted, either relying on the performance indicators initially used by the Ministry, or on alternative measures of research performance. In the following paragraphs we will address both issues in an attempt to answer several questions related to the classification and ranking processes.

Research questions

Given the unique nature of the classification and ranking processes undertaken by the Romanian Ministry of Education several important aspects invite questioning and empirical study. We will confine our analyses to the following:

1. Did the overlap in methodology with the program rankings have empirically discernible consequences for the more general process of classification? Is there a significant degree of association between particular classes of universities and particular classes of study programs? If so, which types of programs are more common in which types of university?
2. Since the classification process relied heavily on research outputs, can an alternative assessment of the research productivity of universities confirm the threefold classification? Are there significant differences with regard to the research productivity of faculty members *between* the three university classes? Furthermore, are there significant differences with regard to the research productivity of faculty members *within* the three university classes?

The first set of questions addresses the official classification and ranking processes in tandem and implies an investigation of data on the official results. The second set of questions only addresses the classification process and will be explored using a distinct approach, which will be described in the subsequent section.

Methodology

In order to investigate our first set of research questions we created a comprehensive data set of the results of the ranking process for all the study programs evaluated in 2011. We then added the results of the classification of universities in order to obtain a final data set comprising all the study programs, the ranking class in which they were placed following the evaluation process and the class in which the university managing them was placed following the separate evaluation for classification. This primary data set contains 1056 observations of distinct study programs. To test for the level of association between ranking and classification results we created contingency tables for the occurrence of particular types of study programs (i.e. ranked in class A, B, C, D, E) in the three classes of universities (i.e. class A, class B and class C). Additionally, a chi-squared test was also used to investigate the association between the classification and ranking categories.

To explore the second set of research questions we used a distinct data set composed of information on 1,z385 Romanian faculty members active in the fields of political science, sociology and marketing. Specifically, we used their *g*-index to conduct an alternative assessment of university research output. These staff members represent the full populations of staff employed in political science, marketing and sociology study programs and they are spread out across 64 departments (study programs) and 34 distinct universities. Information on the identity of the staff members was obtained from ARACIS and, for each of the staff members in this second data set, the *g*-index was extracted using Anne Harzing's Publish or Perish software (Harzing, 2007) using a procedure previously employed in Vîiu et al. (2012) in an examination of political science departments. With regard to this secondary data set, the results of the official classification of Romanian HEIs would imply that there are significant differences between the staff employed in the three university classes with respect to their research output. To test this we employ analysis of variance and subsequent Tukey HSD tests to reveal the instances where differences between *g*-indices are significant. We first compare the university classes globally, and then refine our analysis to take into account more granular differences between staff types. We thus compare the four staff types – assistants, lecturers, associate professors and full professors – across the three university classes in order to determine whether or not there is a structural difference between these classes.

Results and Discussion

Relation between official ranking and official classification results

With regard to our first set of research questions a review of Table 2 and Figure 1 indicates that universities classified as being focused on education have a limited number of top-performing study programs (90 ranked in A and B, i.e. 17% of all study programs in this class of universities) but cluster the most programs with middle and low performance (those ranked in classes C, D and E add up to 83% of programs managed within the universities focused on education). On the other hand, universities focused on advanced education and research hold a total of 185 study programs and 121 of these (over 65%) are ranked in class A. Another 39 are ranked in class B (thus, over 86% of the programs in this class of universities are ranked in classes A and B) and only less than 5% belong to the lower performing classes D and E. Universities classified as being focused on both education and research have mixed results: out of a total of 344 study programs managed by these universities 189 (55%) are ranked in classes A and B, 28% are in class C and the remaining 17% are ranked in C, D and E.

Table 2. Contingency table of ranking classes of study programs and university classes.

University class	*A - Education*	*B - Education and research*	*C - Advanced research*	*Row total*
Class of study program in official ranking				
A	22 **4.17%**	60 **17.44%**	121 **65.41%**	203
B	68 **12.90%**	129 **37.5%**	39 **21.08%**	236
C	147 **27.90%**	97 **28.20%**	17 **9.19%**	261
D	112 **21.25%**	16 **4.65%**	3 **1.62%**	131
E	178 **33.78%**	42 **12.21%**	5 **2.70%**	225
Column Total	527 **100%**	344 **100%**	185 **100%**	1056

Chi-Square test of ranking classes of study programs and university classes

	Value	df	Asymp. Sig. (2-sided)
Pearson Chi-Square	495.433	8	.000
N of Valid Cases	1056		

A more detailed study of the relationship between observed and expected count values of the different classes of study programs within each of the three university classes is also instructive. This study indicates a negative association between programs ranked in classes A and B and universities from class A. A further negative association can also be observed with regard to programs ranked in classes A, D, and E and universities from class B. Finally, universities from class C are negatively associated with study programs ranked in classes B, C, D, and E. On the other hand, a positive association exists between universities from class A and study programs ranked in classes C, D and E. A further positive association exists between universities from class B and programs ranked in classes B and C. Universities from class C are positively associated only with programs ranked in class A.

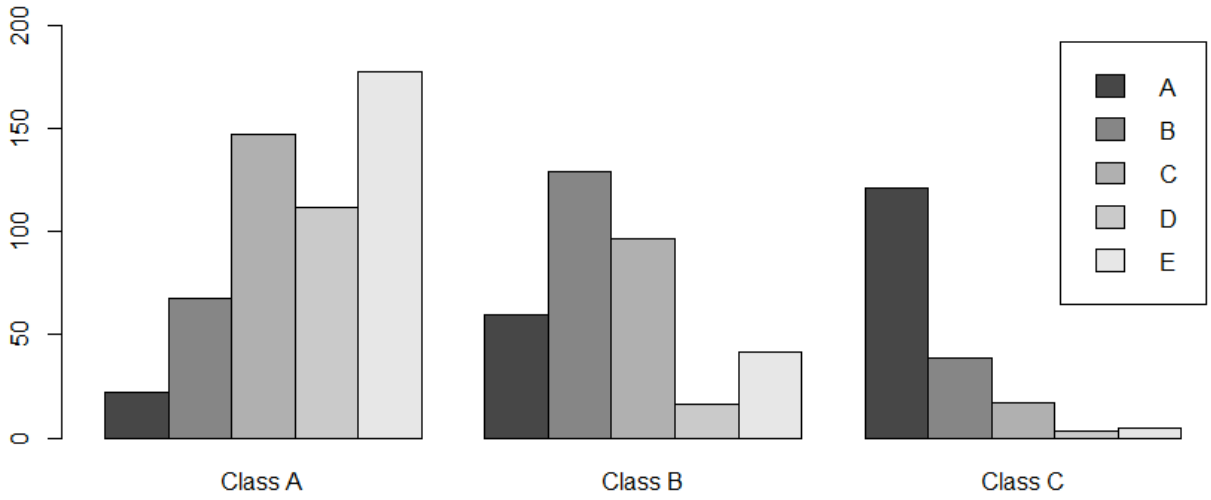

Figure 1. Distribution of study program types across the three university classes.

The results of this analysis paint a rather clear and polarized picture in which universities focused on education generally cluster study programs with poor performance while universities focused on advanced research cluster the programs with high performance. In addition, universities focused on advanced research are fewer and more selective (accounting for a total of only 185 study programs) as compared to universities focused on education (which manage a total of 527 programs). A certain hierarchy is implicit: universities focused on advanced research seem to be 'better' than those focused on both education and research which, in turn, are 'better' than those focused solely on education. However, as we mentioned earlier, these results were to be expected since both the classification and the ranking evaluation relied on a common methodology, which was mostly concerned with research performance. This leads us to our second set of research questions.

Differences in research productivity across and within university classes

We now move to explore whether our secondary data set enables us to distinguish between three university classes. In particular, what we want to see is whether the average *g*-index of all academic staff in class A universities is significantly lower than the average *g*-index of staff in class C universities and also in class B universities. The ANOVA procedure yields the results presented in Table 3. The subsequent Tukey HSD test indicates significant differences between all three means (although the confidence level for the class A – class B distinction is lower, but still above 95%) and therefore seems to provide empirical ground for the threefold classification, which was legally mandated in 2011.

Table 3. ANOVA of *g*-index with regard to university class (N=1,385).

Model summary for ANOVA of g-index with regard to university class

	Sum of Squares	df	Mean Square	F
Between Groups	953	2	476.3	81.62
Within Groups	8065	1382	5.8	Sig.
Total	9018	1384		0.000

Tukey HSD values for ANOVA of g-index with regard to university class

Comparison	Difference	Lower bound	Upper bound	*p*-value
Class A – Class C	-2.119	-2.513	-1.725	0.000
Class B – Class C	-1.714	-2.136	-1.293	0.000
Class B – Class A	0.405	0.054	0.756	0.019

However, the results presented in Table 3 only provide information on the global differences between university classes with regard to the *g*-indices of their entire staff, without further consideration of academic titles. Therefore, in order to test the consistency of the threefold model of classification imposed by the 2011 law, we must explore in greater depth the differences between universities, taking into account not only their classes, but also more granular differences between their academic staff. We thus set out to test not only the global aggregate differences, but also the *structural* patterns of the three classes of universities, taking into account the academic titles of the teaching staff.

In other words, bearing in mind the results of the official evaluation from 2011, we wish to know whether, for example, associate professors from class A universities are significantly different from associate professors in class B universities and from those belonging to class C and, still further, if the associate professors from class B institutions are different from those from class C. Similarly, we also wish to know whether assistants, lecturers and full professors from one class of universities are different from those belonging to the other two classes of universities. Based on such analyses we may draw more general conclusions regarding the degree of structural differentiation that exists between the three classes of universities.

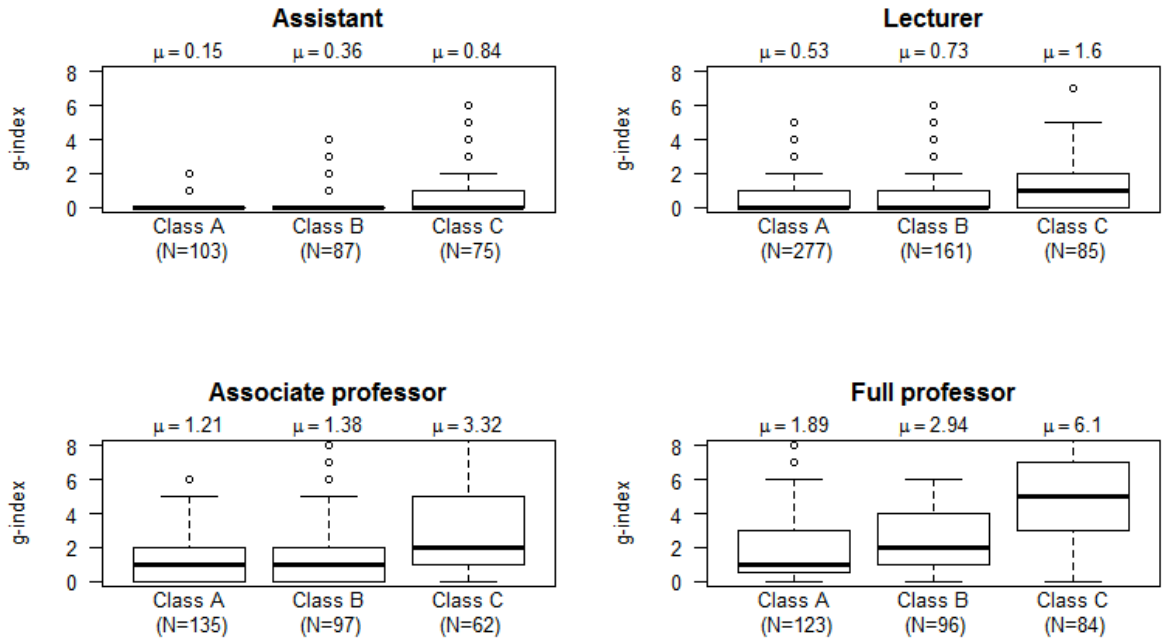

Figure 2. Distribution of g indices by academic title and university class.

Figure 2 illustrates the distribution of academic staff in our secondary dataset with respect to academic titles and also with regard to the class of university they belong to. Mean values are presented in the upper sections as μ. An initial visual inspection of the data would seem to indicate that in the case of assistants, lecturers and even associate professors there are no substantial differences between class A universities and those from class B. On the other hand, all three staff types working in class C universities seem to have substantially different *g*-indices compared to the ones from both class A and class B universities. A somewhat more nuanced picture emerges when looking at full professors. In this case the *g*-indices are more easily distinguishable between university classes and there indeed seem to be differences not only between class C and the other two university classes, but also between these two.

Based on the information contained in Figure 2 and on the ANOVA procedures presented in Appendix 1 we may now answer our secondary research questions. In the case of all staff members (be they assistants, lecturers, associate or even full professors) the parametric

statistical procedures show that universities classified within the official evaluation of 2011 as focused on advanced research (class C) are indeed significantly different from the other two types. In other words, assistants, lecturers, associate and full professors working in these universities focused on advanced research have significantly higher *g*-indices than their counterparts from education-centred universities, as well as from those in universities focused on both research and education. Beyond the clear distinction of staff members working in class C universities, statistical procedures also confirm something that Figure 2 reveals in a more intuitive manner: virtually no statistically significant distinction can be made between class A universities and the universities classified in 2011 as belonging to class B: assistant staff from class A universities are in no way significantly different form assistant staff working in class B universities, lecturers from one are in no way different from lecturers in the other and neither are associate professors. Even the apparent differences described by Figure 2 between full professors from class A universities and those from class B universities do not seem to be statistically meaningful either, as can be observed in Appendix 1. This suggests that a dichotomous classification would fit the data better than the threefold model imposed by the 2011 law.

So far we have argued that the data we have available clearly indicate significant *inter*-university differences (at least insofar as class C universities are made up of staff with higher indices than both class A and B universities). We now turn to *intra*-university differences. We have a reasonable expectation that within research universities there is a greater gap between the four staff types with regard to their scientific productivity. In other words, within class C universities we expect that the *g*-indices of assistants, lecturers, associate and full professors show greater dispersion than the corresponding indices of the equivalent staff that are employed in class A and class B universities. If we review the mean *g*-index values in Figure 2 we can observe that they appear to confirm our expectation. Whereas in the case of class A universities the gap between an average assistant and an average full professor is 1.74 and in the case of class B universities this gap is 2.58, in class C universities the difference is no less than 5.26. This indicates that full professors in research-centred universities have a substantially larger scientific contribution in their fields of study, not only when compared to staff employed in class A and class B universities, but also in comparison to their colleagues from the same university class. This suggests more competitive selection mechanisms of highly qualified academic staff in the research-centred universities compared to the other two university classes. These more competitive selection mechanisms may actually explain the institutional differences.

Concluding Remarks

The boundaries between classification and ranking of higher education institutions are often hard to establish and it is even harder to properly communicate the differences to intended stakeholders. When classification and ranking processes are carried out simultaneously and using common criteria the task of disambiguation becomes virtually impossible and the risk that a classification is perceived as a ranking increases exponentially. In the case of the evaluation conducted in Romania in 2011 the boundaries between classification and ranking were weak from the very inception of these evaluation processes in the law on education. The official methodology for classification and ranking further obscured the differences between the two due to its reliance on common criteria and indicators, most notably the research performance of academic staff employed by the HEIs.

By analysing the official methodology we have shown that the classification of Romanian HEIs carried out in 2011 had the underpinning of a ranking. By further analysing the results of both the classification and ranking processes we have shown that there is a clear association between the outcomes of the global process of classification and those of the more

specific process of program ranking: a polarized landscape thus emerges in which HEIs classified as focused on education cluster the overwhelming part of poor performing programs, while universities classified as focused on advanced research cluster the better part of the top performing programs.

The intermediate class of universities focused on both education and research presents mixed results. However, by conducting an alternative assessment of the research performance of the individual staff employed by Romanian universities in three fields of study we have shown that the threefold classification may not have a sufficiently robust empirical grounding, at least insofar as social sciences are concerned. By using the *g*-index as a concise measure of research performance we have illustrated the fact that the intermediate universities focused on both education and research may not be sufficiently distinct from the universities focused on education and therefore this intermediate class might have a certain degree of redundancy. When looking in our data set of 1385 staff members only at the aggregate results across university classes we do find some empirical grounding for the three classes defined in 2011. However, when analysing in greater detail the structure based on the academic titles and positions, we find less empirical grounds for the threefold classification as most of the staff employed in class A and class B universities are virtually indistinguishable from one another (i.e. assistants, lecturers and associate professors). It is only full professors that seem to make a more substantial difference between class A and class B universities, thus narrowly substantiating a threefold classification, which might otherwise well be a simpler dichotomous one. Previous extensive studies on the quality of Romanian higher education (Păunescu et al., 2012; Vlăsceanu et al., 2011; Miroiu & Andreescu, 2010) revealed the structural isomorphism of the Romanian higher education organizations. The undifferentiated set of standards that all institutions must comply with for purposes of accreditation and public funding led the institutions to adopt similar strategies for achieving these objectives. This is reflected in the poor differentiation and homogeneity of HEIs as shown by their similar scores in the external evaluation of the accreditation agency, similar missions, similar achievements on various performance indicators, etc. While there is empirical support for the vertical differentiation between advanced research universities (usually traditional, older universities) and the rest (more recent, including all private initiatives), the actual structures of the bulk of HEIs, including class A and class B universities, reveal more similarities than differences. These findings should of course be considered under the due caveat that our results are based only on data collected for social sciences.

Abstract
In the recent Italian Evaluation of Research Quality exercise for the period 2004-2010 (VQR), promoted by the Italian Ministry of Education and carried by the National Agency for Research Evaluation (ANVUR), metrics were massively employed. The use of Impact Factor or article citations (or both) are usually considered a powerful tool for supporting the peer review process but the replacement of the latter with an automatic evaluation tool has been always considered risky. Here we propose a possible prescription to overcome some limitations of the bibliometric evaluation carried out within the context of the VQR, while, at the same time, keeping the main distinctive features of the evaluation approach unchanged, namely, a simple evaluation tool based on the combined use of the CIT and IF variables While maintaining the basic elements of the previous algorithm unchanged and keeping the method simple and feasible on a large scale, we argue that the main flaws and limitations can be overcome.

Conference Topic
University Policy and Institutional Rankings

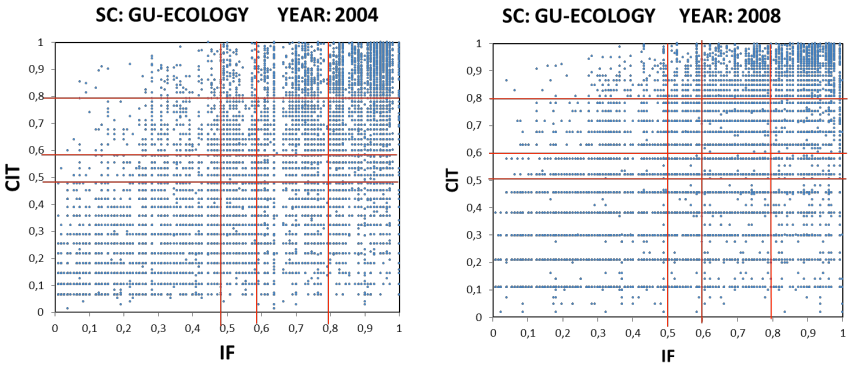
Introduction

The most popular European national research evaluation is the Research Assessment Exercise (RAE) in Great Britain, which started in 1986 and has been replaced, in 2013, by a new exercise - Research Excellence Framework (REF) - where citation-based metrics were employed to inform and supplement Peer Review (PR) evaluation.
In Italy, the first evaluation exercise was carried out in 2005 by the CIVR with reference to the period 2001-2003 (VTR). The VTR was fully based on the PR evaluation method, each submitted research product being assessed by a pool of experts (Minelli et al., 2008). Some studies (Reale et al. 2007; Abramo et al., 2009; Franceschet et al., 2011) analysed the outputs of the VTR comparing peer quality opinions on papers with metrics based on the Impact Factor of the journals publishing the papers, concluding that the two evaluation methods significantly overlap. However, comparison of PR and bibliometric evaluation methodologies has been largely debated in the literature (Barker, 2007; Moed, 2006; Harnad, 2009; Norris et al. 2003, Butler et al., 2003; Bence et al., 2009, Asknes, et al. 2004) with not always concordant outcomes. The use of Impact Factor or article citations or both are usually considered a powerful tool for supporting the PR process but the replacement of the latter with an automatic evaluation tool has been always considered risky.
In the recent Italian Evaluation of Research Quality exercise for the period 2004-2010 (VQR), promoted by the Italian Ministry of Education and carried by the National Agency for Research Evaluation (ANVUR), metrics were massively employed. Around 200.000 research outputs, mainly journal articles or reviews (both called 'paper' in the following), were evaluated, of which 46,5% by use of a bibliometric algorithm (Ancaiani et al., 2014).

Bibliometric Evaluation in the VQR 2004-2010

According to the Ministerial Decree number 17 of July 15th, 2011 promoting the VQR, each paper submitted for evaluation is classified in one of four possible classes of merit, defined as follows: "Excellent" (E): when the paper falls in the top 20% of the world production in a given Subject Category (SC) and in a given year; "Good" (G): when the paper falls in the following 20%; "Acceptable" (A): when a paper falls in the following 10%; "Limited" (L): when a paper falls in the bottom 50%.

In bibliometric areas, the strategy to assign a paper to a given class was based on the combined use of two variables: (i) CIT: number of citations collected by the paper up to December 31st, 2011 and (ii) IF: Impact Factor (or equivalent indexes) of the Journal in the year of publication of the paper. Each paper was submitted by the Organization (i.e. universities or public research bodies) and then uniquely assigned to a thematic evaluation panel (called Group of Experts for Evaluation, GEV) and to a Subject Category (SC), or All Journal Science Category (ASJC) as defined by ISI Web of Knowledge® or Scopus databases, respectively. In each SC/ASJC and for each year it is possible to construct the cumulative distribution function of the two variables[1], thus assigning to each paper its CIT and IF percentile. In the VQR three thresholds for both IF and CIT were defined to distinguish among the four classes specified in the Ministerial Decree. In the space spanned by IF (x-axis) and CIT (y-axis) it is therefore possible to focus on the region Q = [0,1]x[0,1] and plot the publications distribution defined on the basis of their CIT and IF percentile (Fig. 1, where each dot represents a paper denoted by its CIT and IF percentile). Each GEV had the freedom to assign the "off-diagonal" sub-squares (blocks) of the whole region Q, identified by the intersection of the "threshold segments", to a class of merit, thus completing the automatic phase of the evaluation process. Indeed, the diagonal blocks were quite naturally assigned to the four classes: the intersection of "top 20% for CIT" with "top 20% for IF" was straightforwardly associated to the "Excellent" class of merit, and so on. The choice to assign an off-diagonal block to a class was performed according to basically two drivers: first and foremost, the qualitative insight of the GEV on the scientific field and its publication practices (e. g. lag in citations, etc.) and second, the attempt to keep the final assignment as close as possible to the world distribution D specified in the Ministerial Decree.



(a) (b)

Figure 1. Papers distribution in a given SC and in two different years.

Such an approach showed some limitations that we summarize schematically:

[1] CIT: by ordering the total number of paper published in that SC and in that year in decreasing order from the highest to the lowest cited; IF: by ordering the Journals belonging to that SC in that year in decreasing order from the highest impact factor to the lowest.

Absence of "micro calibration": all the GEVs except for GEV 02 (Physical sciences) chose a single assignment (typically, one for years 2004-2008 and one for years 2009-2010), i.e., association of blocks to classes of merit, and did not went through a micro calibration at the level of the single SC and single year. Considering that: (i) for each GEV the number of relevant SC[2] was typically of the order of 50 and (ii) the distribution of the papers in Q was totally not uniform and invariant, rather, it varied significantly from one SC to another and form one year to another (see for instance Fig. 4). The absence of a micro calibration affected the possibility to comply with the distribution D punctually (and not only on average).
Structure of the blocks: (i) as showed in Figure 1 the threshold segments are parallel to the x/y axis. This is not convenient given the discrete nature of the two variables under consideration. (i) It can be easily noted in the plot that the points (corresponding to papers) are distributed in rows, according for instance to the limited number of journals present in a SC. As a consequence, the evaluation may not be robust enough, in the sense that a slight perturbation in the thresholds can modify the final class allocation for whole set of papers. (ii) It is quite hard, if not impossible, to comply with the distribution D by leveraging on the sole degrees of freedom given by the possibility to assign the off-diagonal blocks to a final class of merit. In other words, the constraint of assigning to a single class an entire block is too binding and tends to move too many paper from one class of merit to an another. (iii) The degrees of freedom are even reduced by the need to avoid that two non-adjacent classes of merit (say, "Good" and "Limited") can be adjacent in Q, as shown in Fig. 2.

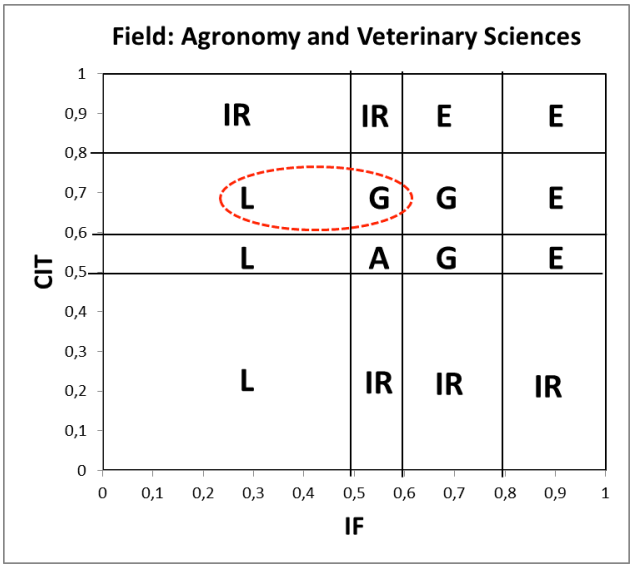


Figure 2. Algorithm used to evaluate research products in the Agronomy and Veterinary Science field: two non-adjacent classes of merit are adjacent in Q (red circle). "IR" indicates products that are lefd undecided by the algorithm and are eventually evaluated by peer review.

The new proposed approach

In the following we discuss a possible prescription to overcome these limitations while, at the same time, keeping the main distinctive features of the evaluation approach unchanged, namely, a simple evaluation tool based on the combined use of the CIT and IF variables. This can be done through the use of three diagonal segments with generic slope (Fig. 3).

[2] By relevant we mean that a great number (more than one hundred) of papers to be evaluated fell under that SC.

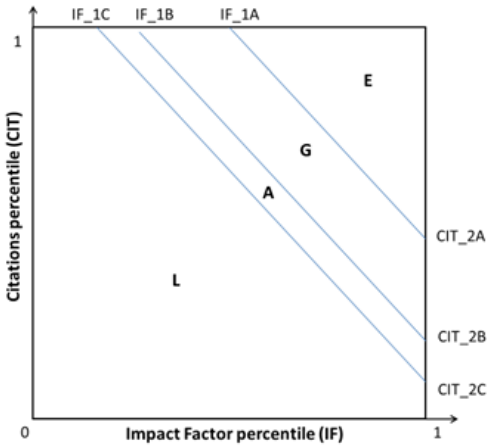

Figure 3. New prescription for combining the CIT and IF variables.

Such a new prescription builds upon three main pillars:

1. The segments identifying the thresholds are now drawn as a linear combination of the CIT/IF thresholds, thus being diagonal and no more parallel to the axes;
2. CIT/IF thresholds do not have to separately satisfy the 20-20-10-50 distribution;
3. The calibration, i.e. where to position the diagonal segments in Q in order to comply with the distribution D, is now performed at the micro level of each SC, for each year and for each GEV (according to general guidelines provided by the GEV itself and based on GEV's proficiency in the specific scientific field);

This would in turn guarantee the effectiveness and the simplicity of the whole process. In Figure 4 we apply this method to some SCs.

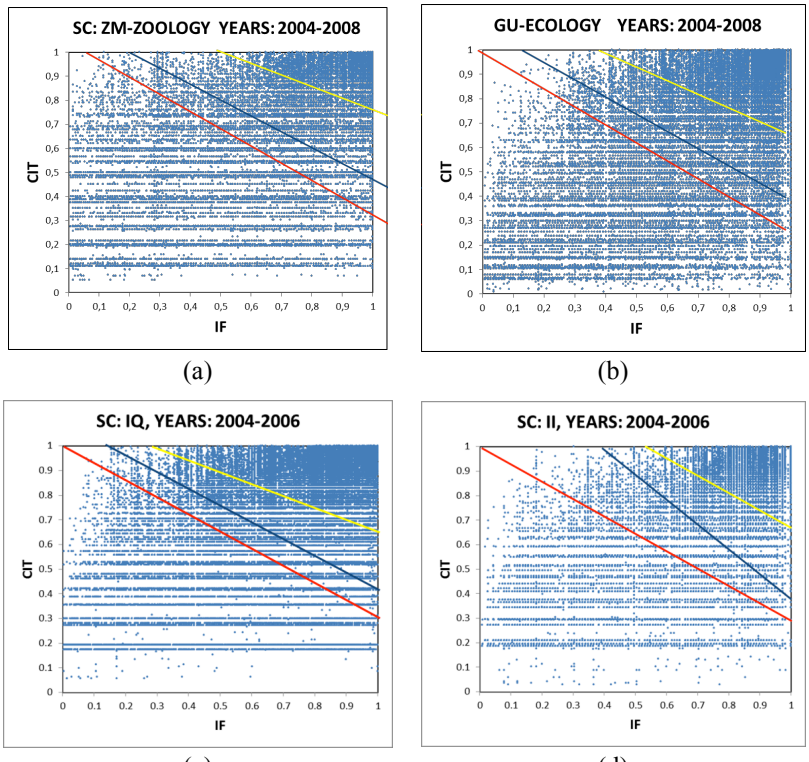

Figure 4. The application of the new algorithm in various SC and years. IQ stands for Electrical and Electronic Engineering, II stands for Engineering Chemical. The straight lines indicate the thresholds for the four classes of merit.

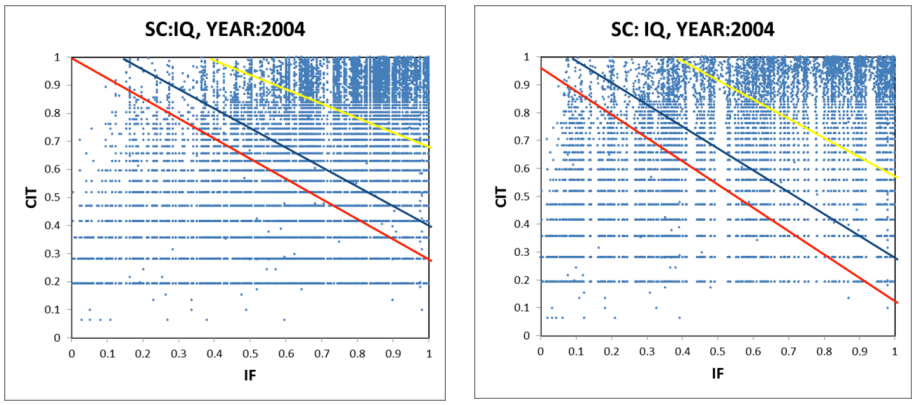
Comments and future developments

This new approach is characterized by a rather marked level of freedom in the choice of the position of the diagonal segments (or, equivalently, of the CIT/IF thresholds). Indeed, there is typically more than one choice that satisfies the distribution D. On the other hand one could impose additional constraints, such as for instance the parallelism between segments, based on additional empiric work and on scientific validation of the procedure (eg. by a PR comparison of the evaluation outcomes). Furthermore, such a freedom might be exploited to accommodate GEV's requirements. For instance, it would be possible to give more relevance to one of the two dimensions (IF, CIT) depending on, say, the year of publication or the citation praxes of specific disciplines (Mathematics vs Medicine being a paradigmatic example).

A significant possibility to further improve the accuracy of the method we discussed comes from a different definition of the cumulative distribution function for the IF variable. Instead of considering the number of journals belonging to a SC, one could consider the number of items (papers) published in the SC (in a given year). Actually, it is common that some journals host few thousands of items per year while other few tens or units. This induces a possible distortion that is quite evident in the plots shown below. As an example, In Figure 5 we analyze the distribution of the SC Electrical and Electronic Engineering in 2004. The distribution of the papers according to the IF and CIT percentile are depicted both considering only the number of journals in the calculation of the IF percentile and by considering also the number of item for each journal. The distributions are subdivided with different lines in order to obtain the target percentages D. It is evident that the equation of the lines is substantially different to guarantee the same final result. It is worth underlining that the lines used to subdivide the distribution reported in Figure 5(a) would result in very different percentages if applied to the distribution in Figure 5(b).



(a) (b)

Figure 5. Distribution of the papers according to the number of journals and papers. (a) IF percentile calculated based on the number of journals (b) the IF percentile is calculated considering the number of items. The distributions are subdivided with lines in order to obtain the target percentage D.

Finally, it would be possible to improve also the CIT dimension by overcoming the concept of SC as "reference set" and move on to clustering strategies based on semantic or on citation networks. This would be more rigorous and meaningful considering the existence of a great number of journals that publish very different subjects, but it would come with a significant enhancement of the complexity of the evaluation procedure, probably not feasible for the numbers implied by a national formal evaluation, at the moment.

Results obtained so far are already highly informative about the existing strength and weakness of the Italian University research system, and provide reliable input for policy interventions. Our proposal is intended to further improve the mix of peer review and bibliometric methods through a more precise calibration of the biblio(metrics) used.
The output turns out to be rather general, thus being applicable to other national assessments based on bibliometric analysis.

Abstract
A regression analysis of results from the Times Higher Education World University Rankings (THES-Ranking) from 2010-2014 shows high fluctuations in the rank and score for lower scoring universities (below position 50) which lead to inconsistent "up and downs" in the total results. We conclude that these fluctuations do not correspond to actual university performance. They create the impression of the THES-Ranking as a "gamble" for universities below rank 50. We suggest that THE alters its ranking procedure insofar as universities below position 50 should be ranked summarized only in groups of 25 or 50. Additionally, we argue for introducing a standardization process for THES-Ranking data by using common suitable reference data to create calibration curves represented by non-linearity or linearity.

Conference Topic
University Policy and Institutional Rankings

Introduction
Global higher education rankings have received much attention recently and, as can be witnessed by the growing number of rankings being published every year, this attention is not likely to subside. Besides the arguable use of results from global rankings as an instrument for rational university management, they remain influential for stakeholders inside and outside academia. A plethora of regional and national rankings exist, and 10 global higher education rankings are currently attempting to rank academic institutions worldwide. Numerous studies have analyzed and criticized higher education rankings and their methodologies (van Raan, 2005; Buela-Casal et al., 2007; Ioannides et al., 2007; Hazelkorn, 2007; Aguillo et al., 2010; Benito and Romera, 2011; Hazelkorn, 2011; Rauhvargers, 2011; Tofallis, 2011; Saisana et al. 2011; Safon, 2013; Rauhvargers, 2013). This casts justified doubt on a sensible comparison of universities hailing from different higher education systems and varying in size, mission and endowment based on mono-dimensional rankings and league tables (Hazelkorn, 2014). Several studies have demonstrated that data used to calculate ranking scores can be inconsistent. Thus, bibliometric data from international databases (Web of Science, Scopus), used in most global rankings to calculate research output indicators, favor universities from English-speaking countries and institutions with a narrow focus on highly-cited fields, which are well covered in

these databases. This puts universities from non-English-speaking countries, with a focus on the arts, humanities and social sciences, at a disadvantage when being compared in global rankings (Calero-Medina et al., 2008; van Raan et al., 2011; Waltman et al., 2012). Data submitted by universities to ranking agencies (e.g. personnel data, student numbers) can be problematic to compare due to different standards. These incompatibilities are being amplified because university managers have become increasingly aware of global rankings and try to boost their performance by "tweaking" the data they submit to the ranking agencies (Spiegel Online, 2014). Beyond all the data issues, there is the effect that universities with lower positions in the rankings often encounter volatile ups and downs in their consecutive year-to-year ranks. This creates the sensation of contending in a "gamble" in which results are calculated at random by ranking agencies. Such effects make global university rankings in many cases an inappropriate tool for university managers: the ranking results simply do not reflect the universities' actual performance or their management strategies. Volatile jumps are also difficult to explain to the media, which often engage in sensationalism when covering rankings by interpreting subtle changes of scores, even within the margins of statistical deviations, as substantial shifts in performance. Bookstein et al. (2010) found unacceptably high year-to-year variances in the score of lower ranked universities caused by statistical noise in the Times Higher Education World University Ranking (THES), one of the currently most popular global rankings. We again observed puzzling variances in the THES-Ranking 2014-2015, published in October 2014. Accordingly, we here analyze the fluctuations in score and rank of the THES-Ranking by calculating a regression analysis for consecutive years for 2010-2014 to determine the random component of these fluctuations. The methodology of the THES-Ranking was revised several times in varying scale, before and after the split with Quacquarelli Symonds (QS) in 2010 and the new partnership with Thompson Reuters. Times Higher Education (THE) calculates 13 performance indicators, grouped into the five areas Teaching (30%), Research (30%), Citations (30%), Industry income (2.5%) and International outlook (7.5%). However, THE does not publish the scores of individual indicators, only those of all five areas combined. Since 2010, the research output indicators are calculated based on Web of Science data. Most of the weight in the overall score is made up by the normalized average citations per published paper (30%), and by the results of an academic reputation survey (33%) assessing teaching and research reputation and influencing the scores of both areas (Rauhvargers, 2013; THE, 2014). In the past, criticism has been levied against this survey. Academic peers can choose universities in their field from a preselected list of institutions and, although universities can be added to the list, those present on the original list are more likely to be nominated. This leads to a distribution skewed in favor of the institutions at the top of the rankings (Rauhvargers, 2011; Rauhvargers, 2013). THE allegedly addressed this issue by adding an exponential component to increase differentiation between institutions, yet no information is available on its mode of calculation (Baty, 2011; Baty, 2012).

Methods

We used the publicly available data on scores and ranks from the THES-Ranking for the years 2010, 2011, 2012, 2013 and 2014, including only those universities ranked from 1 to 200. We performed the following analysis: i) we regressed the scores of the ranking of the year t-1 on the scores of the year t; ii) we regressed the ranks of the ranking of the year t-1 on the ranks of the year t; iii) we plotted the scores in descending order and iv) we determined the random component of the fluctuations in the ranks from year to year.

Results

Regression of the scores and ranks of two consecutive years

The regression of the scores—particularly of the ranking 2010-2011 regressing on the scores of the ranking of 2011-2012—shows a very high fluctuation/noise (Figure 1a), especially for the lower ranked universities. Moreover, the noise among the lower ranked universities seems to be higher compared to the already very noisy THES-Ranking performed by QS before 2010 (Bookstein et al., 2010, Figure 1). Note that in the rankings in the years following 2010-2011, the noise in the THES-Ranking did improve (Figure 1b-d).

Association between Scores and Ranks

Nonetheless, a general problem of the THES-Ranking remains: the difference in the scores among the 50 highest scoring universities is considerably higher compared to the difference among the lower scoring universities. This clearly suggests a non-linear relationship between scores and ranks (Figure 2 a-e). The consequence is that the ranks of the high scoring universities are much more robust to deviations in the scores from year to year. In the lower ranking universities, however, even very small, more or less random deviations (around 0.5%) lead to unexpected "high jumps" in the ranks from year to year (Figure 1e-h).

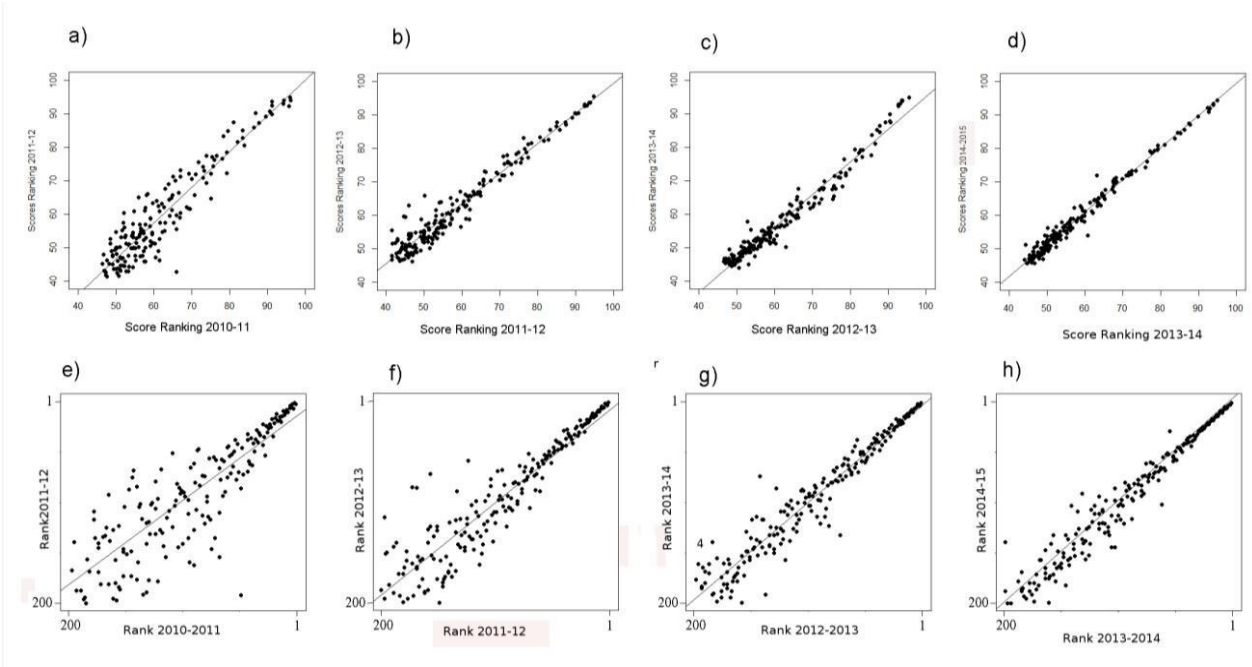

Figure 1a-1d) Scores of the year t-1 regressing on the score of the year t from the ranking 2010-11 on. Figure 1e-1h) Ranks of the year t-1 regressing on the ranks of the year t from the ranking 2010-11 on. Linear regression line indicates perfect association, e.g. no changes in ranks and scores between two consecutive rankings.

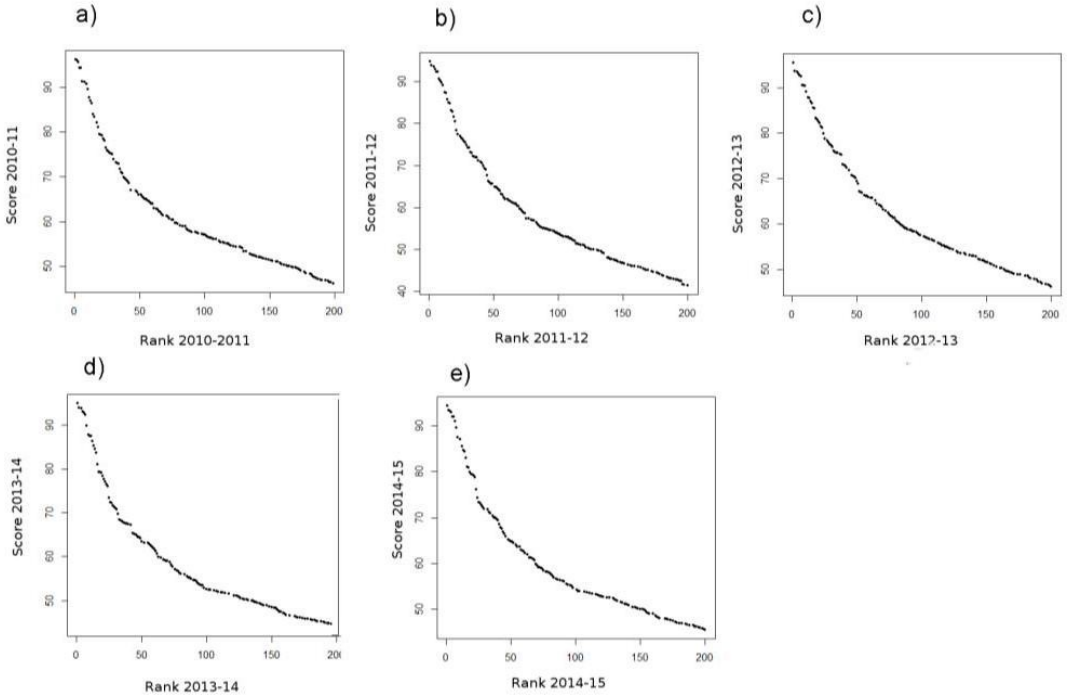

Figure 2 a-e). Ranks plotted against scores for the THES-Ranking a) 2010-11; b) 2011-12; c) 2012-13; d) 2013-2014; e) 2014-15

Discussion and Outlook

High ranking positions achieved by a small group of universities are often self-perpetuating, especially due to the intensive use of peer review indicators, which improve chances of maintaining a high position for universities already near the top (Bowman & Bastedo, 2011; Rauhvargers, 2011). This phenomenon also corresponds to the Matthew effect, which was coined by Merton (1968) to describe how eminent scientists will often get more credit than a comparatively unknown researcher, even if their work is similar: credit will usually be given to researchers who are already famous. The intensive and exaggerated discussion in the media of the "up and downs" of universities in the THES-Ranking is particularly misleading for the lower scoring universities (below approximately a score of 65% and a rank of 50; above scores of 65%, the relationship between ranks and scores is steeper, and it flattens for scores below 65%). This is because the ranking positions suggest substantial shifts in university performance despite only very subtle changes in score. In fact, merely random deviations must be assumed. One reason lies in the weighing of indicators by THE, with the emphasis on citations and peer review (totaling more than 65% of the total score). For lower ranked universities, a few highly cited publications, or the lack thereof, or few points asserted by peers in the reputation survey, probably make a significant difference in total score and position. In a follow up study that is currently under review we compared the results from THES with the results of the ARWU-Ranking (aka Shanghai-Ranking). Although the ARWU-Ranking seems to be more robust than the THES-Ranking (less year-to-year fluctuations probably due to the omittance of peer review indicators), we also found fluctuations below rank 50 and patterns of non-linearity between ranks and scores. Furthermore we found out that year-to-year results do not correspond in THES- and ARWU-Rankings for universities below that rank.

Ranking results have a major influence on the public image of universities and even impact their claim to resources (Espeland & Saunder, 2007; Hazelkorn, 2011). Accordingly, such fluctuations in the THES-Rankings can have serious implications for universities, especially when the media or stakeholders interpret them as direct results of more or less successful

university management. Our initial data in combination with the data from the literature strongly suggests that universities as well as policy makers and stakeholders should avoid to use rankings, especially league-tables, for management purposes or for strategic planning.

More specifically, the THES-Rankings in their current form have very limited value for the management of universities ranked below 50. This is because the described fluctuations in rank and score probably do not reflect actual performance, whereby the results cannot be used to assess the impact of long-term strategies. Thus, results from the THES (and to some extent also the ARWU) should be used only with great discretion. The low correlation between the ranks of the THES and the ARWU ranking, particularly for the universities ranked below 50 in both rankings, creates another serious doubt if rankings should be used for any management purposes at all. Maybe a "meta-analysis" of rankings could be reasonable to derivate consistent and reliable results from rankings. If done, such a meta-analysis should include as many rankings as possible to reduce random perturbations.

Multidimensional rankings, like the U-Multirank (http://www.u-multirank.eu), seem to offer a more versatile picture that reflects both the diversity of higher education institutions and the variety of dimensions of university excellence, allowing university managers to compare institutions on various levels. Although multidimensional rankings do get less public attention than league-tables and they can be prone for errors for the same reasons as monodimensional rankings (e.g., incompatibility of data provided by the universities), from the perspective of a university manager, they offer a more diverse toolset to gauge an institutions strength and weaknesses and to benchmark comparable universities.

"Rankings are here to stay, and it is therefore worth the time and effort to get them right," warns Gilbert (2007). That is especially true for monodimensional rankings, like the THES, that spark a lot of media attention. What could be done to address the fluctuations in the THES-Rankings for universities below rank 50 and to avoid the impression of a "gamble" in which THE "rolls a dice" to determine scores and ranks? THE has already addressed fluctuations to some extent by ranking universities only down to position 200, followed by groups of 25 from 201-300 and groups of 50 from 300 to 400. Nonetheless, based on our data we believe that this is not going far enough and suggest that universities should be summarized in groups of 25 or 50 below the position of 50.

The analyzed curves of scores vs. ranking positions in Figure 2 do have analogous characteristics for example to semi-logarithmic curves produced in analytic biochemistry. The accuracy of such curves is limited to the steepest slope of the curve, whereas asymptote areas deliver higher fuzziness (Chan, 1992). Thus, a further suggestion to avoid the blurring dilemma is the methodological approach of introducing a standardization process for THES-Ranking data. This would involve using common suitable reference data to create calibration curves represented by non-linearity or linearity. However, more research in this area is necessary.

The results presented in this paper are only the starting point and we plan to do more in-depth analyses of the variations in the various indicators in the future. We already have extended our analysis to include the ARWU-Ranking (paper currently in review) and we plan to analyze and compare other major higher education rankings (e.g. the QS-Ranking) in future publications to assess their usability for university management purposes.

The Vicious Circle of Evaluation Transparency – An Ignition Paper

Miloš Jovanović[1]

[1]*milos.jovanovic@int.fraunhofer.de*
Fraunhofer Institute for Technological Trend Analysis, Appelsgarten 2, 53879 Euskirchen (Germany)

Introduction

The present paper introduces a model, which describes different phases that typically occur in situations, in which a researching subject (e. g. an author, an institution, a country etc.) needs to be evaluated and in which some kind of reward (e. g. monetary in the form of a bonus or funding) is based on this evaluation. This model, the present author calls it the "vicious circle of evaluation transparency", will be underlined by giving examples for each of its phases. In order to be able to observe a process that is described by this model, there first needs to be something that is to be evaluated, for example a research group at a university. Such a need normally comes up, when money is to be divided among different groups or focused on one. The problem of evaluation and rewarding is at the core of the model (see Figure 1).

Figure 1. The "vicious circle of evaluation transparency"-model.

Phase I – Evaluation and rewarding by subjective and intransparent criteria

The first question that might come up in such a situation is the question of how to evaluate a research group. In hierarchically organized universities the leader of a department will decide whether or not and how this group is evaluated. Very often, this person is also the one that conducts the evaluation and, based on this, determines the type and amount of a reward or funding (or some kind of penalty, if the evaluation is negative). In today's world of vast amounts of digital data, it might be hard for only one person to do such an evaluation. Naturally, having one person alone evaluate a group's performance and decide on rewards will lead to a number of persons feeling unfairly evaluated, because the evaluator might not know about their achievements or their work in detail. This criticism might be alleviated in part by expanding the number of evaluators, for example by having a board of evaluators. Another possibility is to improve the transparency of the evaluation by documenting and publishing certain evaluation criteria by which the evaluated subjects can read about the evaluations and try to strive to get a better evaluation. These evaluation criteria are a first step towards phase II of the model.

Phase II – Introduction of "objective" and transparent criteria

These evaluation criteria might be subjective. For example "Quality of work" can be a criterion that is evaluated differently by different people. In order to make evaluation criteria comparable and independent of the evaluating person, "objective" criteria are often introduced. The reason why the word is put into quotation marks is due to the fact that very often these "objective" criteria are not objective at all. The introduction of "objective" and transparent criteria is a simplification of reality, an attempt to put parts of reality into some kind of a score in order to compare them with each other. Bibliometric indicators are one example of such a simplification. In many countries, different kinds of "objective" and subjective evaluation criteria have been introduced, for example in Italy (Abbott, 2009). Normally, these "objective" evaluation criteria (often in the form of different kinds of indicators) are communicated transparently. And while transparency is an important factor for these evaluations, it also leads to one problem in this phase: the fact that the evaluated subjects, in our example researchers at universities, react to the evaluation by starting to change their behavior, in order to maximize their scores in the evaluation. Of course, one reason behind evaluation is to positively influence the behavior of the evaluated researchers. But in Germany, for example, this has led to authors aiming to publish more in internationally known journals that have a US publisher and which are more general in their scope (Michels & Schmoch, 2013). This underlines the fact that authors do not base the decision in which journal they wish to publish in on scientific reasons

alone and constitutes a negative change of behavior. Also, some of the evaluated subjects might complain that the evaluation criteria do not reflect their work adequately and need to be refined. This leads to the next phase.

Phase III – Adaptation and enrichment of "objective" criteria

The need to fairly represent and evaluate researchers' work in the evaluation criteria and to adapt these in order to not allure unwanted change of behaviour leads to reforms in the evaluation system, e.g. new or a mix of indicators are proposed. The current discussion on alternative metrics is an example for phase III (e.g. in Haustein et al., 2014). The problem here is, that phase III is actually reintroducing parts of the simplification of reality, which was conducted in phase II. The evaluation criteria become more complicated again. A country example for this phase is the Czech Republic, which introduced performance-based research funding (phase II). A study by Vanacek (2014) found that the number of publications increased very quickly. He shows that in comparison to the quickly growing number of publications the quality seems to have stagnated and recommends reworking the procedure of evaluation and performance-based funding in order to increase not only the number of publications but also their quality (phase III). But for some research communities, the adaptation and enrichment of the "objective" criteria is no option. Instead, these criteria are rejected. For example, there is an ongoing discussion in the mathematical community. Authors note that bibliometric data lose "crucial information that is essential for the assessment of research". It is pointed out that bibliometric indicators can be manipulated and lead to undesirable publishing practices (Adler, Ewing, & Taylor, 2009). The authors also dismiss reputation, as determined by surveys as a possible way of measuring the quality of a journal. The evaluation of journal editorial processes is not seen as a good way of ranking journals either. Instead, the authors recommend an "honest, careful rating of journals based on the judgment of expert mathematicians", which is the point, where phase IV starts.

Phase IV – Removal of "objective" criteria and return to phase I

Concretely, the IMU recommends that a rating committee of 16-24 experienced and respected mathematicians should be appointed. Without going into too much detail, this committee (via various panels) is then supposed to rate the different journals and assign them to tiers (ranging from tier 1 = high quality journal to tier 4 = low-class journal) (Journal Working Group, 2011). This system is similar to the peer review process. Introducing evaluation by a committee of experts, either by rejecting "objective" evaluation criteria or because the evaluation system has become too complicated, brings the model full circle. The evaluation has reached phase I again. One should note that in phase II of this new cycle, the criteria probably will not be the same as in the first cycle. Newly developed and more sophisticated criteria will take their place.

Conclusion

It is this author's personal opinion that the above described model of evaluation transparency not only describes a typical process in which bibliometric indicators are involved but rather evaluation processes in general. If this is the case, one may discuss possibilities to change this, since a cycle like this is not an optimal solution. An option might be the introduction of diametrically opposed evaluation criteria so that an evaluated subject could not be good in all criteria. Another idea that might serve to fan the discussion on this topic would be the introduction of a changing system of criteria, akin to the disciplines at Olympic Games. The criteria could be published a year before the evaluation takes place and would change each year. This would be a transparent system, while the evaluated researchers would not need to change their behavior in a negative way because the next year the criteria would be different. Whatever changes might be introduced, it is this author's opinion that the vicious circle has to be stopped and replaced by a different system that leads to the desired goal: a fair evaluation of research.

Introduction

With the gradual promotion and implementation of China's national innovation-oriented strategy, research universities are playing an irreplaceable role in leading scientific development and technological innovation. Scientific research is one of the basic functions of a research university, which cultivates high-quality innovations and supports research universities in serving their societies (Rhoads, 2014). While high-level research universities need presidents with outstanding quality and ability. Research-oriented presidents, as the scientific research managers and experts, play a very important role in constructing and developing their universities, and they also focus on talent cultivation to realize social missions.

Therefore, the research on the influence of the research-oriented president's competency on research performance has profound connotations and value, which can provide references to guide and explore the systems for selecting, cultivating and assessing research-oriented university presidents.

Method

Research-oriented presidents, as senior managers of research universities, are responsible for teaching university management and for the direct leadership of scientific research. This special position determines the universality and complexity of the factors related to empirical studies on competence characteristics (Angeles, 2014; Sydney & Frances, 2013; Liu & Xu, 2013; Snyder, 2012).

Based on the theoretical analysis of competence characteristics and in combination with the vocational characteristics and main responsibilities of research-oriented presidents, we first constructed a theoretical framework of research-oriented presidents' competence characteristics (Figure 1). Then, we designed a questionnaire system to collect data and data were analyzed using SMRT PLS2.0 software (one of the leading software tools for partial least squares structural equation modeling). The verification results show that the scale's convergent validity was high, and it also had good discriminant validity. Finally, we used the R^2 statistic to analyze the structural model and received good explanation.

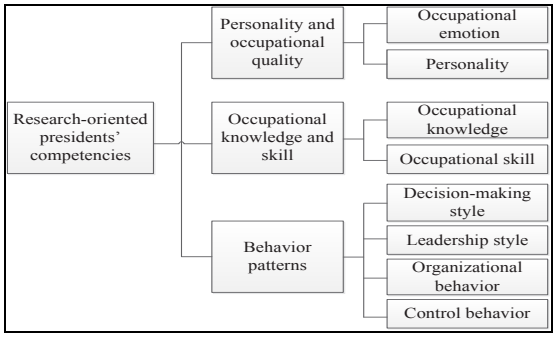

Figure 1. Theoretical Framework of Research-oriented Presidents' Competence Characteristics.

Data

This study selected research-oriented presidents of research universities as its subjects. Therefore, thirty-nine of 985 universities under China's Ministry of Education were selected for the study, and to ensure the comprehensiveness of our investigation, the selected samples included research-oriented presidents, middle management, scientific research management, professors, associate professors, lecturers, assistants, and other research personnel. The descriptive statistics (Table 1) on the study subjects were obtained via statistical data analysis.

Results

Through statistically analysing the sample data, the influence of occupational emotion, personality, occupational knowledge, occupational skill, decision-making style, leadership style, organizational behaviour and control behavior on scientific research performance was respectively checked. The results indicate that the performance had good validity. However, if organizational characteristics are used as an intervening variable, the competence characteristics of research-oriented

presidents have significant positive influences on scientific research performance.

Table 1. Descriptive Statistics on Respondents.

Measurement items		Sample size (N)	Proportion (%)
Gender	Male	292	70.4
	Female	123	29.6
Age	30 and below	37	8.9
	31–35	132	31.8
	36–40	93	22.4
	41–45	63	15.2
	46–50	41	9.9
	51–55	31	7.5
	56 and above	18	4.3
Education	College	3	0.7
	Bachelor's	31	7.5
	Master's	103	24.8
	Doctorate	276	66.5
	Others	2	0.5
Title	Assistant	98	23.9
	Lecture	92	21.9
	Associate Prof.	15	3.6
	Full Prof.	210	50.6
	Academician	0	0
	Others	0	0

Conclusion

Based on the above research results, we constructed a model of research-oriented university presidents' competence characteristics, shown in Figure 2.

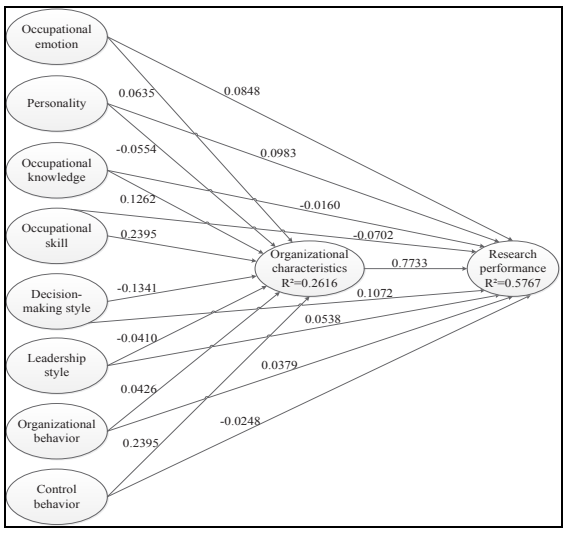

Figure 2. Relational Model of Research-oriented Presidents' Competence Characteristics and Their Universities' Research Performance.

The following conclusions can be drawn by analysing the model of research-oriented presidents' competence characteristics:

(1) From the direct effect perspective: 1) research-oriented presidents' professional emotion, personality traits, decision-making and leadership styles and organizational behavior have significant positive influences on scientific research performance. 2) Presidents' professional knowledge, professional skills and control behavior have significant negative influences on research performance, but further inspection of the analysis results reveals that the negative influence is not absolute.

(2) From the mediating effect perspective, professional emotion, professional skills, organizational behavior and control behavior have significant positive influences on organizational characteristics, whereas personality traits, professional knowledge, and decision-making and leadership styles have significant negative influences on organizational characteristics. However, organizational characteristics as intervening variables between research-oriented presidents' competence characteristics and their universities' scientific research performance can maximize the effects of the presidents' competence characteristics and have significant positive influence on research performance.

Medical Literature Imprinting by Pharma Ghost Writing: A Scientometric Evaluation

Philippe Gorry[1]

[1] *philippe.gorry@u-bordeaux.fr*
GREThA UMR CNRS 5113, University of Bordeaux, Av. Leon Duguit, 33608, Pessac (France)

Introduction

Misappropriation of authorship, honorary or ghost authorship, undermines academic publishing with a substantial proportion of peer-reviewed medical journals targeted (Flanagin, 1998). Pharmaceutical companies pay professional writers or medical communication companies to produce papers whilst paying other scientists or physicians to attach their names to these papers before they are published in medical or scientific journals. This ghost management is meant to support the marketing of drug products (Sismondo, 2007). Companies use this strategy to communicate competitive message, promote unproven off-label uses, and mitigate perceived drug risks (Fugh-Berman, 2010). Publication planning strategy with fraudulent practices were revealed through internal company communications in the course of the well-known Neurontin® litigation case (Vedula, 2012). Even though ghostwriting realized by pharmaceutical companies has been reported, it remains necessary to measure to what extent ghostwritten articles have impacted medical literature. Healy and Catell (2003) started to answer this question with a sample of 16 ghostwritten articles about a peculiar antidepressant. This pioneering analysis should be extended to a larger collection of ghostwritten articles as well as studied for a longer period of time.

Method

Pharma ghostwriting has been documented initially through 3 original papers: first, D. Healy and D. Cattell reported 16 ghostwritten articles in 2003, later on, A.J. Fugh-Berman (2010) reported 23 new cases, finally in 2012, Vedula and colleagues identified 13 more ghost written publications. Based on legal documents, from US district court following class action and lawsuit against pharmaceutical companies concerning several molecules: estrogen (Prempo®/Premarin®, Wyet), sertraline (Zoloft®, Pfizer), gabapentin (Neurotin®, Pfizer), and paroxetine (Paxil®, GSK), 40 more ghostwritten publications were identified. Therefore, a corpus of 92 publications were retrieved from Pubmed, Scopus or Web of Science databases, and subsequently analyzed for main bibliometric indicators. Descriptive statistics were done using Excel.

Result

A corpus of 92 ghostwritten articles was assembled, covering a period between 1997 and 2008. Two third of theses cases were published between 1998 and 2000. 79 different authors have been identified. While the vast majority of them were co-author of only one ghostwriting paper, 10 authors published two ghost papers and one signed three ghost papers (data shown on the poster). 82% of the identified authors were US academics. However, authors of 10 different countries were identified as representing the main drug pharma market with the noticeable exception of Germany and Japan. Among the different affiliation of the authors, only one pharmaceutical company was identified. Most of the institutions were university with affiliated medical school (data shown on the poster).

Ghostwritten articles were published by average productive author (h-index at the time of ghost publication date: mean=15.84), with some exceptions: Bondareff W, University of Southern California, (h-index=92), Seddon JM, Tufts Medical Center, (h-index=53), Freedman MA, Medical College of Georgia & Jermain DM, Pfizer (h-index= 2). Along the 10 years observation period, there is no noticeable variation in the productivity of the authors (data shown on the poster). Indeed average author h-index reach 29.13 in year 2013.

The corpus covers a large spectrum of medical specialties. However, it is interesting to point out that more than a third of ghostwritten papers concern psychiatry and mental illness (Figure 1).

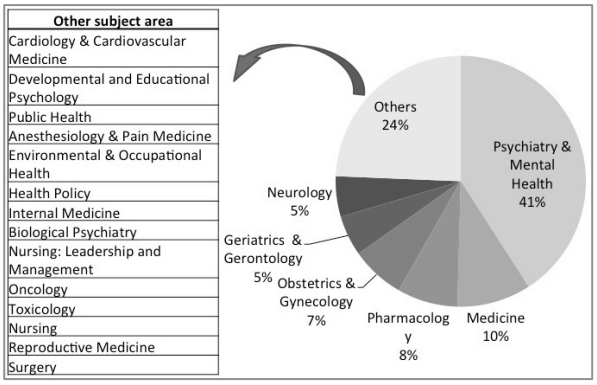

Figure 1. Distribution of ghost written articles by medical specialties.

Publication of ghost articles were scattered throughout 51 different journals. Among these source titles, there are four psychiatric journals, with various impact factor (IF), accounting for a third of the ghostwritten articles (Figure 2 and Table 1).

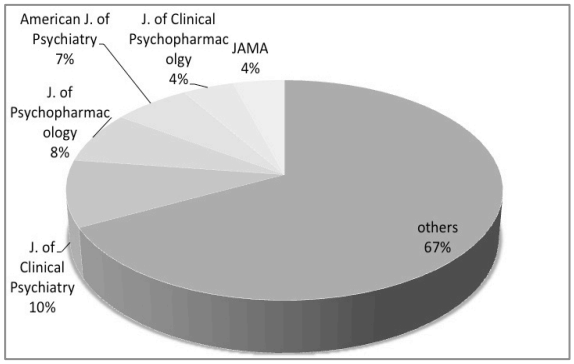

Figure 2. Distribution of ghost written articles by journals.

Table 1. List of the main journal publishing ghost written articles with their impact factor.

Journal	Ghost pub.	SJR impact factor at publication date
Journal of Clinical Psychiatry	9	1,787307692
Journal of Psychopharmacology	7	1,142571429
American Journal of Psychiatry	6	3,599
Journal of Clinical Psychopharmacolgy	4	1,6045
Journal of the American Medical Association	4	3,82875

The average IF of journals where ghostwritten articles are published is in the low-medium range (mean IF=2.51, median IF=1.81). Sometime, there are published in very low IF journal (ex: Climacteric IF=0.091).

Finally, the last evaluation concerns the number of year during which a ghostwritten article can be cited since the date of publication. (Figure 3; no ghostwritten article have been published in 2007). Year after year, ghostwritten articles have on an average 84% chance to be cited.

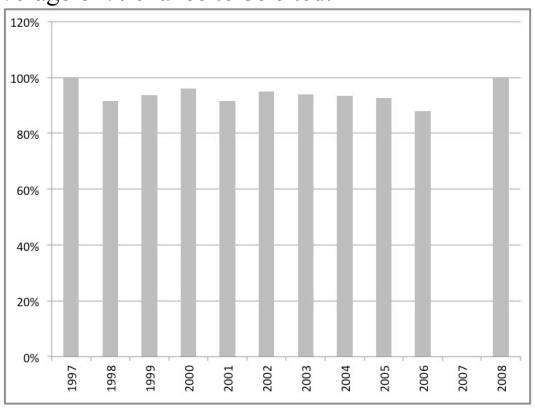

Figure 3. Probability of a ghost written articles to be cited once year since the publication.

On long range, the average ghostwritten article IF is much higher than the average journal IF. Indeed a ghostwritten article is about 10 times more cited than any article published in the same journal (Table 2).`

Table 2. Statistics difference between ghost written & journal article impact factors.

	Ghost Article impact factor	Journal impact factor
mean	7,24	2,68
max	68,13	8,73
min	0,31	0,09

Discussion

With this study, we have been able to conduct a bibliometric analysis on a large number of ghost articles, over a long period of time. Overall, ghostwritten articles are published by average productive author, in low IF journals; they are cited during a long period of time and therefore have a high number of citations (Table 3). Thus, ghostwritten articles might influence the medical community and its practice, which subsequently raises public health concerns.

Table 3. Main bibliometric indicators of ghost written articles.

	Journal impact factor	Ghost written article citations	Last year citation	Total number year citations	author h index
Mean	2,697	84,951	2013	13	29,731
Max	6,984	351	2014	16	68
Min	0,091	4	2008	8	4

Despite numerous declarations by medical journal editors and the conduct of ethics declared by professional medical writers, we would like to underline that none of these ghostwritten articles involved in lawsuit case have been retracted whilst companies have been sentenced by Justice.

Moreover the efficiency of ghostwriting publication strategy could be questioned since only a third of articles have an impact superior to what would be expected. Therefore the return on investment for the pharmaceutical industry might be very low, especially regarding the risk of litigation and the disclosure of such fraudulent marketing practices.

Introduction

The success of researchers and research institutions is increasingly determined by measurable aspects of their performance, in particular the quantity and citation-impact of their publications. The effects that these growing "pressures to publish" might have on publication and research practices are a matter of growing concern and increasing academic interest (de Winter & Dodou, 2014; Fanelli, 2010, 2012, 2013; Tijdink, Vergouwen, & Smulders, 2013; van Dalen & Henkens, 2012).

Much criticisms and concern has been expressed, in particular, for the risk of overemphasising the quantity of a scientist's publication record at the expense of its quality. In order to show a longer lists of publications in their CVs, it is commonly hypothesised, scientists might increasingly resort to questionable practices such as inappropriately subdividing ("salami slicing") their results, publishing trivial and incomplete studies, conducting research hastily and sloppily, selecting out of their findings those that are least "publishable", or even resorting to outright scientific misconduct in the form of duplicate publication, plagiarism and data fabrication (e.g. Angell, 1986; Hayer et al., 2013).

Performance-evaluation policies of institutions in various countries have responded to these concerns by formally removing any quantitative consideration from their performance assessments (e.g. VSNU, 2015). However, there is little evidence to support these policies. No study, in particular, has ever verified whether scientists are have actually responded to growing pressures by churning out more papers. We present preliminary results of a project aimed at filling this gap in the literature.

Methods

We identified individual researchers who published in the Web of Science across the 20th century by selecting all authors identified by three initials (first name and two middle names, plus surname, e.g. Vleminckx-SGE), which reduces the likelihood that these researchers have homonyms. From this initial sample we selected authors who had at least two publications, and from these we then selected authors whose publications spanned a period of at least 15 years. For each of these authors we then counted the total number of papers published in the first 15 years of activity – the period were pressures to publish are hypothesised to be stronger – and we also measured the average number of co-authors.

Results

The raw number of papers published by individual authors has grown very rapidly across the century (Fig. 1). Fractional productivity, however, as measured by dividing the author's total number of papers by the average number of co-authors, shows a net decline (Fig. 2).

Discussion

Although still preliminary, these results suggest that our beliefs about the effects of pressures to publish might be partially incorrect. Authors might have responded to growing performance expectations not, as commonly believed, by subdividing or trivializing their results or by multiplying their effort at the expense of other activities, but by enlarging their network of collaborations in order to make ever smaller contributions to a growing number of projects. Since neither publication nor citation metrics are counted fractionally, this strategy allows scientist to increase their measurable publication rate without necessarily increasing their total research effort.

If scientists' net effort devoted to research is not increasing, then concerns for growing "salami slicing" and other questionable practices might be unjustified. Explanations for recent evidence that retraction and correction rates are growing (Fang & Casadevall, 2011), that publication bias is growing (Fanelli, 2012) and that research bias might be higher in scientifically productive countries (Fanelli, 2010) might need revising. And policies that are currently de-emphasizing "quantity" in

favour of "quality" (e.g. VSNU, 2015) might not have a solid basis in evidence, and could therefore be ineffective or even damaging.

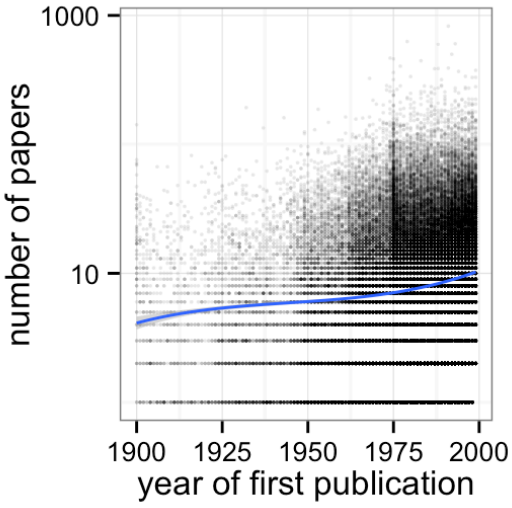

Figure 1. Total number of papers published during the first 15 years of career (N= 70,310). Blue line: cubic polynomial regression fit, with grey areas representing 95%CI.

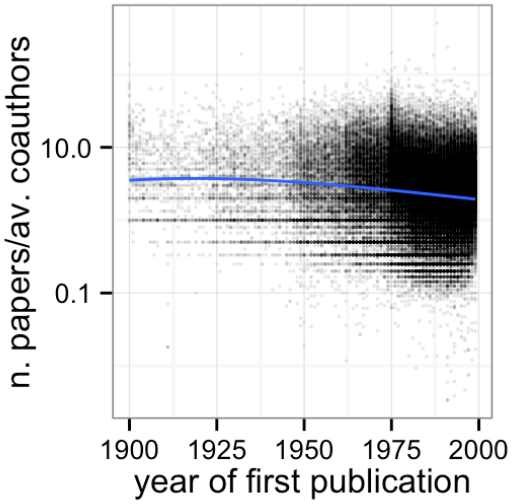

Figure 2. Ratio of total number of papers to average number of co-authors during the first 15 years of career (N= 70,310). Blue line: cubic polynomial regression fit, with grey areas representing 95%CI.

Several limitations to these results, however, remain to be addressed. First, since the likelihood of having two middle names is very unequally distributed amongst countries, our sample might not be sufficiently representative of the corpus of literature in the Web of Science. Second, our method might not be sufficiently robust against disambiguation errors for names from South-East Asian countries, a problem which might have skewed our results. Third, the Web of Science database does not cover a significant proportion of the literature, and its coverage varies by discipline and across the years. Future work will aim at adjusting for these factors, in order to verify whether scientists are actually publishing more or just collaborating more extensively.

Abstract
We present a new technique to semantically analyze knowledge flows between countries by using bibliometric data. Using a new approach to keyword-based clustering, the technique identifies the main topics of the research output of a country, as well as the main topics of the citing research of other countries. In this way it provides insight into how research produced by one country is used by others. We present a case study to illustrate the use of our proposed technique in the subject area of Renewable Energy during 2005-2010 using data from the Scopus database. We compare the Japanese and Chinese papers that cite the scientific literature produced by researchers from the United States in order to show the difference in the use of same knowledge. While the Japanese researchers focus on research areas such as efficient use of Photovoltaics and Superconductors, Chinese researchers focus in areas related to Power Systems, Power Management and Hydrogen Production. Such analyses may be helpful in establishing more effective multi-national research collaboration.

Methods and techniques; Country-level studies

Introduction
The research collaboration facilitated by the Internet and the greatly increased global mobility of researchers have resulted in a new highly dynamic global marketplace for ideas. The possession of knowledge, the value of which depreciates at an increasingly rapid rate, is no longer as valuable as the ability to participate in the knowledge flows associated with these marketplaces. As observed by Hagel et al. (2009) in the context of business competitiveness, "Knowledge flows – which occur in any social, fluid environment where learning and collaboration can take place – are quickly becoming one of the most crucial sources of value creation". Similarly in Science, understanding a research landscape increasingly requires understanding the dynamics of the relevant knowledge flows.

International scientific leadership and influence are commonly viewed as important measures of a country's scientific intellectual strength. This has traditionally been measured in terms of international scientific collaboration and the ability of a country to attract strong researchers and graduate students from abroad. But a further, more direct measure is the extent to which results generated by a country's researchers are influencing and being utilized by researchers abroad, particularly researchers who are not yet directly collaborating with that country's researchers.

In this paper we present a new technique to measure and semantically analyze knowledge flows between countries by using publication and citation data. We select a set of papers authored by the researches of a given source country. Further, we identify the papers cited by the papers only authored by researchers from outside the source country. We cluster these internationally cited papers to identify the main topics. Then, we procure the sets of papers (authored by researchers outside the given country) citing each of the topic clusters. Finally, we in turn cluster each set of citing papers to again identify main topics in order to identify how the knowledge from the topics in the cited papers is being used.

Related Work

In bibliometrics there have been efforts to measure knowledge flows using scientific literature at different levels of detail, namely: among scientists, among journals, among subject categories, among institutions and among countries.

Zhuge (2006) argues that ideas in a scientific article inspire new ideas, which will be recorded and published as new articles after peer review. Therefore, citations between scientific articles imply a knowledge flow from the authors of the article being cited to the authors of the articles that cite it. Zhou and Leydesdorff (2007) use journal-journal citation analysis to investigate international visibility of journals. Zhou et al. (2010) also use journal-journal citation analysis to study the specialization of a research community within a discipline. Johannes and Guenter (2001) measure knowledge export and international visibility of journals by determining the unique subject fields to which the citing journals have been assigned and the unique countries to which the citing authors belong, respectively.

Rowlands (2002) proposes a method to measure the spread of scientific knowledge that is published in a journal. He focuses on journals as units of spread and introduces an indicator to measure the spread of knowledge by looking at the number of different journals that cite the papers published in the primary journal, as shown in Equation 1.

$$RDI = \frac{U}{Cit}, \tag{1}$$

where U stands for the number journals that cite the papers published in the primary journal in a given time window (say T). Cit is the total number of citations received by the articles in the primary journal in T time window and the notion RDI is for Rowlands Diffusion Index. Naturally, diffusion can only increase in an absolute sense, however, empirical results show that the diffusion index proposed by Rowlands is negatively correlated with the total number of citations received (Rowlands, 2002). This leads Frandsen (2004) to provide a different diffusion index, as shown in Equation 2.

$$FDI = \frac{U}{Pub}, \tag{2}$$

where Pub stands for total number of publications in the primary journal, U is the same as above and FDI stands for Frandsen Diffusion Index. Note that Cit is replaced by Pub (i.e. publications). When publications do not change, the Frandsen Diffusion Index cannot decrease, and thus, the Frandsen Diffusion Index is positively correlated with the total number of citations.

Burrell (1991, 1992, 2005 and 2006) shows that the Leimkuhler Curve can provide an intuitive visual representation for the Gini Coefficient Index in giving graphical and numerical summaries of the concentration of bibliometric distributions. Guan and Ma (2007) illustrate the use of the Leimkuhler Curve to reveal the impacts of research outputs of countries. Using the Gini index, Liu and Rousseau (2010) study knowledge diffusion through publications and citations, as shown in Equation 3.

$$G = \frac{2q - 1}{N}, \text{where}$$

$$q = \sum_{i=1}^{N} i \frac{x_i}{M}$$

$$M = \sum_{i=1}^{N} x_i \tag{3}$$

N denotes the number of subject categories, and x_i denotes number of citations in journals mapped with a given subject category i. Note that the Gini index (Burrell, 1992, 2005) can be equally computed using Equation 4.

$$G = 1 - \frac{\sum_{j=1}^{\infty} (r(j))^2}{N.M}, \quad (4)$$

where M and N are the same as in Equation 3, $r(j)$ stands for the number of subject areas with at least j citations and the sum is finite as there is always a subject category with the largest number of citations. Note that Gini based indexes can only characterize the knowledge diffusion and do not quantify the volume of knowledge flow.

Ingwersen et al. (2000) present international citations as an indicator to measure export of knowledge produced by institutions. They measure knowledge export of institutes by calculating the proportion of citations received by a given institute from other countries (outside the host country where the institute is located) relative to total citations received by the institute. Using citation exchange among the scientific articles, we introduce a notion of International Scholarly Impact of Scientific Research (ISISR) to measure international knowledge flows among countries and institutions (Hassan & Haddawy, 2013). However, the measure of ISISR only quantifies knowledge flows and does not elucidate the contents of knowledge that flows across the countries.

The above survey discusses the salient research to quantitatively measure knowledge flows using bibliometric data. However, we believe that apart from the quantitative measures it is extremely important to analyze the contents of the knowledge flows. The scientific work of Zhuge (2009, 2010, 2011 & 2012) sets the theoretical base of semantic analysis in order to extract knowledge from large scale corpus.

Methodology

This section presents analytical techniques used to semantically analyze the knowledge flow from a given source country. We consider a set of papers P` authored by the researchers of a given source country in a given subject area in a given time window. Among the selected papers, we identify the papers P cited by the papers only authored by researchers from outside the source country. We cluster the papers from P to identify the main topics. We procure the sets of papers (authored by researchers outside the given country) citing each of the topic clusters. Next, we in turn cluster each set of citing papers to again identify main topics in order to identify how the knowledge from the topics in the cited papers is being used. The research topics are identified using our proposed Topic with Distance Matrix (TDM) model, an extension of the Latent Dirichlet Allocation (LDA) model proposed by Blei et al (2003).

A number of approaches to model scientific paper content have been proposed (Blei et al., 2003; Hofmann, 1999). These approaches are based upon the idea that the probability distribution over words in a paper can be expressed as a mixture of topics, where each topic is a probability distribution over words. We utilize one such popular model, LDA, proposed by Blei et al. (2003). In LDA, the generation of a paper collection is modeled as a three step process. First, for a given paper, a distribution over topics is sampled from a Dirichlet distribution. Then, for each word in the paper, a single topic is selected according to this distribution. At Last, each word is sampled from a multinomial distribution over words specific to the sampled topic.

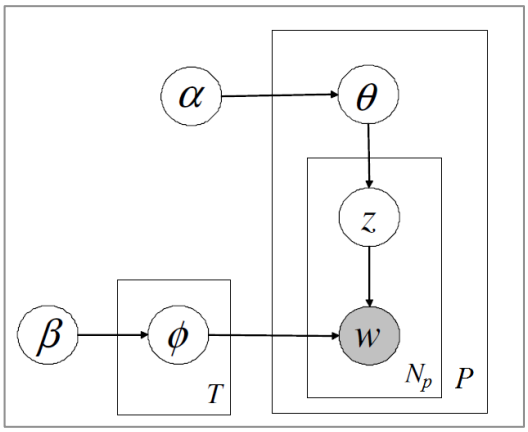

Figure 1. Latent Dirichlet Allocation (LDA) Model.

Using plate notation, the generative process corresponding to the hierarchical Bayesian model is shown in Figure 1. In this model, Φ stands for the matrix of topic distributions for each of T topics being selected independently from a symmetric Dirichlet prior (β). Θ is the matrix of paper specific mixture weights for these T topics, each being drawn independently from a symmetric Dirichlet prior (α). For each word, z denotes the topic responsible for generating that word, drawn from the Θ distribution for that paper, and w is the word itself, drawn from the topic distribution Φ corresponding to z. A paper p is a vector of N_p words, w_d, where each w_{id} is chosen from a vocabulary of size V and P is a collection of papers.

Estimating Θ and Φ provides information about the topics that participate in a publication corpus and the weights of those topics in each paper respectively. A variety of algorithms have been used to estimate these parameters, including variational inference (Blei et al., 2003), expectation propagation (Minka & Lafferty, 2002), and Gibbs sampling (Griffiths & Steyvers, 2004). To induce the probability distribution of Θ and Φ, LDA uses Gibbs Sampling which starts from randomly selected initial states and then revises distributions by changing topics to find correct distributions. Finally, the model provides topic-word relationship by the vector formed probabilistic representations.

Using the LDA, we obtain topic vectors where each value in the vector is associated with a given word that shows the probability of the word occurring under the given topic. For instance, vector T_1 ($word_1$: 0.3, $word_2$: 0.1, $word_3$: 0.2, …, $word_n$: 0.8) shows the probability distribution of all n words for the given topic t_1. Using this information, we represent each paper (from the set P) in the form of a vector where each value in the vector represents the probability distribution of a given word from vocabulary V in the paper for the topic under consideration (say t_1). For instance, P_1 ($word_1$: 0.4, $word_2$: 0.2, $word_3$: 0.0, …, $word_n$: 0.7) shows the probability distribution of words in the paper p_1 for the topic t_1. Note that if a word from V does not appear in p_1 then we assign default zero probability for that word.

Using the Minkowski distance between a given paper-vector P and topic-vector T, we choose papers in order to classify them as belonging to a specific topic (see Equation 5).

$$D = \sqrt{\sum_{i=1}^{n} | a_i - t_i |^2}, \tag{5}$$

where a_i denotes the probability of the term i in paper p_1 for the given topic T, and t_i denotes the probability of term i for the topic T. In order to obtain a set of papers relevant to topic T, a threshold TH is applied with the given percentage of the distance between the minimum and the maximum distance of paper vectors from T. Our experimental results show that the highest F-measure is achieved with TH = 25%. The size of a topic is determined by the

number of papers associated with it. The numbers of topics are determined by computing inter and intra topic similarity. We minimize inter topic similarity and maximize intra topic similarity to obtain the optimal number of topics. To compute the inter similarity between two topic, we use the Jaccard distance index (Jaccard, 1901).

Case Study: Semantic Analysis of Knowledge Flows across Countries in the Field of Renewable Energy

Dataset

We present a case study to illustrate the use of our technique in the subject area Renewable Energy. Using All Science Journal Classification (ASJC), we procured 46,518 publications (journal articles, reviews and conference papers) classified as Renewable Energy, a subarea of Energy(all) from the Scopus database during the time period 2005-2010

We procure 8,590 papers ($P`$) (journal articles, reviews and conference papers) published by researchers from the United States. Among the selected set of papers $P`$, we select 4,362 papers (P) which are cited by papers authored only by researchers from other countries. Further, we select candidate terms to represent each paper. In order to procure such terms, we use author defined keywords from the selected papers. In addition, we extract noun terms from the abstracts and titles of the papers using SharpNLP (http://www.codeplex.com/sharpnlp). We then identify synonyms of the selected noun terms using WordNet 3.0 (http://wordnet.princeton.edu/) and include them as candidate terms as well. Next, we apply the Porter Stemming algorithm (http://tartarus.org/martin/PorterStemmer/) to stem all the selected candidate terms. Finally, we feed this data to our TDM model.

Research Topics Cited by Researchers from Outside the United States in the Field of Renewable Energy

Figure 2 shows four research topics in the field of Renewable Energy cited by researchers from outside the United States. Using Wordle.Net (http://www.wordle.net/), we visualize the contents in each topic. Here, each topic is represented with the most frequently occurring author defined keywords collected from the papers in a given topic. The number of papers belonging to a specific research topic and the size of each research topic are written next to its respective topic. The research topics 1 and 4 are the largest topics cited by researchers from outside the United States. The topic#1 is the largest topic, containing 44% of the 4,362 papers. This topic covers research work related to Solar Cells, Solid Oxide Fuel Cells (SOFC) and Proton Exchange Membrane Fuel Cells (PEMFC). The topic#2 is related to Hydrogen Production. This topic also covers research related to Steam Reforming, a method for producing hydrogen, carbon monoxide, or other useful products from hydrocarbon fuels such as natural gas. Finally, the topic#3 is about Li-ion batteries. Li-ion batteries are an important type of rechargeable battery, particularly used in mobile devices. Finally, the topic#4 covers research related to Sustainable Management. Next we explore how the researcher from different countries cites the knowledge produced by the United States.

Research Topics of the Publications Produced by Chinese and Japanese Researchers that Cite Papers Authored by Researchers from the United States

To understand the difference in the use of the same knowledge, we further analyse that how the scientific knowledge diffuses into other research topics used by different research communities. We compare publications of the researchers from China and Japan that cite the same knowledge produced by the researchers from the United States. We select topic#1 from Figure 2 (the largest topic cited by the researchers from outside the United States in the field of Renewable Energy during 2005-2010). This topic covers research topics related to Solar

Cells (including Thin Film Solar Cells, Solid Oxide Fuel Cells and Proton Exchange Membrane Fuel Cells). Furthermore, we procure all the papers (journal articles, reviews and conference papers) authored by researchers from China and Japan that cite papers in the selected topic. We then identify research topics of the selected Chinese authored and Japanese authored papers.

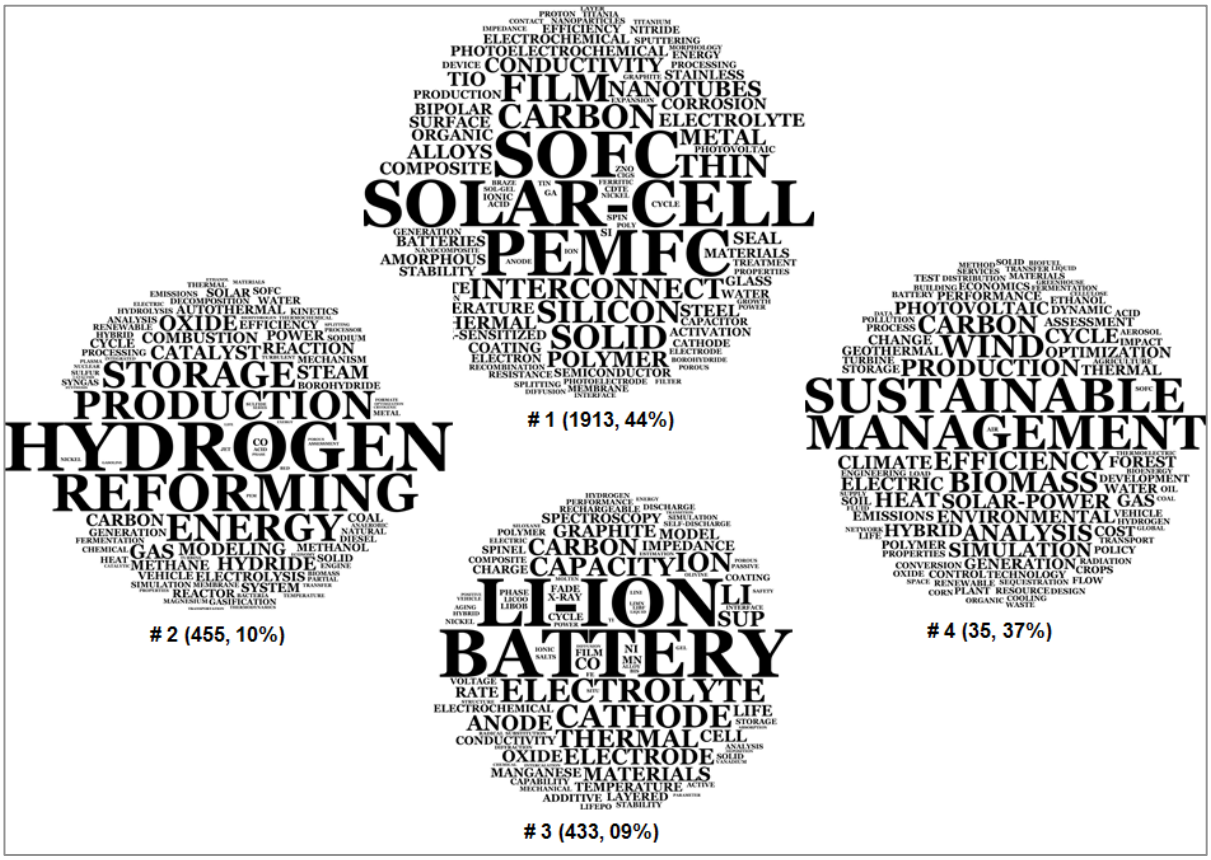

Figure 2. Research Topics Cited by Outside the United States in the Field of Renewable Energy during 2005-2010.

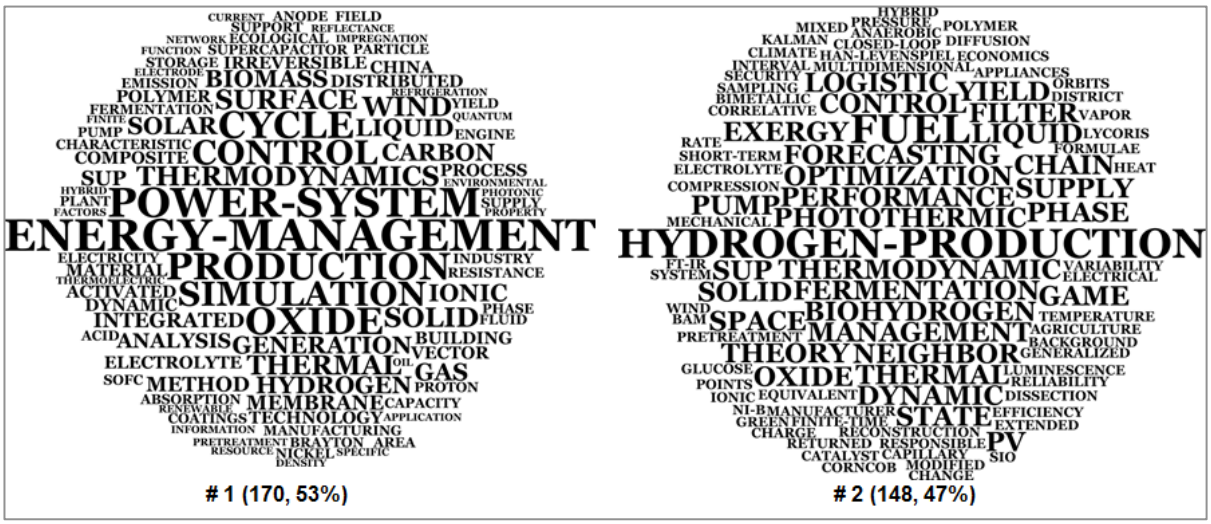

Figure 3. Research Topics of the Scientific Knowledge Produced by the Chinese Researchers (during 2005-2010) that cite the topic#1 in Figure 2.

Figure 3 shows research topics of the scientific knowledge produced by the Chinese researchers during 2005-2010 that cite topic#1 in Figure 2. In Figure 3, topic#1 mainly covers research related to Power Systems, Energy Management and Production. This topic is the largest topic which contains 53% papers out of 318. The topic#2 which contains 47% of the papers mainly focuses on Hydrogen Production.

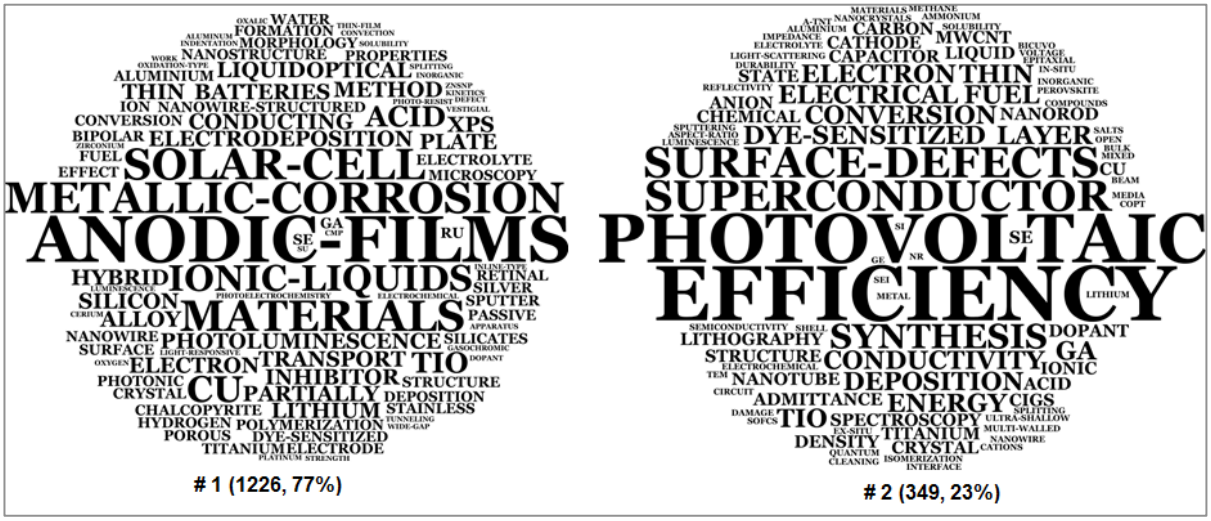

Figure 4. Research Topics of the Scientific Knowledge Produced by the Japanese Researchers (during 2005-2010) that cite topic#1 in Figure 2.

Figure 4 shows research topics of the scientific knowledge produced by the Japanese researchers during 2005-2010 that cite topic#1 in Figure 2. In contrast with China, the Japanese research community utilizes the same knowledge (produced by the United States) in rather different research themes. The Japanese researchers focus on topics related to Metallic Corrosion and Anodic Oxide Films (see topic#1 in Figure 4). Interestingly, we also find another topic (topic#2: 55 papers) describing the efficient use of Photovoltaics, Dye-sensitized Solar Cells and Superconductors. Note that Superconductors play a vital role in providing low-cost renewable energy.

Concluding Remarks

In this paper we have presented a new topic model with distance matrix, called TDM, to semantically analyze knowledge flows across countries by using publication and citation data. We have also presented a case study to illustrate the use of our proposed techniques in the subject area of Renewable Energy during 2005-2010 using data from the Scopus database. We have compared the Japanese and Chinese papers that cite the same scientific literature produced by the researchers from the United States in order to show the difference in the use of same knowledge. The study has shown that Japanese researchers focus in research areas such as efficient use of Photovoltaics, and Superconductors (to produce low-cost renewable energy). In contrast with the Japanese researchers, Chinese researchers focus in the areas of Power Systems, Power Management and Hydrogen Production.

The method of semantic analysis presented in this paper provides an understanding of the internationality of research not provided by studies of researcher mobility and co-authorship patterns. Our case study highlights the diversity in the ways that research produced by a country may be used in different international contexts, even within a relatively narrow research area. Such analyses may be helpful in establishing more effective multi-national research collaboration and in aligning collaboration with national priorities.

Causal Connections between Scientometric Indicators: Which Ones Best Explain High-Technology Manufacturing Outputs?

R. D. Shelton[1], T. R. Fadel[2], P. Foland[3]

[1] *shelton@wtec.org*

ITRI, 518 S. Camp Meade Rd., Baltimore, MD 21090 (USA)

Abstract
Scientometric models can connect indicators via cross-country correlations, but these are not enough to assert causality. Sometimes a causal connection can be argued from the physical process. In other cases the causality or its direction is not clear, and the Granger test is often used to clarify the connection. Here it was shown that gross expenditures on R&D (GERD) Granger caused scientific papers in the U.S., EU, and some others, which has policy implications. Granger causality also reinforces earlier findings on why the EU passed the U.S. in papers in the mid-1990s. Downstream, it is difficult to prove the connection between research and gross domestic product (GDP), since the contributions of science are diluted by other factors. New data allows a focus on a sector that is more closely associated with science: high technology (HT) manufacturing outputs. This value-added data permits more accurate models for today's international supply chains. Correlations show that business expenditures on R&D (BERD) and scientific indicators like patents are closely connected with HT manufacturing outputs. However for BERD, either direction of causality is plausible, and enough countries had significant results to show that causality can indeed be in either direction. The connections between papers and patents with HT manufacturing were also investigated; in several countries patents could be said to have Granger caused HT manufacturing.

Country-level studies

Introduction
Correlation does not imply causality, unless it can be augmented with other evidence. Many researchers have found strong cross-country correlations between national R&D funding and intermediate indicators like papers and patents. These findings bolster the policy argument that researchers deserve more funding, but may sound self-serving. Here however, there is a convincing physical argument that there is philosophical causality. Everyone knows that it take resources to do research. In some "big science" fields like ITER and CERN, it takes international consortia to provide the necessary big funding. Even the lonely bibliometrician needs a computer, data and Internet access, time to do the work, and travel funds to present the results in some pleasant clime.

Downstream in the innovation process, many researchers have also tried to connect those papers and patents to outputs like gross domestic product (GDP), with mixed success. Here the physical connection is not so clear, because science is only one of many factors that are involved. For example, several Asian nations became export powerhouses with skyrocketing GDPs, based initially on imported technologies, which were not reflected in their national papers and patents. Instead, the "New Economic Geography" developed by Paul Krugman (1991) identifies the most significant factors for location of manufacturing, and location of R&D is not high on the list. (He won the 2008 Nobel Prize for this work.) Once prosperous, these nations did invest in indigenous innovation.

In these more difficult cases, analysts rely on statistical tests to provide some evidence of causality. The most common test was devised by Clive Granger (1969). (He also won the Nobel Prize, in 2003.) It is applied to two time series, which the analyst suspects may be related. In simplified terms, a time series x can be said to "Granger cause" a second time series y if the additional knowledge of x allows a significantly better prediction of y than simply the past history of y. The Granger test function is available in several statistical programs; the open source R software was used here (R Core Team, 2014). In the R version, the model order k is the same for both x and y. The null hypothesis that x does not Granger-cause y is not rejected, if and only if no lagged values of x are retained in the regression.
Let y and x be stationary time series. To test the null hypothesis that x does not Granger-cause y, one first finds the proper lagged values of y to include in an autoregression of y:

$$y_t = a_1 y_{t-1} + a_2 y_{t-2} + \ldots + a_k y_{t-k} + \text{residual}_t$$

Next, the autoregression is augmented by adding lagged values of x:

$$y_t = a_1 y_{t-1} + a_2 y_{t-2} + \ldots + a_k y_{t-k} + b_1 x_{t-1} + \ldots + b_k x_{t-k} + \text{residual}_t$$

One retains in this regression all lagged values of x that are individually significant according to their t-statistics, provided that they collectively add explanatory power to the regression according to an F-test; adapted from Seth (2007). Here the smallest model order that produces significant results is preferred.
Granger testing is not a panacea. It requires that both series be stationary, and scientometric series usually fail the standard Augmented Dickey Freeman (ADF) test. This is often because they have trends such as inflation, population growth, or just more journals in the Science Citation Index (SCI). One normally has to de-trend series, usually by differencing them one or more times. Even when both series are stationary, the Granger test often fails, or worse, shows bi-directional causality, raising more questions than it answers. Furthermore, Granger causality is based on a postulate that cause must precede effect, but is this always true? In the stock market, the prospect of future events, like increased earnings, can influence present stock prices. Thus, one cannot prove true philosophical causality with Granger tests, but may be able to show that one series is a leading indicator for another. True causality has perplexed philosophers for millennia, so we are will not settle the question here. Instead we will just present the most interesting results from many Granger tests for scientometric indicators.

Background

Scientometric models are similar to econometric ones. A nation's innovation establishment can be considered to be an economic system that needs inputs of resources like labor and capital to produce outputs such as products and exports. System inputs and outputs can be measured using indicators. Figure 1 shows the relations between the system model and these indicators. This is a simplified linear model of a more complex situation. In reality there are feedback loops--e.g., an overall one that shows that sales of products can provide resources for investments in R&D.
Previous cross-country analysis showed that there is a strong correlation between inputs and intermediate indicators like papers. Leydesdorff (1990) regressed world share of publications in the SCI as output on GERD as an input. Shelton (2006) identified national inputs most important in encouraging papers. His model suggested that changes in the GERD share have been the driver of national changes in paper share, which can account for the rise of China since 2001 (Jin & Rousseau, 2005; Shelton & Foland, 2010). Later, the models were refined

using components of GERD as explanatory variables (Leydesdorff & Wagner, 2009). Similar models showed that government investments in R&D and higher education spending on R&D (HERD) were especially effective, helping to explain Europe's passing the U.S. in papers during the 1990s (Foland & Shelton, 2010). Conversely, the industrial component of GERD was shown to be more effective in encouraging patents (Shelton & Leydesdorff, 2012). Here these methods are applied to high-technology (HT) outputs as an overall measure of the success of a national innovation enterprise. The preliminary cross-country analysis (Shelton & Fadel, 2014) raised questions about the direction of causality, so a longitudinal approach for time series for individual countries has now been added, using the Granger test.

Such analysis is becoming more common in scientometrics, but sometimes with limited results. After considerable effort, Vinkler (2008) found no significant link between economic performance and research. Peng (2010) found some causality between R&D expenditure and GDP in China, but it is not clear that his series had the required stationarity. LC Lee, Lin & YW Lee (2011) used Granger testing of whether research papers can be said to cause GDP output—aggregated by regions. One result was that there is mutual causality between research and economic growth in Asia, but the results are not so clear in the West. Inglesi, Chang & Gupta (2013) tried Granger testing between research papers and economic growth in Brazil, Russia, India, China, and South Africa (the "BRICS"), which mostly failed to demonstrate causality, except for some positive results for India. Inglesi, Balcilar & Gupta (2014) got more positive results for the connections between U.S. paper output and GDP.

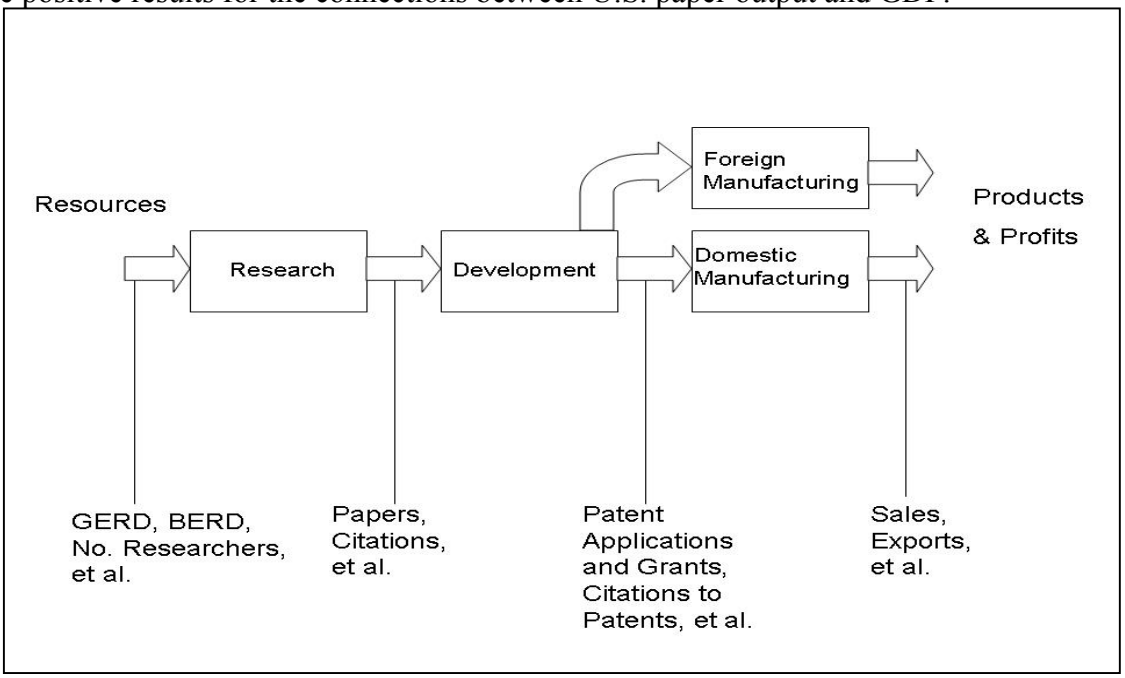

Figure 1. Linear model of an innovation enterprise with some indicators.

While there are some economic papers on factors that best explain *overall* international trade, there are relatively few that focus on the high-technology sector. One economic analysis of whether a country's high-tech exports (as a share of its overall exports) could be explained by R&D investment and country size was done by Braunerhjelm and Thulin (2008). They used the OECD data for 19 countries during 1981-1999. From their economic model, they concluded that overall R&D investment was significant.

Tebaldi (2011) used panel data to analyze factors that are most explanatory of high-technology trade. This approach adds data from more than one year to the usual cross-country analysis. Human capital, inflows of foreign direct investment, and openness to international trade were found to be the most significant of the factors he analyzed.

Data

Indicators like counts of papers and patents come from familiar sources like the SCI (Thomson Reuters 2015), (NSB 2014), and (OECD 2015). They provide insight into the success of national innovation enterprises. However, they are distant proxies for some of the quantities that the public cares most about: jobs, strength of their national economy, and survival of national industries. One scientometric measure of innovation that comes closer to these concerns is the performance of high-technology (HT) industries. Data on HT exports have been complied on a cash basis for decades by the OECD (2015) in its Main Science and Technology Indicators series. However, this measure of industrial output does not capture the nuances of where manufacturing really takes place. For example, the Apple iPad is assembled in China, but most of its components come from Japan, the U.S. and elsewhere (Xing, 2012). Recently a new dataset has been jointly developed by the OECD and the World Trade Organization for manufacturing output on a value-added basis, which avoids double-counting of imported components. This more accurate data, as summarized in (NSB, 2014), allows development of much-improved models that tie these key outputs to inputs like R&D investment. Figure 2 shows some national time series for this measure of HT manufacturing output. Forecasts show that China will soon take the world lead as the U.S. and Japan move final assembly of HT products to China. (Similar graphs for HT exports on a cash basis showed China taking the world lead in 2005.) The Europeans, especially the Germans, seem to have done less of this "off-shoring." There have obviously been big changes in the last decade, and scientometric models might provide insight on why, and what governments might do to respond.

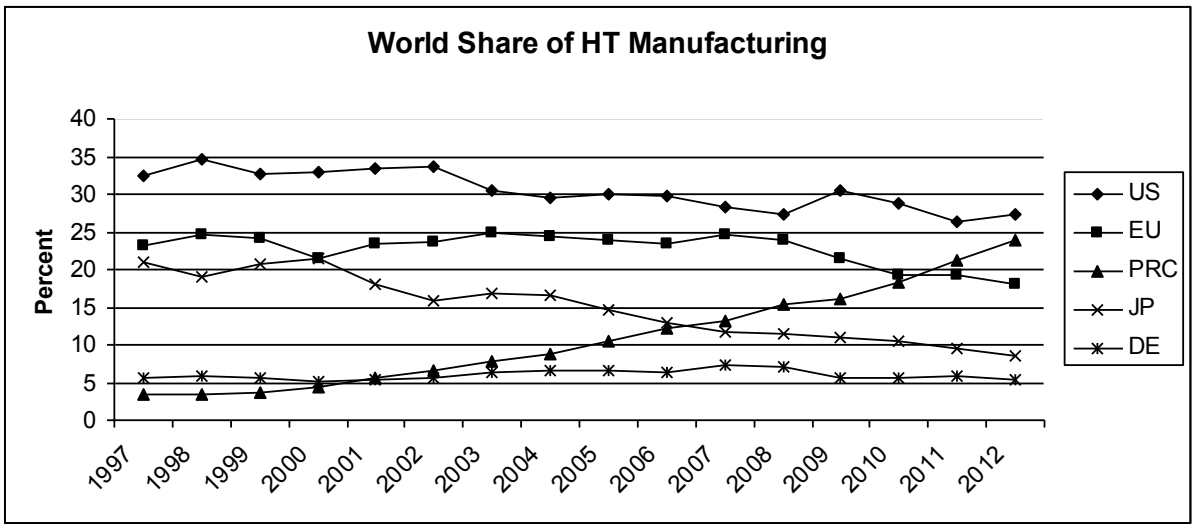

Figure 2. World share of manufacturing of high-technology products, on a value-added basis, for the United States, European Union (28), People's Republic of China, Japan, and Germany.

Causality Methods

Cross-country correlations over the countries in the OECD database are well known. Granger testing can be illustrated by revisiting the key results from Foland & Shelton (2010). That paper provided evidence that the EU passed the U.S. in papers in the mid-1990s because of a U.S. shift in research funding from government to industry, which was less effective in producing papers. At the time, this argument was based on cross-country correlations, and visual inspection of the U.S. and EU15 paper curves, which were very similar to their government GERD (GG) curves, just lagged by a couple of years. Granger testing can now add some quantitative evidence to this conclusion. First the series passed the ADF tests on the

data from 1988 to 2002, once second differences were calculated. The resulting Granger significance probabilities are in Table 1; bold entries are significant ($p < 0.1$).

Table 1. Significance probabilities for Granger tests of Government GERD component (USGGFF) causing papers (USPFF) on the NSI CD--or the reverse. FF means second difference. The "→" symbol means "Granger causes."

Model Order (k)	*USGGFF →USPFF*	*USPFF →USGGFF*
1	**p = 0.095**	p = 0.52
2	**p = 0.041**	p = 0.19
3	**p = 0.092**	p = 0.73

Thus the government GERD indicator can be said to "Granger cause" papers in the U.S. in this time interval. The most significant result was for a model order of two years, and there was no significant reverse causality. This provides additional evidence that relative changes in the Government GERD component led to the EU becoming much more efficient than the U.S. in producing papers, and led to its passing the U.S. in the mid-1990s to become the world leader in this indicator.

The Granger test has low power, that is, it often does not find significant results, particularly when the sample size is small. The sample size for Table 1 is only N = 15, preventing the use of higher model orders, so it is fortunate that some definitive results were obtained. To seek more definitive results, longer series were extracted for US, EU15, Japan, Netherlands, and Turkey from the Web of Science and the OECD for 1980 – 2012 where possible. After the second differences necessary for stationarity, this resulted in N = 30 samples for 1982-2012.

One experiment investigated whether total GERD (using constant $ and PPP weights) could be said to cause papers in the WoS (articles, letters, and reviews), with whole counts from the SCI-E and SSCI indexes. The results showed that U.S., EU15, and Japanese papers were indeed Granger caused by their national GERD with the significance probabilities in Table 2. None showed reverse causality. It did take a much higher model order to demonstrate Japanese causality. It was not possible to demonstrate significant results for the Netherlands or Turkey.

With these longer series, there is also the possibility that structural changes may take place over years. Sometimes a sliding window is used to examine shorter intervals within a longer one (Inglesi, Balcilar & Gupta, 2014). Here an auxiliary analysis simply examined the most recent years 2000 – 2012 (N = 13). The U.S. still exhibited Granger causality with the best result of p = 0.012 for a model order of k = 2. However, the other four country results for this shorter interval were not significant.

Table 2. Significance probabilities for Granger tests of GERD (G) causing papers (P) in the WoS (or the reverse) for 1983-2012. All used second differences.

Order (k)	*USG→USP*	*USP →USG*	*EUG →EUP*	*EUP→EUG*	*JPG→JPP*	*JPP→JPG*
1	**0.0067**	0.53	0.41	0.67	0.30	0.65
2	**0.0024**	0.89	0.53	0.94	0.53	0.53
3	**0.013**	0.90	0.76	0.82	0.54	0.54
4	**0.034**	0.91	**0.085**	0.92	0.54	0.79
5	0.10	0.86	0.14	0.96	**0.064**	0.80
6					**0.0029**	
7					**0.0090**	
8					**0.011**	

A similar test for Patent Cooperation Treaty (PCT) applications (OECD, 2014) in the U.S. was not so conclusive. Only for a model order of k = 6, could it be said that GERD Granger caused PCT patents, with p = 0.09. There was no reverse causality, however.

Another experiment tried to confirm a finding from Foland & Shelton (2010), that higher education spending on R&D (HERD) was closely associated with more papers. The dataset again included the U.S., EU15, the Netherlands, Japan, and Turkey, for the data range 1988-2002. Significant results were obtained only for the last two countries (Table 3). It was necessary to use fairly large model orders for Japan. The series passed the ADF tests with second differences, and there was no reverse causality for these model orders. Thus it can be said that, in Japan and Turkey at least, HERD Granger caused papers in these years. This might be useful for professors in those countries to mention in their battles for more funding.

Table 3. Does higher education spending Granger cause scientific papers?

Model Order (k)	*Japan HERD →Japan Papers*	*Turkey HERD →Turkey Papers*
1	p = 0.56	p = 0.24
2	p = 0.82	**p = 0.049**
3	p = 0.37	p = 0.12
4	**p = 0.090**	p = 0.21
5	**p = 0.016**	p = 0.30

Correlations for the Value-Added HT Manufacturing Indicator

Simple correlation over the 40 or so countries in the database of input resources in (OECD, 2014) can provide insight into which investments might be most productive in encouraging HT exports and manufacture. However, since many indicators simply increase with the size of the country, it is necessary to find explanatory variables whose correlations are much greater than those for measures like population or GDP. Furthermore, the U.S. and China are outliers; it is necessary to either omit them, or use log measures, if the contributions of smaller countries are to affect the results.

Table 4 from Shelton & Fadel (2014) shows the coefficients of determination (R^2) for two measures of performance of national HT industries with a number of explanatory or independent variables. For both measures, business expenditure on R&D (BERD) is best, with gross expenditure on R&D (GERD) not far behind. The correlations are far better for the new value-added data for HT manufacturing in the last column, than for the earlier exports on a cash basis. Indeed a quite accurate regression model can be constructed for this case (Equation 1), where NM9 is HT manufactures and BN9 is BERD, both in current dollars in 2009. Figure 3 shows the scattergram for this model.

$$\log NM9 = 0.385 + 0.944 \log BN9 \quad (R^2 = 84.1\%) \tag{1}$$

One would expect that there would be a delay between R&D investments and downstream benefits. For some indicators like patent grants, models that incorporate these delays can be more accurate (Shelton & Monbo, 2012). Here, correlations do not change much with lags, thus they did not improve the models enough to warrant the increased complexity. To see if a multiple linear regression would improve the model, a step-wise regression on HT manufacturing in 2009 was performed using the nine independent variables in Table 4. None of the other variables was significant in a multiple regression, once BERD was included as an explanatory variable, making a simple univariate regression without lags reasonable.

Table 4. Coefficients of determination (R^2 in %) of HT exports and overall HT manufacturing with explanatory variables in 2009. Uses log scales. More recent data downloads produce somewhat different correlations, and the values are sensitive to missing data points.

	Exports (Cash Basis)	*Overall Output (Value-Added)*
Papers SCI	41.7	71.0
Patents Triadic	48.8	69.9
Patent PCT Apps	34.3	61.5
GERD	44.8	79.8
BERD	49.0	84.5
Researchers	26.2	61.4
Business Researchers	29.3	71.6
Size GDP	27.3	56.9
Size Population	13.1	34.3

Despite the precision of the regression model in Equation (1), however, there is an alternate explanation for the trends of HT manufactures in the last decade. Could it be that HT manufacturing causes R&D investment, instead of the reverse? Indeed, it is the income from these sales that does provide some of those resources. OECD states that it picked the sectors for inclusion in the HT set precisely because these industries invest an extraordinary fraction of their income in R&D. And these correlations are too good to be true for BERD solely causing HT manufacturing--there are simply too many other factors that must also contribute. There have been frequent news accounts of Western and Japanese firms moving manufacturing to China and other low wage countries to increase their profits. China was also favored because its vast market offered potential for huge growth in HT sales.

This alternate explanation brings into question the efficacy of a nation increasing its HT manufacturing by encouraging greater business investment in R&D. It is possible that the results might be disappointing if the executives of the HT companies still prefer to locate the manufacturing abroad, the top path in Figure 1, so that some other nation reaps the benefits of the sales of HT goods. A policy remedy that addresses both explanations would be more likely to succeed. R&D investment policies could be coupled with trade policies that encourage location of manufacturing where the investments were made.

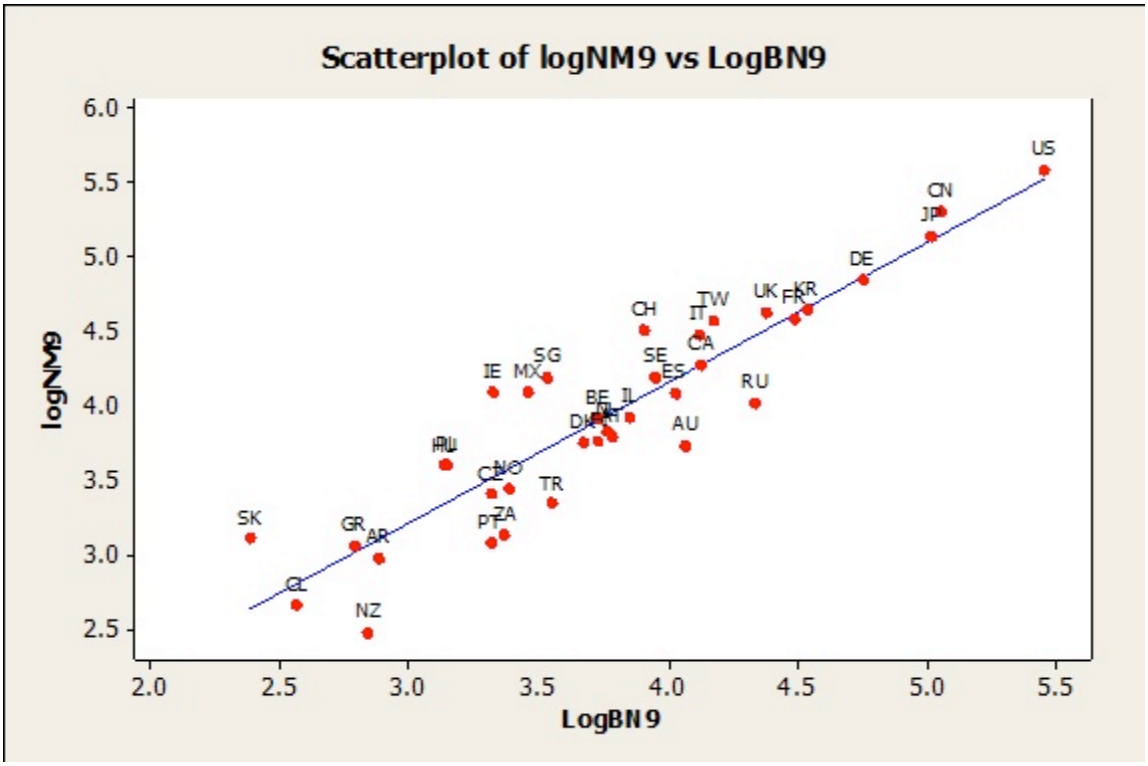

Figure 3. Scattergram of overall high-technology manufacturing vs. business expenditure on R&D in 2009. The cluster in the center contains BE, DK, IL, FI, and NL. HU and PL also overlap.

Further both manufacturing and BERD could be the results of an exogenous variable, some underlying third series. For example many of them seem to be closely tied to recent perturbations of the business cycle over the 1998 - 2011 data range available.

Causality Results for Value-Added HT Manufacturing

Table 1 shows that BERD has the highest correlation with HT manufacturing, so it will be analyzed first. Overall results for the sum of all countries in the OECD database were not significant. Findings for those individual countries with significant results are in Table 5. All are for model order k = 1, but orders up to k = 3 do not add countries to the list. Both series use current dollar values, and BERD used PPP weighting. The data ranges from 1999-2012.

Table 5. Does BERD Granger cause HT manufacturing (Mfg), or the reverse? Entries are significance probabilities; p < 0.1 is significant (bold type).

Country	*Mfg →BERD*	*BERD→Mfg*
Korea	0.21	**0.097**
Hungary	0.16	**0.0013**
Romania	0.57	**0.023**
PRC	**0.025**	0.32
Canada	**0.019**	0.43
Germany	**0.016**	0.19
Russia	**0.060**	0.54
Finland	**0.0014**	**0.010**

Of the some 24 countries with complete OECD data, 15 passed both ADF tests using second differences. The entries in bold type are the only ones that were significant from the Granger tests. While these results do not settle the question, they do show that (Granger) causality can indeed run in either direction for these indicators. Policymakers in Korea, Hungary, and Romania could benefit from knowing their country's business R&D investment did Granger cause its HT manufacturing output in these years, and may want to encourage more of this virtuous cycle. (Taiwan also showed this direction of causality for its available data from 2000-2012, using model order k = 2.) Chinese, Canadian, German, and Russian policymakers might be pleased to find that their country's HT manufacturing output Granger caused more BERD investment. Those in Finland would probably not find bi-directional causality very useful.

The second highest correlation in Table 1 was with overall GERD. As expected, these results were not as conclusive as those for the BERD component. Of the some 40 countries in the OECD Group, 30 had complete data. Of these 13 passed the ADF test for stationarity for both time series, using second differences. Using k = 1, only Hungary and Korea showed positive results (p = 0.0029 and p = 0.069, respectively). In the reverse direction of Mfg causing GERD, only Canada and Germany showed significant results (p = 0.026 and p = 0.0075 respectively. The Slovak Republic showed bi-directional causality with p = 0.091 for GERD causing Mfg and p = 0.025 in the reverse direction. These results seem to show that the higher correlation of BERD with manufacturing is necessary to get more definitive results.

BERD and GERD are not always thought of as scientometric indicators, though. What can be said about causality of HT manufacturing for traditional intermediate scientometics indicators like papers and patents? Only a couple of countries had significant results for papers, but the PCT patent applications were more interesting (Table 6). Using second differences, the ADF tests showed that 29 countries of the 37 countries with data had both series stationary, and 10 countries, plus the EU as a whole, showed Granger causality. The results are for order k =1, except for Denmark and the Czech Republic where k = 2. Two countries had bidirectional causality: Germany and the Netherlands.

Table 6. Do PCT international patent applications Granger cause HT manufacturing, or the reverse? Entries are significance probabilities; p < 0.1 is significant (bold type).

Country	*Patents→Mfg*	*Mfg→Patents*
EU28	**0.060**	0.14
Austria	**0.036**	0.24
Belgium	**0.046**	0.24
Canada	**0.060**	0.15
Czech Republic	**0.055 (k = 2)**	0.54
Denmark	**0.012 (k = 2)**	0.78
Korea	**0.063**	0.92
New Zealand	**0.0064**	0.11
Switzerland	**0.014**	0.40
Germany	**0.0014**	**0.0047**
Netherlands	**0.050**	**0.055**

So, there are quite a few countries where it can be said that their patenting activity Granger causes HT manufacturing output. This connection was suggested by the correlation results in Table 1, of course. There are good physical reasons that make this causality plausible, but the results do *not* imply that a national initiative to file more PCT applications would necessarily

result in more manufacturing. The Granger tests do add quantitative evidence that investments in science and technology indeed bear fruit in outputs that the public cares about.

Conclusions

For further work, statistical testing for causality can enrich study of the connections between scientometric indicators, and there are many others. However, the Granger test often fails, even when strong cross-country correlations exist and there are good physical reasons to suspect causality. There are other tests, like Toda & Yamomoto (1995), which can be employed. And more sophisticated data analysis might also help: other methods of de-trending, sliding windows for long series, panel data, et al. As always, one needs to be cautious of spurious results from data mining; running many tests is likely to turn up some positive results by chance.

The results here show that GERD did Granger cause papers and patents for the U.S., which is probably true for some others as well. This quantitative evidence bolsters the case that R&D funding is important for the success of a nation's science. In particular, the U.S. has a goal of maintaining its science leadership, but is rapidly falling behind in the funding race with China. In a rare good year, the U.S. increases its GERD by a real 3%; Chinese GERD has been increasing by more than 15% annually for decades.

New data on value-added manufacturing outputs provides quantitative insight on which inputs can be most effective in encouraging high-technology industries. Not surprisingly, there is a strong connection between such success and investments in R&D, particularly by the business sector. In countries where this can be demonstrated to be a cause of these successes, governments might wish to adopt policies, such as tax incentives, which can encourage such investment. Intermediate indicators like patents can also be good explanatory variables, showing quantitatively that traditional scientometric measures indeed provide useful information about outputs that directly affect a nation's prosperity.

Of course there are many other benefits of science and technology beyond the manufacture and sale of the HT products considered here. Science can lead to better healthcare, cleaner air and water, solutions of problems like global warming, improved communications that allow more extensive cooperation and collaboration, and many others. Most of these benefits can accrue to everyone, regardless of their nationality. Even in the competitive analysis of national market share of HT manufactures considered here, one should not lose sight of the overall performance of the sector. Worldwide sales have almost doubled over the last decade with only a slight pause during the Great Recession, reaching over $1.5 trillion in 2012. This growth has created millions of new jobs and a cornucopia of wonderful new products most people can enjoy--the ubiquitous cell phone has provided the first rapid communications in some of the poorest countries.

Abstract
Despite the recent changes that occurred in the Brazilian science, this field is still strongly anchored on male figures, as it happened at the beginning of its institutionalization. This paper detaches the contribution of Brazilian Research Institutes for the development of Brazilian science and the importance of contextual, background and academic tasks involvement in scientific production in those institutes, giving special attention to gender differences. Data from government graduate programs evaluation forms were obtained for the analyses presented here which take into account all professor-researchers - 890 women and 1,470 men - affiliated to 72 graduate programs under the responsibility of 31 Brazilian Research Institutes (BRI), the majority of which supported by the Federal Government. The main findings include: women are a minority in those institutes, are concentrated in the health and biological sciences, show higher scientific production than their male colleagues, especially in journal articles and among those involved in highly evaluated graduate programs. We believe the set of results presented in this paper may contribute to a better understanding of women's participation not only in BRI, which are dedicated to specific scientific areas, but also in Brazilian science in general and so contribute to gender governmental policy.

Conference Topic
Country level studies

Introduction
The process of science institutionalization in Brazil started about a century ago, when in Europe and in the USA this activity was already structured, both in science academies and in research institutions. One of the first steps contributing to this process in Brazil was the creation, in 1900, of the Federal Serotherapy Institute at Manguinhos, in Rio de Janeiro (which was afterwards named Instituto Oswaldo Cruz), considered the first Brazilian Research Institute to win international recognition (Weltman, 2002). In the following decades, the first public universities were created, as the University of Brazil (later renamed Universidade Federal do Rio de Janeiro), founded in 1920, and the University of São Paulo, in 1934. However, only in the nineteen fifties, with the creation of the first agencies for the promotion of scientific development in the country, this process advanced significantly: CAPES assumed the responsibility of structuring and monitoring graduate programs (Masters and Doctorate), throughout the country, while the other agency, the CNPq assumed the task of promoting scholarships and research projects.

Considering the above mentioned initiatives, it is possible to say that, in the second half of the twentieth century, one witnesses a strong governmental effort towards structuring scientific institutions, and also an induced and spontaneous expansion of graduate programs. In 2010, three decades later, the country already counted with an extensive system of S&T, including: 83,170 doctors-researchers, 64,588 students enrolled in doctorate courses, 2,840 graduate programs, 27,523 research groups, and 452 research institutes and universities throughout the

country (MCTI, 2014). The effort to train and qualify S&T human resources, build up and modernize the infrastructure of research institutions and, more recently, create legal tools to allow the increase and maintenance of science funding, resulted in an outstanding growth of scientific output in the years 2000, especially output in journals indexed by international bibliographic databases (Regalado, 2010; Leta et al., 2013).

It is important to point out that such growth is also result of a combination of factors, besides the previously mentioned ones. Among these factors, the following could be mentioned: (1) the inclusion of Brazilian journals in databases, which resulted in an expressive growth of Brazilian production in international bases in the last few years (Leta, 2012); and (2) the creation of evaluation mechanisms of graduate programs, which stimulate and reward output in journals, mainly in international journals (Mugnaini & Sales, 2011). About this last aspect, it is important to highlight that graduate programs - which cover all areas of knowledge and a great part of the institutions of higher education and research, especially those of the public sector - became the leading stronghold of Brazilian science. Thus, policies and evaluation mechanisms directed to these programs are reflected in Brazilian scientific outputs and outcomes.

The institutionalization, growth and international recognition of Brazilian science have not promoted significant changes in aspects of scientific stratification, more specifically an equalitarian representation of men and women in scientific activities. Although the last decades have witnessed a significant growth in the number of women in the country's academic and scientific fields – in higher education, in graduate programs and as professors and/or researchers at universities and research institutions (INEP, 2007) – they are still a minority in several areas, in higher academic levels and in administrative functions of higher prestige (Olinto, 2011; Gauche, Verdinelli & Silveira, 2013). This scenario, although not exclusive of Brazilian scientific field, calls attention to the fact that, in face of the many recent changes that occurred in the country's science, this field is still strongly anchored on male figures.

Many factors support the maintenance of this scenario in Brazil and in the world, where women are excluded of certain areas, a phenomenon known as horizontal gender segregation, and they do not advance in their careers, a phenomenon known as the vertical gender segregation (Shienbinger, 2001). In a previous study (Leta et al., 2013), considering the symbolic value of different academic tasks that are part of the academic career, the hypothesis posed was that female Brazilian scientists would be involved in tasks of lesser prestige and, consequently, would be less productive and advance less in their careers than their male peers. We inquired into this issue examining productivity and involvement in academic tasks of the population of over 52,000 professor-researchers who participated in Brazilian graduate programs (our unit of analysis was each professor-researcher linked to a Brazilian graduate program, and whose academic characteristics and performance are yearly included in evaluation forms provided by the federal government). This study revealed a higher participation of men in articles published in annals of events, but major differences between male and female professors-researchers were not observed. Even though it may be considered positive the fact that both sexes have an equal share of academic-scientific tasks, the population analyzed in the mentioned study was very heterogeneous. Subtle differences were found, however, when the analysis considered the area of graduate work in which the professor-researcher was linked to. The health area was the closest one to our hypothesis: women tend to get more involved in activities of lesser prestige, like teaching graduate courses, and less involved in activities of higher prestige, like publishing in journals. Academic area and the nature of the institution are some aspects, among others, that may have an impact in the characteristics and the amount of scientific output of both men and women. In order to reduce diversity, in the present study, the focus turned to the participants of

graduate programs who are affiliated to Brazilian Research Institutes. The central question of this study is: how do gender differences in scientific performance are related to the characteristics of the academic and institutional context, as well as the involvement in several academic tasks of professor-researchers in graduate programs of Brazilian Research Institutes?

Research Institutes and Women

The largest part of the Brazilian Research Institutes belongs to the public sector and is linked to the Ministry of Science, Technology and Innovation (MCTI). Among the oldest is the National Observatory, founded in 1827, in the city of Rio de Janeiro. Presently there are thirteen other Research Institutes linked to the MCTI, the majority directed towards research in exact sciences and engineering. Other ministries also maintain Research Institutes, as the Ministry of Agriculture, responsible for Embrapa, created in 1973 with the purpose of developing research in agriculture; the Ministry of Health is responsible for the Brazilian National Cancer Institute (INCA), founded in 1961, and for the Oswaldo Cruz Foundation (at present – Fiocruz), created in 1900.

Until recently, women's presence and contribution at Research Institutes was poorly explored as a research topic in studies about gender and science. Among a few recent studies, the one by Brito Ribeiro (2011) inquired into the distribution of male and female researchers at Research Institutes linked to the MCTI in two career functions: researcher and technologist. This author points out to the small proportion of women in those institutes: about 30% in both types of careers. Nevertheless, that fraction still decreases substantially when the research areas of these institutions are considered. In the Brazilian Center of Research in Physics, for instance, there are only 17% of women in those two careers. The author also presents data about the distribution of men and women in higher prestige posts at these institutions, like presidency and boards of directors: out of 362 senior administrators, only 36 (10%) were occupied by women in 2010, a clear indication of vertical gender segregation. A more thorough analysis was done recently taking into account 571 researchers, with doctor degrees, affiliated to Fiocruz (Rodrigues, 2014), an institution that plays a central role in health research in the country. This author points out that male researchers have a *per capita* output quite superior to that of female ones. A different situation is found in Fiocruz, however, when the analysis focuses on administrative positions. Differently from other Research Institutes, especially those oriented towards exact sciences and engineering, Fiocruz is concerned with gender equity, and thus started a Pro-Equity Gender Program in 2009. This initiative might explain the large number of women in administrative positions in this institution. In 2013, out of 768 administrators with salary bonus, 382 (49.7%) were women, which is close to parity. However, women are still an absolute minority occupying the highest prestige posts, as president and directors.

The scenario previously described is shared by Research Institutes of other countries. One of the most prominent Research Institutes in the world, the Massachusetts Institute of Technology, has recently published a study on gender equity in the institution. Compared with previous studies (1999 and 2002), it showed major advances in two Schools. In the School of Science and School of Engineering, particularly, "the number of women in faculty increased significantly (from 30 to 52 in science and 32 to 60 in engineering) and in both schools women now hold several senior administrative positions" (Gillooly, 2011). However, despite these advances, women are still a minority, especially among those that occupy positions of higher prestige and salary, as tenured faculty members, of which women represent only 15% and 12% in the two schools, respectively. At the Centre National de la Recherche Scientifique (CNRS), the largest Research Institute in France, a country with a solid tradition in science and a pioneer in actions and policies that benefit women, Hermann

& Cyrot-Lackmann (2002) observed that women represent from 22% to 38% of the total CNRS's researchers and, what seems to be more significant, 31% of the research directors are in the highest prestige positions. Yet, as seen in the MCTI Institutes in Brazil, at the CNRS in France, this representation also varies according to the area of study: in Physical & Mathematical Sciences and Engineering Sciences only 12% and 9%, respectively, are women; and in Life Sciences, 28% of the research directors are women.

Different theories and models are considered by the literature to explain the phenomenon of female segregation in science and they include personal, biological, cultural, social and institutional aspects; and empirical studies based on these theories and models usually point out to gender imbalances favoring men (Barrios, 2013; Epstein, 2007; European Commission, 2009; Fox, 2005; Long, 1992; Meulders et al., 2010; Prpic, 2002).

The present focus on gender differences in institutional contexts suggests that male researchers would show better performance in different academic tasks and also present greater scientific production, like publishing in prestigious journals. Rewards for better performance would include the occupation of prestigious posts. Such arguments allow one to bring about the concept of scientific capital, proposed by Bourdieu (2003): a kind of symbolic or tacit capital, which opens opportunities and promotes recognition and which would tend to help perpetuate gender differences in science. Researchers with higher rates in publications and with high involvement in prestigious academic-scientific tasks accumulate scientific capital and, in a "snow ball" feedback effect, would tend to keep to themselves positions of higher academic prominence. In an opposite movement, researchers with less involvement in the more valued activities accumulate less scientific capital and would tend to be less involved in the more valued tasks, as well as to have a greater burden of less valued tasks, as, for instance, teaching assignments. Considering this model, the present study intends to investigate the relation between gender, academic background, institutional context, including the involvement in academic tasks, and scientific output of professor-researchers affiliated to the BRI.

Data collection and method

This study uses the documental analysis technique applied to information retrieved from three pre-established PDF forms with information used in the 2009 national evaluation of graduate programs (CAPES, 2013). Information provided includes aspects of academic and scientific performance as well as personal and academic characteristics of 52,294 professor-researchers affiliated to 2,247 graduate programs. Since a key characteristic, the professor-researcher's gender, was not included in CAPES' forms, a series of strategies was developed to allow for this classification (Leta et al., 2013).

For the present study, we have selected a subset of the 2009 original population and took into account information about all professor-researchers affiliated to 72 graduate programs under the auspices of 31 Brazilian Research Institutes (BRI), which were classified by us in three main groups: (1) supported by funds from the Federal government (Public/Federal), (2) supported by funds from State governments (Public/States) and (3) supported by the private sector (Private).[1]

[1] First group: Brazilian Center of Research in Physics (CBPF), Centre of Nuclear Technology Development (CNEN/CDTN), Institute of Nuclear Engineering (CNEN/IEN), Institute of Radio Protection and Dosimetry (CNEN/IRD), Oswaldo Cruz Foundation (Fiocruz), Research Centre (FIOCRUZ/ CPqGM), René Rachou Research Centre (FIOCRUZ/CPqRR), Institute of Military Engineering (IME), Institute of Pure and Applied Mathematics (IMPA), Brazilian National Cancer Institute (INCA), National Institute of Metrology, Quality and Technology (INMETRO), National Institute of Research in the Amazon (INPA), National Institute for Space Research (INPE), National Institute of Industrial Property (INPI), Technological Institute of Aeronautics (ITA), Botanical Garden Foundation of Rio de Janeiro (JBRJ), National Laboratory for Scientific Computing (LNCC)

It is important to mention that not all BRI are included in this study since a few of them do not have a graduate program under their responsibility. Examples are Embrapa and IBICT, major research institutes in the areas of agricultural sciences/biology and information science, respectively. These Institutes do have graduate programs but they are organized in collaboration with public universities.

Once the BRI were identified and data cleaned, all information was exported to a matrix of SPSS (Statistical Package for the Social Sciences), version 12. The population of the study represented in this matrix, and focus of the analyses presented here, can be so defined: BRI professor-researchers who participated in graduate programs in Brazil in 2009 (N=2,362). Among the variables that characterize each professor-researcher are: (a) personal and academic characteristics of the professor-researcher (gender, S&T area and year of doctoral title), (b) characteristics of institution of affiliation/ graduate programs (economic sector, area and evaluation grade); (c) academic roles performed by each professor-researcher (graduate courses, graduate advising, banking participation, project leadership) and (d) publication output (journal articles, articles in Annals and other types of publications). For the classification of S&T area of the graduate programs, we utilized the categories considered by CNPq (2013).

Results

The analyses are presented in two main sections: (a) characteristics of the institutional context in which professor-researchers participate and aspects of his academic background and (b) academic tasks and the scientific output of the professor-researchers, with emphasis given to gender differences.

Characteristics of the Institutions and of professor-researchers background

Table 1 shows the distribution of the 2,362 professor-researchers according to three macro-characteristics of the graduate programs of the BRI to which these professionals are linked: the economic sector, the area of knowledge and the performance grade.

Considering the economic sector, data show that the greatest part of professor-researchers are linked to the institutions maintained by the Federal Government and very few of these professionals are active in programs belonging to private institutions: only 3%. These results are different from those obtained for Brazilian graduate programs considered as a whole, which showed that 55% of the institutions belonged to the federal government, 30% states government and 15% to the private sector (CAPES, 2014).

The distribution of professor-researchers according to the academic areas of the BRI graduate programs (which represent the areas of expertise of these professionals) is, however, more homogeneous, although it is clear that a massive number of professors are concentrated in two major groups: Engineering and Exact Sciences, in one hand, and in Health and Biological Sciences, in the other hand. These areas together absorb 80.3% of the professor-researchers in the BRI.

---

and National Observatory (ON). The second group: Nuclear and Energy Research Institute (CNEN/IPEN), Institute of Medical Assistance to the State Civil Servants (IAMSPE), São Paulo Institute of Biology (IBSP), São Paulo Institute of Botanic (IBT), São Paulo Institute of Fishery (IP), Institute of Ecological Research (IPÊ), São Paulo Institute of Technological Research (IPT), Pernambuco Institute of Technology (ITEP) and Institute of Zoology (IZ / APTA). Third group: Recife Centre of Studies and Advanced Systems (CESAR), Brasilia Institute of Public Law (IDP), Latin American Institute of Research and Education in Odontology (ILAPEO) and Institute of Technology for the Development (LACTEC).

Program with grade 2 to 3	14.5	17.9
Program with grade 5 – 7	59.0	55.8
Program with grade 6 to 7	20.6	31.9

Percentages calculated within each gender category. [2] We were not able to attribute the sex of two professor-researchers. [3] Partial and total percentages provided by SPSS.

The final contextual aspect, presented in table 1, refers to the performance grade of the graduate programs issued by CAPES. These grades are recorded in a scale from 2 to 7, and the meaning of these assessments is: from grade 5 the program is considered to be at a good

level, able to participate in institutional programs etc. Grades 6 and 7 are assigned to programs of high performance, and some aspects that contribute to the assignment of these grades, besides scientific productivity, are institutional agreements as well as institutional exchange of researchers, professors and students. In table 1, it is also possible to observe that the great majority of professor-researchers participate in programs that received grades from 5 to 7.

The following Table 2 aims to identify gender differences in institutional affiliation and aspects of personal background of the professors/researchers in BRI.

It is possible to note that women represent less than 40% of this population (N=890), a fraction similar to the one obtained in a previous study which focused on professor-researchers of all graduate programs in the country (Leta et al., 2013). Data also show that women are predominant in the areas of Biological and Health Sciences, whereas men form a great majority in Engineering and Exact Sciences, which points to the phenomenon of horizontal segregation of gender, a characteristic also observed in Brazilian graduate programs in general (Leta et al., 2013).

Table 2 also presents other relevant information related to gender, calling attention to gender differences favoring men: a higher proportion of men show longer careers than women (which in fact might reflect the recent increase in women's entrance in scientific careers), relatively earn more degrees abroad and participate more in graduate programs of higher prestige.

Gender and scientific production of professor-researchers of Brazilian Research Institutes

Table 3 shows the distribution of men and women according to the number and the kind of published work in 2009 - articles in journals, complete works in annals of events and abstracts in annals of events.

Table 3. Distribution (%) of professor -researchers from Brazilian Research Institutes by sex and number of journal articles, annals full article and annals abstract – 2009.

Publication	Journal Article		Annals full Article		Annals Abstract	
	Women	**Men**	**Women**	**Men**	**Women**	**Men**
0	30.6	38.7	76.7	66.7	68.9	80.3
1-2	33.9	31.7	14.7	15.6	15.7	10.9
3+	35.5	29.6	8.5	17.7	15.4	8.8
Total	**890**	**1,470**	**890**	**1,470**	**890**	**1,470**

These results call attention to the high percentage of both men and women without any work published in 2009, particularly those with zero annals full article and annals abstract. This table also stresses the higher women's performance as far as journal articles are considered: a lower proportion of women are included among those with zero contribution to this kind of publication and a higher proportion of this gender group are among those contributing with one or two journal articles, and especially among those considered more productive: three or more articles. It is important to keep in mind that this is the kind of published work that has more value in the scientific field in general, and is also the kind of publication that contributes the most to the grades attributed to the graduate programs by Brazilian Agencies. In Annals, a type of publication that is highly valued in technological fields, as Engineering, it is possible to see an alternate pattern between men and women: men with better performance in annals full articles and women in annals abstracts.

Scientific production is influenced by a large number of factors, including the academic area, years of academic experience (Bonaccorsi & Daraio, 2003), education abroad (Velema, 2012), etc. Table 4 presents the publication mean of the different types of publications of the BRI professor-researchers by gender, as well as by gender controlled by the above-mentioned factors – area, experience and education abroad –, and also the CAPES grade of the program, a particular aspect in the Brazilian scientific area.

Taking into account the general mean performance and gender, table 4 also shows, as in table 3, that women outperformed men in BRI in 2009 in mean number of journal articles (women published a 2.51 and men 2.12 articles, mean results with similar standard deviation) and the mean number of annals abstract (W=1.14 and M=0.75), while men attained higher means of annals full articles (W=0.74 and M=1.48). With these results, and considering the higher academic value attributed to publication in journal articles, one can say that women of the BRA show higher performance in relation to men.

Focusing on differences between academic fields, in Table 4, as expected, mean number of journal articles is higher in biological, health sciences and in exact sciences than in engineering. This difference could partially account for the women's higher general performance in the BRI, previously mentioned. But even considering journal publication in this specific group, it can also be observed that women in the biological and health areas publish, in average, more journal articles than men. Men, on the other hand, show higher performance in journal articles in exact sciences and engineering. These gender tendencies are not clear in the other two types of publication.

Table 4. Mean of types of publications of professor-researchers from Brazilian Research Institutes by sex considering academic area, Graduate Program evaluation and PHD period and PHD country – 2009.

	Publication Means					
	Journal Article		**Annals Full Article**		**Annals Abstract**	
	Women	**Men**	**Women**	**Men**	**Women**	**Men**
GENERAL MEAN PERFORMANCE	2.51	2.12	0.74	1.48	1.14	0.75
ACADEMIC AREA						
Engineering	0.99	**1.11**	2.66	2.96	0.45	0.32
Exact Sciences	2.24	**2.71**	1.88	1.42	0.86	0.65
Health Sciences	**2.99**	2.90	0.28	0.23	1.26	1.51
Biological Sciences	**3.27**	3.19	0.09	0.07	1.25	1.26
GRADUATE PROGRAMS						
Low evaluated (2 and 3)	**1.12**	0.90	0.99	2.07	0.98	0.30
High evaluated (6 and 7)	**3.66**	2.52	1.23	2.26	0.47	0.45
PHD period						
Before 2000	2.97	**2.40**	0.72	1.60	1.07	0.76
2000 and After	1.88	**1.57**	0.77	1.25	1.23	0.74
PHD country						
Brazil	2.59	2.08	0.72	**1.27**	1.25	0.87
Abroad	2.19	2.25	0.88	**2.07**	0.59	0.49

Table 4 also shows that belonging to programs with higher grades seems to have a positive impact in the output of men and women in journal articles and annals full articles. However, what stands out in the comparison of the two types of program (low and high performance) is

that women's mean number of journal articles is much higher than men's in high performance programs, where men are predominant (Table 2).

Data also suggest that professional experience, estimated through the time elapsed since PHD conclusion, contributes positively, for both women and men, to a greater output in journal publishing. On the other hand, both gender groups with more recent PHD degrees tend to publish more annals full articles. The other factor considered - PHD country- suggests that being educated abroad is more relevant to male output: men educated abroad show a much higher performance than women in this category. Regarding this last result, it could be pointed out that full articles in annals is the type of output that appears more often in the technological areas, like engineering, where 20% of the professor-researchers of the BRI are institutionally related (Table 2). It is also possible to consider that this kind of publication, which is associated to the participation in events, especially international events, may contribute to the development of professional contacts, favored by the period of experience abroad. If this is the case, women are not profiting, as much as their male colleagues, of their experience abroad.

Professor-researchers have several assignments besides publishing results based on their research projects. These assignments comprise, among others, graduate teaching, dissertation advising, banking participation and tasks involved in project leadership. How the involvement with these assignments is related with their publication output, and how gender might interfere in this process is explored in table 5.

Table 5. Mean number of involvement in academic tasks of professor-researchers from Brazilian Research Institutes by publication level and gender – 2009.

Academic Task	Professor-researchers			
	with no journal article		with 3 or more journal articles	
	Mean		Mean	
	Woman	**Man**	**Woman**	**Man**
Graduate Teaching	0.90	1.10	1.17	1.08
MS Advisor	0.59	0.70	0.83	0.98
PHD Advisor	0.37	0.63	**0.80**	**0.98**
Banking participation	0.94	1.42	1.00	1.18
Project Leader	0.87	0.82	**1.64**	**1.37**

Table 5 show that, in average, those BRI professor-researchers who have not published in 2009 – those with zero articles – tend to have less involvement with the different academic tasks considered, notably involvement with doctoral degree advising and project leadership. Besides, the comparison between men and women shows that men, independently of publication quantity, tend to be more involved in academic tasks, except in graduate teaching and project leadership, in which women show higher performance, but only a small positive difference. Women higher involvement in this specific task - project leadership -, especially among the more productive ones, might contribute to explain their higher performance in journal articles as previously shown in tables 3 and 4.

Concluding remarks

This work focused on gender differences in scientific production of professor-researchers attached to in BRI, aiming at identifying how institutional and background aspects may be related do their production, as well as how the diverse academic tasks performance by these men and women might interfere with their scientific production.

Considering institutional and background aspects, the results show that these professor-

researchers are allocated in the public sector, are concentrated in four academic areas, and the majority in programs that received high grades from government evaluation process (Table 1). Results also show that women are a minority in those institutes and are concentrated in the health and biological science, whereas men are concentrated in engineering and exact sciences (Table 2). Women also show higher scientific production, especially in journal articles, the most valued type of academic publication (Tables 3 and 4). Women's performance is especially outstanding when they are involved in highly evaluated graduate programs. Female professor-researchers only show lower production output in relation to their male colleagues in journal articles of traditionally masculine areas: exact sciences and engineering. But male predominance in these areas is not consistently maintained when the other types of scientific productions are considered. The last results highlighted here refer to the involvement in academic tasks by level of production. Data show that the involvement of both men and women in those tasks seems to be positively related to their productive levels, especially PHD advising and project leadership. Men, however, tend to be more involved in most academic tasks, regardless of their productive levels, with the exception of project leadership, in which women are more involved, notably the highly productive ones (Table 5).

The originality of the data presented in this study is the inclusion of different types of scientific production in the analyses of gender differences in science, as well as the examination of associations of these different types of productions with contextual and academic background, as well as with involvement in academic tasks. The originality of this study is also in the selection of a particular study field: the research institutes that have an outstanding place in the development of modern science, as institutions created with the specific purpose of scientific development. Despite their relevance for the scientific field, only few studies about gender and science focus on these institutions. In Brazil, the great majority of BRI are supported by the Federal Government, are dedicated to specific scientific areas and the graduate programs under their responsibility are well recognized by the scientific community and, as data analyses shown here, tend to receive high grade marks from the national graduate programs evaluation. These indicators of excellence make it valuable the analysis of gender differences in those institutions aiming at contributing to better understand women's participation in Brazilian science and also contribute to gender governmental policy.

Intended further analyses with the BRI data will make use of statistical multivariate models trying to evaluate the relative contribution of the different contextual, background and academic tasks involvement, as well as gender in scientific production of professor-researchers. These analyses will help to indicate the importance of institutional and gender cultures, and patterns of academic practices in scientific production.

Abstract
In this paper, by modeling national and regional research systems as complex systems, we compare the dynamics of their disciplinary profiles using extensive (size dependent) indicators as well as intensive (size independent) average productivity indicators of scientific production. Our preliminary findings show that the differences between the disciplinary profiles among countries in the world is of the same order of magnitude of the differences among European countries, that in turn, is of the same order of magnitude of the dynamics among regions within a country. While additional research (that is in progress) is needed to confirm these findings, we describe the main advantages (features) of our approach and outline its usefulness to support evidence-based policy making.

Introduction, scope and structure of this paper
The dynamics of national or regional research systems is one of the most important topics in quantitative science and technology research. Interestingly, a lot of studies have analyzed the disciplinary specialization of countries (see e.g. Glanzel, 2000; Glanzel & Schlemmer, 2007; Glanzel et al., 2006, 2008; Hu & Rousseau, 2009; Tian et al., 2008; Wong, 2013; Wong et al., 2012; Yang et al., 2012; Horlings & Van den Besselaar, 2013; Radosevic & Yoruk, 2014) or have investigated the disciplinary specialization of regions within a particular country, or have conducted case studies on individual regions and/or on a few number of selected disciplines (see e.g. Zhu et al., 2009; Glanzel, Tang & Shapira, 2011).
Much less studied are the disciplinary profiles of European countries at the regional level. To the best of our knowledge there are not empirical analyses at European level, investigating the evolution of the disciplinary composition (i.e. the 27 Scopus Subject categories) of regions. Moreover, none of the existing studies have analyzed in a comparative way, the range of variability (briefly: the dynamics) of national and regional research systems which is the aim of our paper. We investigate here this dynamics in terms of both extensive measures of scientific production (i.e. total number of scientific publications, citations and so on) and in terms of intensive average scientific productivity (i.e. number of publications per author).
In particular, the investigation of the dynamics of intensive measures of scientific production has an important policy relevance. According to the macroeconomic theory, we have growth convergence when smaller (poorer) countries, in terms of output per capita (e.g. GDP per capita), grow faster than larger (richer) countries. In the context of research systems, we can say that there is a convergence if smaller scientific systems, in terms of scientific output per capita, grow faster than larger one. This is an important question, related to the policy

decision of supporting catching up countries depending on whether there is convergence or not. This question is extremely important also at the regional level, for which there is an increasing interest in the smart specialization of regions, defined in terms of technological specialization, linked to the degree of innovativeness of the regions, to develop effective policies of cohesion (McCann & Ortega-Argilés, 2013; Camagni & Capello, 2013). Despite the fact that scientific specialization is commonly considered as a relevant factor for the technological specialization of regions, there is not available evidence on the scientific specialization of regions and their dynamics. Even more scant is the empirical evidence aiming at analyzing the dynamics of the scientific profiles of regions together with those at the national level, to derive informative policies to support research at national and regional level, able to take into account the complementarity/substitution relationship between national and regional research systems. We try to fill this gap, providing an investigation of the dynamics of the disciplinary profiles at the national and regional level using extensive and intensive measures.[1]

Bongioanni, Daraio, Moed and Ruocco (2014) provided a first exploration at the world country level. In the current paper, the analyses are extended systematically in the following three manners.

a) The paper analyzes a series of both extensive (size dependent) and intensive (size independent) bibliometric indicators of research productivity, impact and collaboration. Table 2 gives a list of all indicators included in the study. Data was extracted from the Scopus database and relate to the scientific production of world countries and 27 Scopus subject categories from 1996 to 2012.
b) The analyses do not only relate to *national* research systems, but also to *regions* within European countries. In terms of the Nomenclature of Territorial Units for Statistics, NUTS-2 units were analyzed.
c) We describe the main features and advantages of our approach to investigate the scientific convergence of national and regional research systems.

The model

A spin glass is a disordered assembly of spins (e.g. dipole magnets) that are not aligned in a regular pattern. The term “glass” comes from an analogy between the “magnetic” disorder in a spin glass and the positional disorder of a conventional, chemical glass, e.g., a window glass. In window glass or any amorphous solid the atomic bond structure is highly irregular; in contrast, a crystal has a uniform pattern of atomic bonds. In ferromagnetic solid, magnetic spins all align in the same direction; this would be analogous to a crystal. The individual interactions in a spin glass are a mixture of roughly equal numbers of ferromagnetic bonds (where neighbors prefer to have the same orientation) and antiferromagnetic bonds (where neighbors tend to orientate in the opposite directions). These patterns of aligned and misaligned magnets create what are known as frustrated interactions - distortions in the geometry of atomic bonds compared to what would be seen in a regular, fully aligned solid. They may also create situations where more than one arrangement of spins is stable.

In the physics of complex systems, a mathematical framework is developed to analyze spin glass systems. This paper uses certain elements of this framework. National or regional research systems are conceived as analoga of spins and their complex interactions give rise to disordered, spin glass like, systems. Their orientation is described in terms of the distribution of a research system’s publication output or related bibliometric measures over the various research disciplines. A research system’s disciplinary orientation is described as a vector the

[1] This is the first step of our analysis. Further research will be subsequently devoted to the exploration and investigation of the link between scientific and technological profiles of regional and national research systems.

elements of which contain the percentage of publications in the various disciplines. The rationale for using the spin glass model lies in the ability to analyze the dynamical interactions among research units in a wider system analogously to the analysis of spin orientations in spin glasses.
The following Table 1 summarizes the analogy between the main physical notions of a spin glass model and the corresponding notions in the research system model (see also the Appendix of Bongioanni, Daraio & Ruocco, 2014).

Table 1. Spin glass model: main physical notions and their corresponding notions for research system.

Notion in the physical system	Notion in the Research system
Spin	Country/region
Spin components	Scientific disciplines
J couplings	Country-to-country or region-to-region interactions
Energy (it has to be minimized to find stable solutions)	Generalized cost function (to be minimized)
Overlap	Similarity measure

Within the framework of this model, Bongioanni, Daraio & Ruocco (2014) proposed to compare the disciplinary patterns of research systems, by computing the 'overlaps' quantities, that are similarity measures between disciplinary patterns, borrowed from the physics of complex systems. The main variables analysed here are the Pa(i) i.e. the shares of articles published in a subject category i for a given country (or region) a over the sum of publications made during 1996-2012. Similar variables are based on the number of citations received, or the number of internationally co-authored papers. Table 2 gives an overview of all indicators used in this study. The measure of the overlap between the pattern of disciplinary profiles of two countries a and b, $P_a(i)$ and $P_b(i)$ respectively, that is the measure of similarity between systems, is defined as:

$$q_{ab} = \frac{1}{D}\sum_{i=1}^{D} \sigma_a(i)\sigma_b(i),$$

where

$$\sigma_a(i) = \frac{P_a(i) - \langle P_a \rangle}{\sqrt{\langle {P_a}^2 \rangle - \langle P_a \rangle^2}},$$

in which <A> stands for average of A, $\sigma_a(i)$ and $\sigma_b(i)$ represent the normalised shares of the indicator considered, for country (or region) a and b, respectively; and D is the number of subjects or disciplines analysed, which in this study amounts to 27 and are derived from Scopus. We note that if we use as variables $\pi_a(i) = P_a(i) - \langle P_a \rangle$ instead of $P_a(i)$, q_{ab} coincides with the Salton's cosine (calculated with the variables π).
The overlap measure or similarity of profiles between two countries a and b, q_{ab}, ranges from −1, meaning precisely the opposite profile, to 1, meaning precisely the same profile, with 0 representing independence and intermediate values indicating in-between levels of similarity or dissimilarity. Moreover, the overlap can be calculated with respect to another country, with respect to an average or standard value or with respect to a given distribution.

Interpreting the distribution of the overlaps to shed lights on the dynamics of the overall system.

An interesting property of the computed overlap measures between two countries (or regions)' profiles relates to their distribution. The distribution of the overlap reveals whether there is a *converge*nce in the overall system towards a unique disciplinary profile or whether there is a divergence of the system towards different disciplinary configurations. In particular, according to Bongioanni, Daraio and Ruocco (2014) the interpretation of the distribution of the overlap values is as follows: one pick on one shows a convergence towards the *same* disciplinary profile for all countries, while two picks point to two *different* configurations of disciplinary profiles.

We point out that this is one of the main advantages of our approach compared to currently bibliometric approaches used for comparing disciplinary profiles. Although a systematic comparison of our approach with other existing methods is in progress, we think that our approach offers an easy way, based on the investigation of the distribution of the overlap, to check whether there is convergence or not without having to adopt one of the alternative methods developed in the theory of growth to measure convergence. The most applied method to assess convergence in this context, adopted also in the context of scientific convergence (see e.g. Horlings & van den Besselaar, 2013), is based on *regressions*. Within this framework (see e.g. Barro & Sala-i-Martin, 1992), it is said that there is *beta-convergence* (where beta is the coefficient of the initial level of per capita output in the growth regression) when poor economies tend to grow faster than rich economies (and hence the beta coefficient is lower than zero, implying that the higher initial level of output per capita negatively affects the growth rate). Another related concept is that of *sigma-convergence*, which happens when the dispersion of the output per capita decreases over time. The sigma-convergence is often measured by analyzing the variation of the standard deviation (or the coefficient of variation or the concentration) of the output per capita over time. However, this regression based approach has been questioned in the growth literature (see e.g. Durlauf, 2000) and other studies of convergence have applied different methods, including a test on the distribution of the output and how it evolves over time, reaching often very different results (see e.g. Durlauf, Kourtellos, & Tan, 2005). Our approach, offers an interesting alternative to estimate the convergence, by analyzing the distribution of the overlaps and their dispersion.

Another interesting property of our approach is related to the exploitation of the *ultrametric* structure of the overlap values to obtain "automatically" clusters of the national or regional research systems analysed, without having to carry out a specific clustering exercise.[2]

Note that the indicators reported in bold in Table 2 are average productivity indicators, that is intensive (size independent) indicators of the scientific production, while the others are extensive (size dependent) indicators of scientific production.

In this paper the following overlaps were computed:

- Of each main country in the world against all other countries, using a set of 41 countries, including all member states of the European Union and major countries from the rest of the world.
- Of each 27 European country against all other European countries, to provide an aggregate benchmark for the regional analysis.
- Of each NUTS-2 region against all other regions, using a set of 266 NUTS-2 regions in member states of the European Union.

[2] Research on this point is in progress.

Table 2. Indicators applied in the study

Indicator	Description
PUB	Number of articles (integer count).
PUBf	Number of articles (fractional counts based on authors affiliations).
C	Total citations (4 years window, i.e., for articles in 2006; citations are from 2006-2009).
CPP	Total citations per paper (4 years window, i.e., for articles in 2006; citations from 2006-2009).
HCPUB	Number of articles in top 10 per cent of most highly cited articles in a discipline.
PUBINT	Number of internationally co-authored papers.
PUBNAT	Number of nationally (but not internationally) co-authored papers.
PUBINST	Number of papers co-authored by members of different institutions within a country.
PUBSA	Number of non-collaborative (single address) papers.
NA	Number of publishing authors in a particular year, by discipline.
APUB	Number of articles (integer count) divided by NA
APUBf	Number of articles (fractional counts based on authors affiliations) divided by NA
AC	Total citations (4 years window, i.e., for articles in 2006; citations are from 2006-2009) divided by NA
ACPP	Total citations per paper (4 years window, i.e., for articles in 2006; citations from 2006-2009) divided by NA
AHCPUB	Number of articles in top 10 per cent of most highly cited articles in a discipline divided by NA
APUBINT	Number of internationally co-authored papers divided by NA
APUBNAT	Number of nationally (but not internationally) co-authored papers divided by NA
APUBINST	Number of papers co-authored by members of different institutions within a country divided by NA
APUBSA	Number of non-collaborative (single address) papers divided by NA

Legend to Table 2: Data was extracted from the Scopus database and relate to the scientific production of world countries and NUTS2 European regions for 27 Scopus subject categories from 1996 to 2012.

Results are presented in two sections. The first part explains the base notion of a disciplinary profile, compares pair-wise profiles of countries and NUTS2 regions, and analyzes the structure within the set of profiles. It focuses on one single indicator: the number of articles (PUBf) published in 2012. The second part analyzes also average productivity indicators (APUBf) and dynamical aspects.

Disciplinary profiles of countries and regions

Figure 1 shows large differences in the distribution of research articles among subject fields between USA and China. The first country has a strong focus on medical sciences and biomedical research, including biochemistry, genetics and molecular biology, neurosciences, and on social sciences and humanities. The latter shows a large publication activity in physical sciences and engineering: chemistry, materials science, physics, and engineering and computer science.

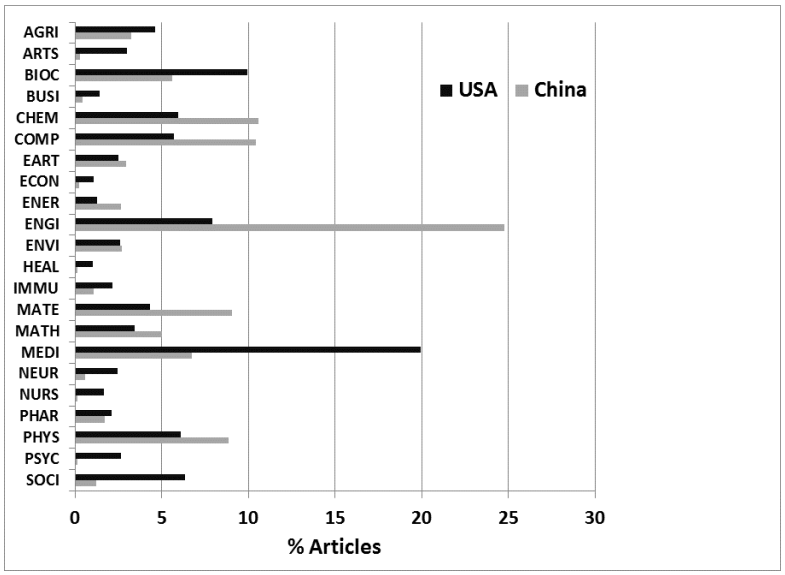

Figure 1. Disciplinary profiles of two countries large countries: China vs. USA. Data relate to the year 2012, and are extracted from Scopus.3 In this figure, four small disciplines have been left out: Dentistry, Decision Sciences, General, and Veterinary Sciences. Chemical Engineering is merged with Chemistry.

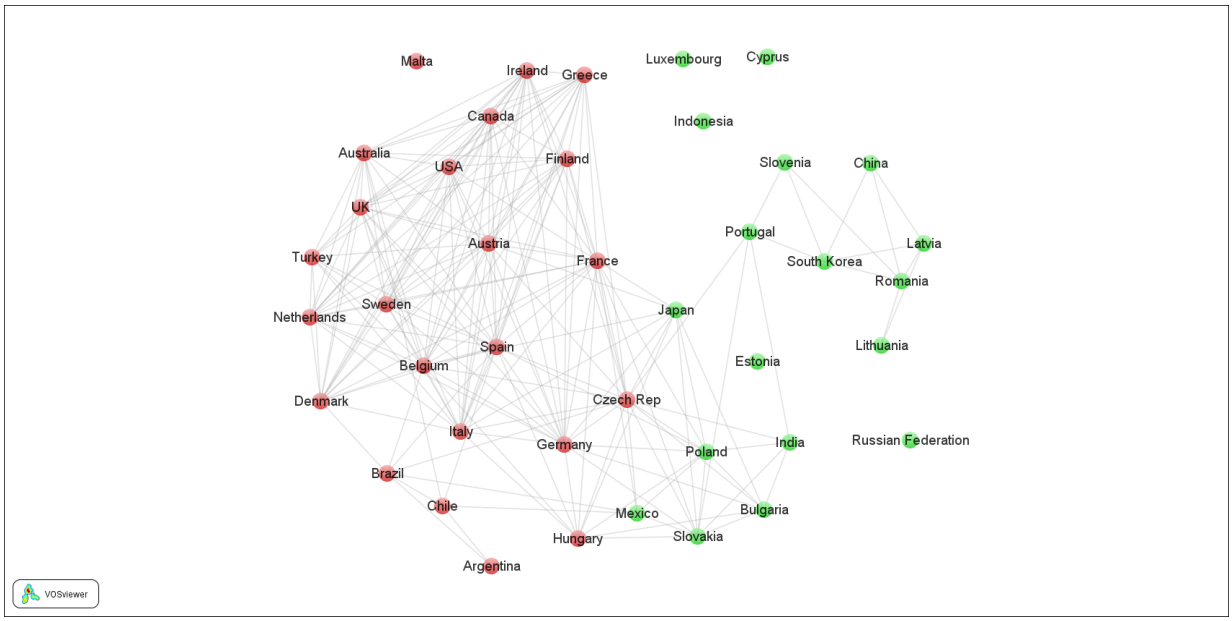

Figure 2. VoS-Viewer Map of the de degree of overlap of disciplinary profiles among 41 countries. For more details about VoS viewer, the reader is referred to www.vosviewer.com

Figure 2 shows a map of a set of 41 countries, including all member states of the European Community, and major countries from the rest of the world. Interestingly, the cluster module in the VoS Viewer identified two clusters of countries. These clusters correspond to the

3 The labels of the disciplines are the following: AGRI: Agricultural and Biological Sciences; ARTS: Arts and Humanities; BIOC: Biochemistry, Genet, Mol Biol; BUSI: Business, Managmnt, Accounting; CHEM: Chemistry; COMP: Computer Science; DECI: Decision Sciences; DENT: Dentistry; EART: Earth and Planetary Sciences; ECON: Economics, Econometrics and Finance; ENER: Energy; ENGI: Engineering; ENVI: Environmental Science; GENE: General; HEAL: Health Professions; IMMU: Immunology and Microbiology; MATE: Materials Science; MATH: Mathematics; MEDI: Medicine; NEUR Neuroscience; NURS: Nursing; PHAR: Pharmacology, Toxicology and Pharmaceutics; PHYS: Physics and Astronomy; PSYC: Psychology; SOCI: Social Sciences; VETE: Veterinary Sci.

different profiles illustrated in Figure 1. The countries indicated with red circles, located at the left hand side of the plot, tend to have a biomedical disciplinary profile, similar to USA and the Netherlands. At the right hand side a group of countries indicated by green circles tends to have a physical-sciences profile, like China, and Russia. Many Central and Eastern-European countries belong to this group: apart from South Korea, also India, Indonesia, Mexico, Portugal, and the small countries Luxembourg and Cyprus.

Several studies in the past have found differences in disciplinary profiles between countries. But to the best of our knowledge, no study has systematically analyzed geographical regions within countries. Figures 3 and 4 show results for the so called NUTS-2 regions. In total, 266 NUTS2 regions were identified. Table 3 presents the quantiles of the distribution of the number of published articles (year 2012) among regions. The distribution is highly skewed. The top 25 per cent of regions has published more than 4,146 articles in 2012. 5 per cent has published more than 11,612 articles. The bottom 25 per cent has published less than 496, and the bottom 10 per cent less than 89. Figure 3 shows disciplinary profiles of two pairs of NUTS2 regions: Inner London and the German city Stuttgart. The figure reveals the same main profiles as Figure 1 did at the level of countries: a biomedical profile in Inner London, and a physical sciences profile in Stuttgart.

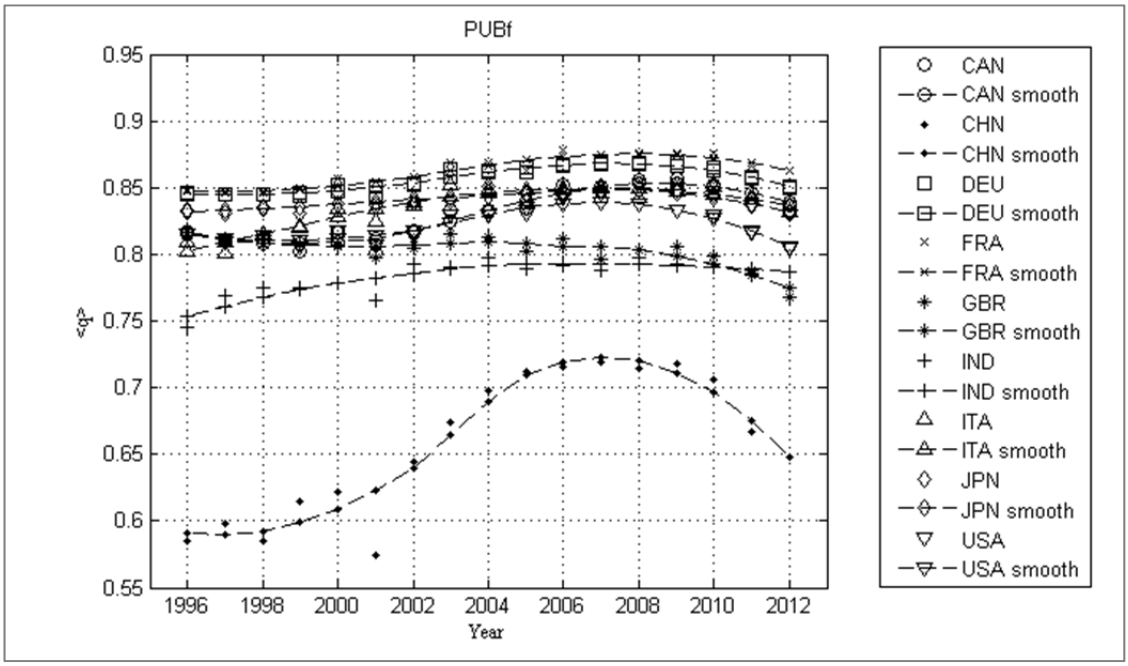

Figure 5. Dynamics of overlaps between 9 leading nations and all other countries for the fractional number of publications (PUBf).

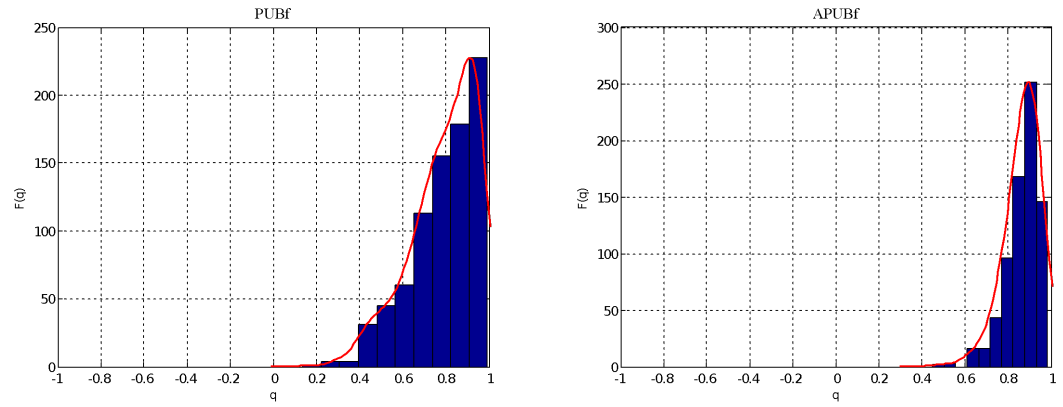
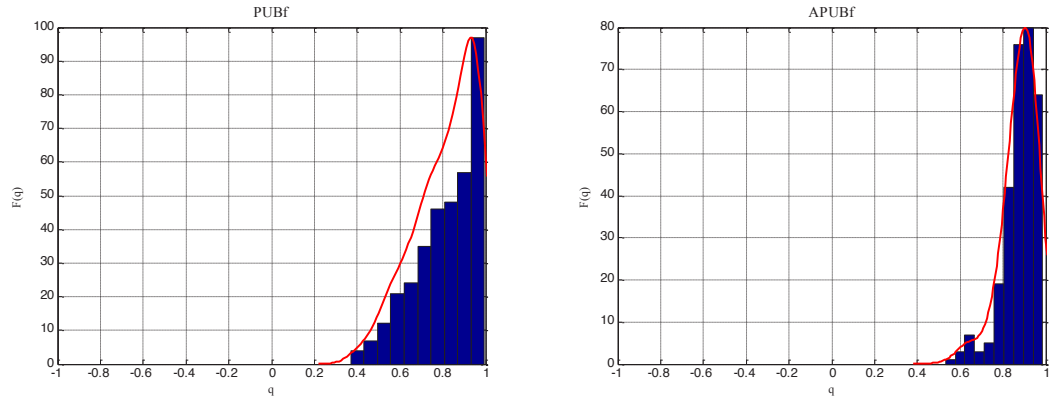
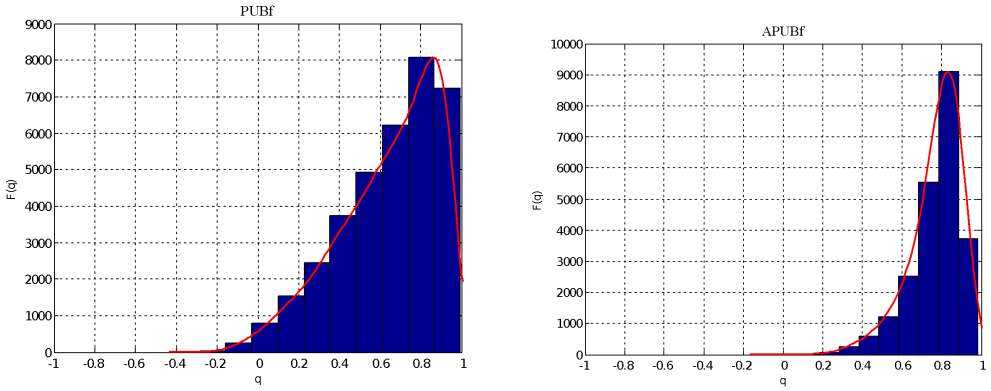


TOP PANEL. World Distribution of the overlaps calculated on each country against all other countries in the world for the *extensive* (size dependent) indicator of scientific production PUBf (top-left panel) and the *intensive* average productivity indicator APUBf (top -right panel).



MIDDLE PANEL. European Distribution of the overlaps calculated on each European country against all other European countries for the *extensive* indicator of scientific production PUBf (middle-left panel) and the *intensive* average productivity indicator APUBf (middle-right panel).



BOTTOM PANEL. European Regions (NUTS2 units) Distribution of the overlaps calculated on each European region against all other European regions for the *extensive* indicator of scientific production PUBF (bottom-left panel) and the *intensive* average productivity indicator APUBf (bottom-right panel).

Figure 6. Distributions of the overlaps calculated at World, European and Regional level for extensive (PUBf) and intensive (APUBf) indicators.

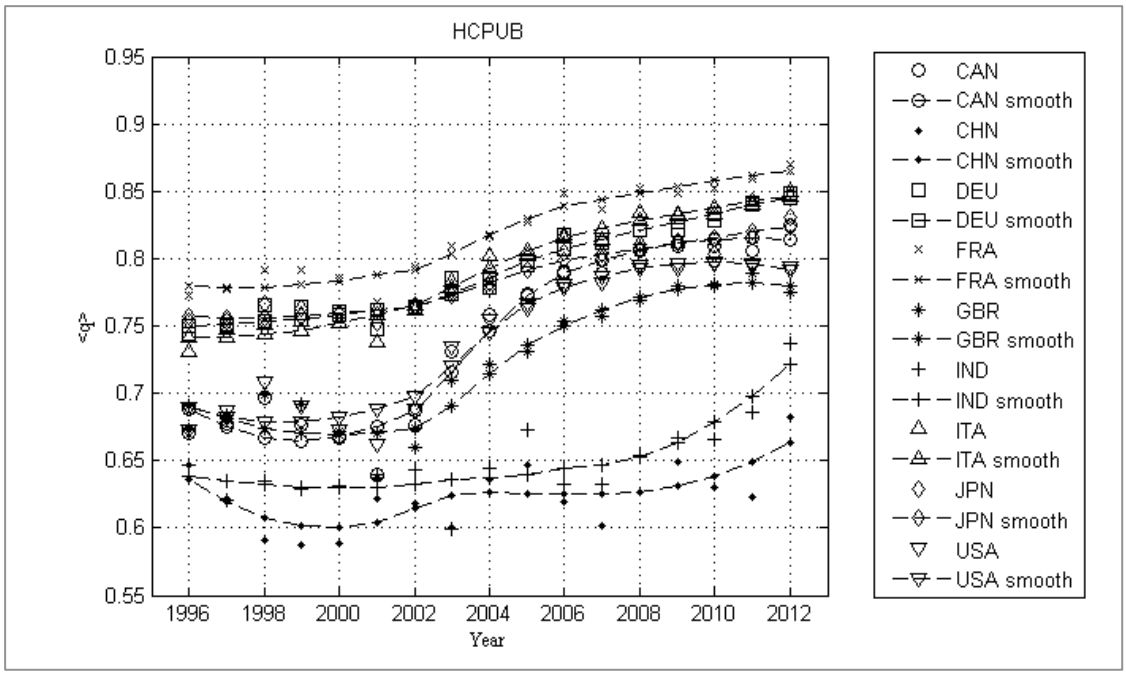


Figure 7. Dynamics of overlaps between 9 leading nations and all other countries for the number of highly cited publications (HCPUB)

An important aspect is the *dynamics* of the overlap values: how do the overlap distributions develop over time, and how does the position of specific countries evolve. Figures 5 and 7 present for 9 leading nations the development over time of the average overlap with all other countries, for the fractional number of publications (PUBf) and the number of highly cited publications (HCPUB), respectively. Although Figure 6 shows during the last 4 years a slight decline in overlap for most countries, Figure 7 reveals a trend towards convergence, especially for India and China. Perhaps the latter two countries increased their contribution to the international research front, but they maintained to some extent their own disciplinary profiles.

Conclusions

A tentative conclusion that should be substantiated in future empirical research is that the *variability of disciplinary profiles among countries is of the same order of magnitude of the variability among regions within a country and that the same happens for their convergence* rates, as shown by the distributions of the overlap calculated and displayed in this paper. The same dynamics observed for the extensive measures of scientific production is observed for the intensive average productivity, which appears to have a more concentrated distribution for all the level of the analysis carried out. Further research is in progress to support these preliminary findings and to illustrate the advantages of our approach, including the application of the ultrametric property of the overlap values to determine "automatic" clustering of the investigated national and regional systems of research. The step further will be then to link the scientific structure of national and regional systems with their technological structure to evaluate their dynamics at national and regional level.

Abstract
This study applies scientometric approach to meso level data. The objective was to evaluate Institutional level h-index's (IHI) reliability with respect to other Journal Related Indices (JRI). Most of the studies in the literature considered journal's h-index as contrasted measure. Nevertheless, there has been no study that explores the relation between IHI and institutional level JRI. To get further evidence, we have explored the inter-correlation of IHI with a set of JRI. For this purpose data from Web of Science, Journal Citation Report and time cited features were used. Our unit of analysis was Malaysian engineering research with a wider time span of 10 year's data (2001-2010) and a larger set of journals (1381 journals). Previous studies are are used for comparative analysis. This paper puts forward a better understanding to considering new impact indices at meso level for evaluation purpose.

Conference Topic
University policy and institutional rankings, Science policy and research assessment

Introduction
Journal Impact Factor (JIF) was introduced by the Institute of Scientific Information (ISI) via Journal Citations Report (JCR) about 30 years ago. It has a long tradition as an Impact Factor (IF) indicator for scholarly research output. Alike, h-index and many of its variants have been introduced and displayed on JCR site (www.webofknoweldge.com). IF can be used as a measure of research quality/impact of journals (Braun, Glanzel & Schubert, 2006). In general research performance evaluation (RPE) practices, it has become a "chief quantitative measure of the quality of researcher, and even the institution" but, it cannot be used as a direct measure of quality (Amin & Mabe, 2003; Bornmann et al., 2011). JIF remains the primary criterion when it comes to assessing the quality of journals and authors (Raj & Zainab, 2012). IF should not be used as a sole measure of a journal rank (Bornmann, et al., 2011).

To overcome the limitations, of IF, researchers suggested that it should be used with new alternative tools (Braun, Glanzel, & Schubert, 2006; Prathap, 2011; Bornmann et al., 2011; Yang Yin, 2011) or as a measure of research quality / impact of journals (Braun, Glanzel & Schubert, 2006). An interesting debate was started by Braun, Glanzel, and Schubert, (2006) who suggested that the h-index can be used as a measure of research quality or impact of a journal. The notion of Journal h-index was introduced by (Braun, Glanzel, & Schubert, 2005). Who found it a promising measure for the journal (Braun, Glanzel, & Schubert, 2006). After the introduction of h-index, a number of studies made a comparative analysis of both measures and their variants. Both impact indices (h and IF) are easily comprehensible (Leydesdorff, 2009) and have received worldwide recognition. However, prior studies, as reviewed in the subsequent paragraphs were concerned with the evaluation of journal's h-index to JRI.

Mingers, Macri and Petrovici (2012) examined Journal level h-index against Impact Factor 2year (JIF), Impact Factor 5 year (IF5y) and peer judgment for management journals. They preferred journal h-index to IF because of the former's selective time frame and the formulaic problem. Another study in the field of management was carried out by Moussa and Touzani (2010) using Google-Scholar (GS) as source data. They used a variant of the h-index, the hg-index along with two and five years IF. There was a substantial agreement found (>0.85) between JIF 5y and the hg -index ranking. They suggested hg-index as an alternative to the GS based journals. Soutar and Murphy (2009) studied 40 marketing journals and ranked them according to IF and h-index, and compared their list with Australian journal ranking. They suggested these indices as the basis for moving some journals up and other journals down. Their study supported the use of GS as an alternative way to measure citations in marketing. Harzing and Van der Wal compared h-index calculated from GS with the impact factors computed from the Web of Science (WoS^{TM}) and with peer reviewed journal ranking (2009) by undertaking a larger-scale investigation of over 800 business and management journals.

A comparative analysis of IF and h-index was carried out by Bador and Lafouge (2010) on pharmacology and psychiatry journals from JCR with two-year publications. The journals correlation coefficient between IF and h-index was high. They inferred that IF and h-index can be totally corresponding when analyzing journals of the similar scientific subject. Bornmann, Mutz and Daniel (2009) studied the journal's h-index of twenty organic chemistry journals from WoS^{TM} database for two years time span. They analyzed a number of impact indicators including the IF, and journal's h-index and its variants *g* index, h^2 index, A, and *R* index. They found "a high degree of correlation between the various measures" (Bornmann, Mutz & Daniel, 2009).

Yang Yin (2011) analyzed 20 top journals in the field of science and engineering using data from WoS^{TM}. The researcher hypothesized "that the combination of complementary journal indicators could provide a simple, flexible and practical alternative approach for evaluating scientific journals" (p.2). Yang Yin considered the journal h-index with another JRI e.g. EigenFactor score. There is a positive correlation although not strong among these indices. They suggested getting published research work in high Eigenfactor scores journals. These indices can also be combined to complement each other.

Research Objectives

The objective of past studies was to evaluate a journal's h-index validity and reliability with respect to other JRI. Most of these studies considered journal's h-index as contrasted measure with JIF, JIF (5Y), and EigenFactor Score (EF). These studies are meaningful to understand the properties of newly introduced indices and potential use of journal's h-index as a complement aid with IF and its variants (Bador & Lafouge, 2010; Bornmann et al., 2012; Yang Yin, 2011) or, as a supplement (Braun, Glanzel, & Schubert, 2006).

Nevertheless, there has been no study to explore the relation of IHI with JRI. To have further evidence of validity of h-index at the institutional level, we hypothesized that IHI is a potential index for RPE that can be used to complement or as a supplement along with JRI for RPE at the institution level.

Methods and Materials

The empirical part of this study focuses on one non-Western country, Malaysia, which has a developed and well-defined scholarly publishing industry based in its universities. Research productivity, citations record, and institutional journal data of twelve Malaysian universities are retrieved from WoS^{TM} and JCR'2011 from the Web of Science. Only those universities that have at least fifty publications during the past ten years were selected. "The statistical methodology of EFA can be used to examine for latent associations present in a set of

observed variables, and reduce the dimensionality of the data to a few representative factors" (Schreiber et al., 2012, p.349). It is mainly used to identify a smaller set of salient variables from a larger set and to explore the underlying dimensions or factors that explain the correlations among a set of variables (Conway and Huffcutt, 2003). Initially, we used eleven indices for the present study. These are Total publications (TP), Total Citations (TC) Citation Per Publications (CPP), Institutional H-Index (IHI), JIF, Cumulative Journal Impact Factor (CIF), Journal Impact Factor 5y (JIF5y), Cumulative Journal Impact Factor 5y (CJIF5y), Average Impact Factor (AIF), Median Impact Factor (MIF), Immediacy-index (Imm-index) and EigenFactor Score (EF).The definitions and the acronym used are described in Table 1.

Table 1. Definitions of indices used at Meso level.

Indicators	*Definition*
1. Total Publications (TP)	Total publications of a university over the set criteria
2. Total Citations (TC)	Total citations of a university over the set criteria
3. Institutional H-Index (IHI)	An institution has index h if h of institutional publication has at least h citation each and other publication have fewer than or equal to h citations each.
4. Journal Impact Factor (JIF)	The average number of times articles from the journal published in the past two years has been cited in the JCR year (Thomson- Reuters 2015).
5. Cumulative Journal Impact Factor (CIF)	This is the cumulative value of Journal Impact Factor of each university.
6. Impact Factor five Years (IF5y)	The average number of times articles from the journal published in the past five years have been cited in the JCR year (Thomson-Reuters 2015).
7. Cumulative Impact Factor Five Years (CIF5y).	This is the cumulative value of five years Journal Impact Factor of each university.
8. Average Impact Factor (AIF)	This is the average of the Impact Factor of each university.
9. Median Impact Factor (MIF)	This is the median of the Impact Factor of each university.
10. Immediacy-index (Imm-index)	This is calculated by dividing the number of citations to articles published in a given year by the number of articles published in that year Thomson-Reuters 2015).
11. EigenFactor Score(EF)	**"**Eigenfactor score is calculated by the ratio of the total number of citations for the JCR year to the total number of articles published in the last 5 years". Thomson-Reuters 2015).

Data Processing

To get a meaningful evaluation, we used a wider set of WoS^{TM} engineering journals (1381 journals) considered by our sample (12 Malaysian universities) institutions with a wider horizon of ten years (2001-2010) under specified nine categories. Our research term was "Malaysia" in "Address", limited to document type research article and reviews only and

refined by nine engineering research categories. These engineering categories are engineering electrical, electronic, engineering manufacturing, engineering biomedical, engineering industrial, engineering civil, engineering chemical, engineering mechanical, engineering environmental and engineering multidisciplinary.

Data were suffered from affiliation problem, change of journal title and abbreviation of a journal name. All the data were checked manually for publications, citations, institutional affiliation, and journal name change or emergence cases. The selected twelve universities got their articles published in 1381 journals. According to JCR'2011, almost all journals in our data set were IF. There were only 22 journal articles published in six journals, and ten proceedings had no impact factor. It is assumed that the said journals/proceedings may have IF prior to 2011. These records were included in the journal list for analysis purpose. Firstly, all the records were retrieved in a spreadsheet file, and IBM SPSS version'19 was used for statistical analysis purpose.

Table 2 provides the university-wise total journal records. The publication share of research university (RU) status was 66 % (908) while; the non-RU status universities shared 34 % (473) of the total journals.

Table 2. Distribution of journals (N=1381).

No	*University*	*Total journals and proceedings*	*University Status*	*Contribution%*

12	Universiti Tenaga Nasional (UNITEN)	38		
	Total	1381		100

The RU universities are more bound to published in IF journals to get more research funding. These universities receive a big amount of budget for R&D purposes and have to face pressure and make policies accordingly (http://www.hir.um.edu.my), and this is especially prevalent in Asian countries (Leydesdorff, 2009). The first five public universities (RU) published in 150-200 journals. Comparatively the private universities had fewer publications and published in 50 to 100 journals. The average number of journals for RU and non-RU universities is 182 and 68 respectively.

Analysis and Findings

Exploratory Factor Analysis (EFA)

In a tie with the problem, this section proceeds accordingly with descriptive statistics, data normality and EFA for our set of indices as presented in Table 3.

Descriptive Statistics and Normality Analysis of Complete Dataset

Descriptive statistics along with Skewness and Kurtosis are presented in Table 4. The results of the normality test based on raw data (excluding outliers) are reported in Table 5. The Skewness and Kurtosis are valid tests to find the normality of data. Their values show a normal distribution of data adequately normal. Keeping in view the requirement of EFA statistical application we used two other options as well. We also examined the relation between the raw, logarithmically transformed shifted (ln(x + 1) and square root transformation.

Table 5 shows a better Kaiser-Meyer-Olkin (KMO) results and a slight better-explained variance for log data. For this reason, we found the logarithmic transformed data more adequate for EFA. Bornmann, Mutz and Daniel (2008; 2009) used a cut-off threshold >0.6 for extraction loading factors while Schreiber, Malesios and Psarakis (2012) fixed it at > 0.685 for Varimax rotation.

Schreiber *et al*. (2012) argued that small sample size for EFA can produce reliable results. Quite a few factors and high communalities are in favour of small sample sizes (Preacher and MacCallum, 2002). Further, to measure a sampling adequacy, a specific test Kaiser-Meyer-Olkin (KMO) of value >5 is acceptable (Kaiser, 1974). KMO value (Table 6) of the present data sample is >0.5 with high communalities (>0.85) (Table 7). Based on KMO values and variance explained (Table 6 and 7), we finally utilized logarithmically transformed data. We identified two unknown factors through Eigen values (>1) via variance explained.

This is evident that EFA can be used and is appropriate for our formulated problem and dataset. Initially, we considered eleven indices, TP, TC, IHI and 8 of JRI (JIF, CIF, IF avg, MIF, CIF, CIF5Y, Imm-Index, and EF). This set of indices produced inadequate results for EFA. After omitting the TP, we applied EFA to TC, IHI, and 8 JRI (IF, CIF, IFavg, MIF, CIF, CIF5Y, Imm- Index, and EF).

Table 6. Kaiser-Meyer-Olkin (KMO) measure of sampling adequacy

	X	*√x*	*ln(x + 1)*
KMO	0.564	0.540	0.695
Sig.	0.00	0.00	0.00

Table 8 provides Initial Eigenvalues >1 and indicates that the total variance explained by first two factors is 75%, and 17 % of cumulative variance explained by both factors are 91%.
Component matrix (Table 8) illustrates that the set of indices clearly loads on two extracted factors. Rotated Component Matrix Table (9) for EFA model shows that the indices have

substantial loading on two established factors. It indicates the loading of two institutional 'impact of the productive core indices' (TC and IHI) and six others JRI have high loading (> 0.90) and a slight less for EF (>0.891).

Table 7. Communalities for 3 EFA models

	X		*√x*		*ln(x + 1)*	
Indices	*Initial*	*Extraction*	*Initial*	*Extraction*	*Initial*	*Extraction*
TC	1	0.893	1	0.9	1	0.896
IHI	1	0.883	1	0.877	1	0.866
IF	1	0.94	1	0.951	1	0.953
CIF	1	0.934	1	0.958	1	0.962
IF(avg)	1	0.854	1	0.865	1	0.841
MIF	1	0.869	1	0.844	1	0.87
IF(5Y)	1	0.954	1	0.963	1	0.967
CIF(5Y)	1	0.879	1	0.925	1	0.950
Imm- Index	1	0.918	1	0.943	1	0.955
EF	1	0.869	1	0.861	1	0.870

AIF and MIF both have substantially high loading on the second factor>0.9. MIF is more accurate measure than the average value, due to the impact factor's skewed distribution (Costas & Bordons, 2007). IF and CIF and IF5y and CIF5y require two years and five years time span with different strengths of productivity. EF is another index based on 5-year data excluding journal self-citation to rate the total importance of journal. Journals generating higher impact on the field have larger Eigenfactor scores (Bergstrom, 2007). "EF improves upon JIF and somewhat robust indicators of quality and prestige of the journal due the inclusion of 5 year's data, exclusion of journal self-citations" (YangYin, 2010, p.3). Rather a high journal EF depicts producing of high-impact scientific findings in a specific area (YangYin, 2010; Saad, 2006). IF (5y) indicates the speed with which citations to a specific journal appear in the published literature. Immediacy index that is based on one-year data shows the same value as CIF on the first factor. They both require a different strength of data. Surprisingly they all loaded on the same factor along with IHI.

Conclusions

The caveats of h-index, JIF, and traditional metrics have been discussed in the abundant literature. Previous studies are meaningful to understand the properties of newly introduced indices and potential use of Institutional's h-index as a complement aid with IF and its variants. (Bador & Lafouge, 2010; Bornmann et al., 2012; Yang Yin, 2011) or, as a supplement (Braun, Glanzel & Schubert, 2006).

The present study describes the case of Malaysian engineering research applying the scientometric approach, method and techniques for RPE. Based on the ten years data analysis from WoS^{TM}, we applied a set of comparatively new indices. To achieve the research objectives, empirical analyses were carried out, and hypotheses were examined statistically.

The major findings of the study demonstrate that there seems to be increasing the trend to get published in IF journals. A steady increase of IF publications is observed from 2001 in the Malaysians scientific productivity of all studied disciplines including engineering. The ambition to publish in IF WoS^{TM} recognized publications is reinforced by the Malaysian Research Assessment (MyRA) exercise, which requires institutions to publish papers that are indexed in the citation database. This is due to the Malaysian Ministry of Education policies towards research and publications during two five years plans (2001-2005; 2006-2010). RU status universities (shared 68% and 74% publications and citations). These universities have published in 66% of total journals. Overall, the RU universities lead in positioning order with the application of indices. USM is an exceptional case and remained in position one with respect to almost all indicators. While others showed a noteworthy change in their positioning order. IHI has stronger functional relation with institutional citation data followed by publication record. Institutional citation data is the best predictor of IHI. Often used metric C (as total impact indicator) and the EF (as prestige indicator) have a high association with IHI. This establishes the property of h- index as prestige impact measure of scientific productivity. This index appears a useful yardstick, because of good functional relationship with C and P and has shown some discriminatory power for ranking purpose. The EFA suggests the same distinguishing behaviour of IHI like P and C. The findings put forward a better understanding

about the consideration of new impact metric for RPE at the meso level. Malaysian engineering institutional case indicates that h-index and others metric have not only strong association for total institutional citation data but also with institutional cumulative journal indices. However, the total variance explained for two components yields about 75% for its first component and 16% for the second component. Therefore, findings are based within the limitations of the statistical analysis.

Publishing in high-quality IF journals is important if a country is to realize its ambition to have its universities amongst the top rated universities in the world. This is not peculiar to Malaysia. The Ministry of Education Malaysia is targeting two research universities in the country to be in the top world 100 best universities by 2020. Other countries also place a high emphasis on publishing in IF journals and would want to be ranked as top world universities, even if they are not always explicit in saying so. Given the significant number of papers that have now been published by Malaysian institutions (56, 571 in Web of Science, Essential Science Indicators, Web of Science 2015), there is an opportunity to carry out further analysis. It would be interesting, for example, to provide analysis at a discipline level to get a feeling for the strengths of the institution at a lower level. It would also be informative to consider other normalization measures to ascertain if they provide a better correlation with the MyRA ranking.

Abstract
The study sought to explore the underlying factors that influence research collaboration in Library and Information Science (LIS) schools in South Africa. The population for the study consisted of 85 academic teaching staff employed by LIS schools in South African universities. A survey design was used to obtain data for the study, through a questionnaire containing open- and close-ended questions. A total of 85 teaching staff in 10 LIS schools in South Africa were alerted, through email, to the location of the Web-based questionnaires, developed using the Stellarsurvey software. A total of 51 questionnaires were completed and returned for analysis. The findings suggest that factors such as networking, sharing of resources, enhancing productivity, educating students, overcoming intellectual isolation, and accomplishments of projects in a short time as well as learning from peers influenced research collaboration in LIS in South Africa. Factors that are likely to hinder effective collaboration in LIS research include bureaucracy, lack of funding, lack of time, as well as physical distance between researchers. The findings further suggest that even though there are drawbacks to collaboration, majority of LIS researchers thought that collaboration is beneficial and should be encouraged.

Conference Topic
County-level studies

Introduction
In today's global economy, there is an increasing importance of collaborative relationships between individuals, organisations, and even countries. Collaboration, defined as a "process where two or more individuals or organizations deal collectively with issues that they cannot solve individually" (Ocholla, 2008:468) and "the working together of researchers to achieve the common goal of producing new scientific knowledge" (Katz & Martin, 1997), can be found in all the spheres of human life, for example in politics, economics or even in religion. Katz & Martin (1997) are of the opinion that research collaboration has significant benefits such as intellectual championship, joint development of skills, effective transfer of knowledge and the improvement of potential visibility of researchers. For example, collaboration can build partnerships and help empower researchers to accomplish projects that were never going to be easy to do individually. Collaboration brings together experiences, skills, knowledge and the know-how of different researchers into one particular project. By way of research collaboration, researchers from different countries (both developed and developing countries) come together for different purposes, among which are sharing of information, knowledge and technological transfer as well as finding solutions to specific problems (Onyancha, 2009). Researchers collaborate in order to accomplish tasks that cannot be accomplished as isolated individuals. Onyancha & Ocholla (2007), too, note that securing research grants is to a large extent becoming increasingly pegged on whether the intended research would be conducted collaboratively. Collaboration can be important especially in developing countries where there might be a lack of scientists and resources in certain fields. The few available researchers in developing countries can collaborate with those in developed countries for the former to be active in research as well as flourish as scientists.

According to Katz and Martin (1997), collaboration among scholars in both natural and social sciences has been steadily increasing for decades, covering different disciplines, development categories, institutions, geographic regions and countries. The increasing attention on research collaboration in LIS has also been pointed out by Onyancha and Maluleka (2011). Sugimoto (2011) argues that research in the field of LIS has followed similar patterns of increased collaboration as in other fields. According to Ocholla (2008), collaboration and partnerships could be forged amongst LIS institutions in a country and internationally or regionally in areas such as teaching, research, student and staff exchange, conferences and workshops, curriculum development, publications, research supervision and examination and distance teaching/research.

Rationale for the study

An examination of the published literature reveals that several studies have been conducted to examine research collaboration in different fields or disciplines including LIS. The focus of these studies includes identifying the collaborating authors, institutions, and/or countries (e.g. Sun, 2006; Onyancha & Ocholla, 2007), measuring the strengths of research collaboration (e.g. Yamashita & Okubu, 2006) and examining the nature of collaboration (e.g. Katz & Martin, 1997; Smith & Katz 2000). Several other studies have majorly focused on answering the question 'who' or 'what' of collaboration. In other words, studies that have been conducted previously on collaborative research have largely focused on the frequency of collaboration between the authors, the nature of collaboration and the strength of collaboration across disciplines. To the best of the researchers' knowledge, little has been done to answer the question 'why?' The current study therefore aims to investigate those factors that may influence collaboration in LIS schools in South Africa. The main objective of this study is to find out the underlying reasons and/or factors that influence collaboration, a situation that may explain the quantitative results (e.g. trends, patterns, and type of research collaboration) reported in previously published works.

Research Questions

The following research questions were posed in order to fulfil the study's main objective;

- What factors hinder and/or would hinder effective research collaboration in LIS schools in South Africa?
- What factors do and/or are likely to foster effective research collaboration in South African LIS schools?
- To what extent do the enhancers and inhibitors of collaboration influence research collaboration in LIS schools in South Africa?

Methodology and Materials

The study adopted a survey design to seek for the LIS academics' views on factors that influence research collaboration in LIS research in South Africa. Neuman (2007:273) argues that survey research is developed within the positivist approach and it is the mostly and widely used design in the social sciences. Similarly, Leedy and Ormrod (2010:187) argue that survey research *involves acquiring information about one or more groups of people – perhaps about their characteristics, opinions, attitudes, or previous experiences by asking them questions and tabulating their answers.*

In this study, the survey involved all academic teaching staff employed by LIS schools in South African universities. They include teaching assistants, junior lecturers, lecturers, senior lecturers, associate professors, and professors. Honorary professors, research fellows, extraordinary professors, or any other scholars who are linked to a particular department but without being fulltime were excluded as they appeared to have more than one institutional

affiliation. With only ten LIS schools offering LIS education in South Africa, there was no sampling conducted as all schools were included in the study. The total number of the teaching staff was also small, leading us to include all academics in the target population for this study. Table 1 shows the number of staff in the LIS departments by the parent University.

Table 1. LIS Schools in South Africa

School name	Acronym	Number of teaching staff
University of South Africa	UNISA	19
University of Pretoria	UP	24
University of KwaZulu-Natal	UKZN	6
University of Zululand	UZ	7
University of Fort Hare	UFH	4
University of Cape Town	UCT	8
University of the Western Cape	UWC	6
Durban University of Technology	DUT	5
University of Limpopo	UL	4
Walter Sisulu University	WSU	2
TOTAL		85[1]

The instrument of data collection for the study was a questionnaire, which was deemed to be the most appropriate. The questionnaire contained both closed-ended and open-ended questions, the former being the majority. There were a total of 20 questions focusing on specific items that were linked to the research questions. We used the "*Stellarsurvey*" online survey software as a platform for the questionnaires.[2] We then sent emails to all the identified LIS researchers in South African LIS schools. The emails contained a link directing them to the website which invited them to participate in the study. Respondents were given three weeks to complete the questionnaire online. After three weeks a reminder was sent to participants again reminding those who had not responded to do so.

Results and discussion

Profile of the respondents

Out of the 85 teaching staff members that were approached to participate in the study, only 51 completed the questionnaires, leading to a response rate of 64.6%. It was found that 43% (i.e. 22) of the respondents were male while 29 (57%) were female. All respondents had a university qualification ranging from a bachelor's degree to doctoral degree. The majority of the respondents (i.e. 21 or 41%) had a master's degree as their highest qualification, followed by those with a doctoral degree (i.e. 19 or 37%) and then those with honours (11 or 22%). The majority of the respondents were employed as lecturers (27 or 54%), followed by junior lecturers (9 or 18%) and full professors (5 or 10%) while senior lecturers and associate professors stood at 3 (3%) each. The results shows that the majority of the respondents are actively involved in research either as masters and doctoral students or as supervisors and mentors for these students.

[1] The number of the teaching staff was retrieved from the LIS departments' websites.
[2] The software is available at: http://stellarsurvey.com/.

The status of collaboration in LIS research

It was found that 43 (84%) of the respondents collaborated in the conduct of research while only 8 (16%) indicated that they never collaborated before. The results in Figure 1 (a) reveal that 45 (88%) respondents believe and agree that collaboration in research is important while 2 (4%) were neutral with only 4 (8%) saying collaboration in research is not important.

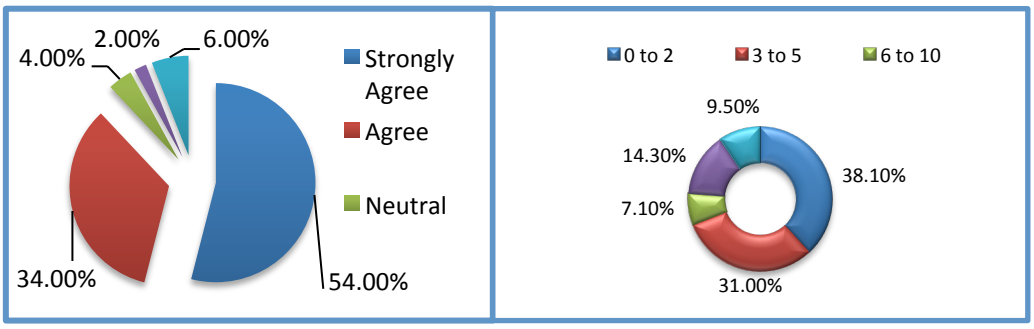

Figure 1. (a) Importance of collaboration (N=51) (b) The number of collaborated projects that are already published.

It is strange to note that while 84% of the respondents indicated that they collaborated, there was a sizable number, who may have included the ones who reported that they collaborated, who might have felt that collaboration is not important. This group could include researchers who are forced, by circumstances (e.g. institutional policies on co-supervision of students or mentorship of junior colleagues). When we looked at collaborative projects already completed (Figure 2 (b)), 32 (62%) respondents had already completed three or more projects collaboratively while only 19 (38%) had completed between 1 and 2 projects collaboratively.

It was worth noting that the current generation of researchers are actively engaged in collaborative research. Results tend to imply that the researchers prefer sharing and working together as compared to the past where the degree of collaboration among researchers has been reported to be low.

It has been shown that research collaboration in South Africa has increased tremendously in the previous decade (i.e. 2001-2009) (Sooryamoorthy, 2009). There are a number of reasons that may have influenced this pattern on collaborative research. Universities in South Africa have realised that they are losing their most experienced researchers who were approaching retirement age before the young developing researchers were fully equipped in the area of research. In some universities such as UNISA, huge funds have been invested into the development of young researchers through initiatives such as the mentorship programmes. This is done in view of Liebowitz's (2009) suggestion that formal mentoring programmes are popular techniques used for knowledge sharing, knowledge retention, knowledge transfer, and also to enhance worker skills. In this programmes, senior researchers are assigned mentees who learn from them on a daily basis for a specific period of time. Research funding organisations such as the National Research Foundation (NRF) of South Africa are also making funds available for collaborative and multidisciplinary research. Doctoral students are also funded to conduct post-doctoral research in collaboration with their mentors. The responses from the questionnaire also suggest that other universities have made it compulsory for supervisors to publish at least one article collaboratively with their students from the latter's theses and dissertations. The above is evident from the feedback from the respondents and it may be the reason why the majority of the respondents in the survey indicated that they are engaged in collaborative research, although some of them also indicated that collaboration is not important.

Looking at the group of people that the respondents mostly collaborated, it was noted that the researchers in LIS schools in South Africa largely collaborate with fellow researchers when taking the occasional, often and most often times of collaboration into account; the three account for 80% (see Table 2). This suggests that LIS researchers prefer collaborating with fellow researchers, preferably in their own field of interest. The main reason may be that working on a project with someone who understands one's subject area and the methodologies involved may result in the project being completed at a faster pace than if the opposite had to happen.

Another point worth highlighting is the results on collaboration with international researchers which was very low, with over 70% of the respondents indicating that they never collaborated at this level. This pattern is contrary to previous studies' findings, which revealed that most research in Africa is published in collaboration with international researchers (see Narvaez-Berthelemot, Russell, Arvanitis, Waast, & Gaillard, 2001). It is therefore unfortunate to find that researchers in LIS schools largely collaborate locally as opposed to engaging in international collaboration as researchers collaborating at the international arena have a competitive advantage over their peers because they have a chance of using resources from both institutions to which they are affiliated. The other notable advantage worth mentioning about international collaboration is the fact that it allows researchers a chance to publish in international journals, share international experiences which will allow them an opportunity to gain international visibility. Narvaez-Berthelemot, Russell, Arvanitis, Waast, & Gaillard (2001) note that researchers in developing countries would also benefit from their peers in developed countries in terms of publication of their research in international journals. The authors opine that "*the less productive the developing country, the greater the dependence on international co-authorship for mainstream publication*". Katz and Martin (1997) observe that most governments have been keen to increase the level of international collaboration engaged in by the researchers whom they support in the belief that this will bring about cost-saving or other benefits. The main reason given by respondents for not collaborating at this level was distance and logistical problems that exist when working with someone from another country. The other reason worth noting is the fact that researchers from bigger institutions or developed countries may undermine the contribution of the other researchers from poorer countries or smaller institutions. The opposite may also happen where researchers from smaller institutions may lack self-belief, contribute less and end up not playing an equal role in the whole collaborative venture.

Table 2. Group of persons that respondents collaborated with

	Never	Rarely	Occasionally	Often	Most often
Students	33.3%	7.7%	25.6%	23.1%	10.3%
Mentor	24.3%	18.9%	13.5%	16.2%	27.0%
Mentees (other than students)	50.0%	14.7%	20.6%	11.8%	2.9%
Fellow Researchers	5.0%	15.0%	30.0%	45.0%	5.0%
Senior Researchers	28.2%	15.4%	15.4%	20.5%	20.5%
International Researchers	45.9%	24.3%	10.8%	13.5%	5.4%

It seems like there is need for institutions to initiate programmes geared towards supporting the researchers in overcoming problems faced during international collaboration. The researchers also need to take advantage of the latest technologies that can easily allow them to work together without having to travel between countries. For LIS researchers in South Africa to remain at par with their international counterparts, they need to engage with them and work with them collaboratively so that they don't work in isolation.

Table 3. Groups likely to collaborate with in the future

	Never	Rarely	Occasionally	Often	Most often
Students	2.6%	7.9%	23.7%	39.5%	26.3%
Mentor	24.3%	16.2%	16.2%	21.6%	21.6%
Mentees(other than students)	25.7%	14.3%	34.3%	20.0%	5.7%
Fellow Researchers	0.0%	12.2%	22.0%	43.9%	22.0%
Senior Researchers	12.5%	20.0%	10.0%	35.0%	22.5%
International Researchers	12.5%	20.0%	30.0%	20.0%	17.5%

Enhancers and Impact of collaboration

Merlin (2000), Katz and Martin (1997), Bozeman and Corley (2004) give a summary of the following factors that are likely to foster effective collaboration in research:

- Collaborative research allows young researchers, access to expertise /experts with specialised knowledge and expertise in a particular area and learns directly from them.
- These partnerships gives researchers an opportunity to share resources where researchers from smaller institutions will get access to resources from big institutions and again institutions to supplement each other
- Multidisciplinary research allows a cross pollination of ideas and collaborative research allows partners to learn from one another
- There are more chances of getting funds if a collaborative initiative is submitted to funding organisation. Secondly a project can get funds from both organisations with will make it possible to carry out
- Working alone in a particular project can make one feel lonely and isolated. Working in a team helps one to overcome that intellectual isolation.

For this study, respondents were asked to indicate the extent to which factors such as networking, sharing of resources, enhancing productivity, educating students, overcoming intellectual isolation, accomplishment of projects in a short time, learning from peers, and incentives influence them (researchers) to engage in collaborative research.

The results indicated that over 44 (86%) respondents engage in collaborative research to strengthen their networks with other scholars. The respondents reported that networking helps to bring these scholars who happen to have common interests together and create partnerships that often last for longer. Researchers usually work alone on their projects which leaves them isolated. Networking or coming together with fellow researchers to work on a project together may help overcome that isolation. The importance of networking was also highlighted by 37 (73%) respondents who indicated that they collaborate in research to overcome intellectual isolation. Another patch of respondents numbering 38 (75%) also agreed to be collaborating with an aim of sharing resources. This can be very significant to researchers from smaller institutions and underdeveloped countries with little resources. Such partnerships can allow them to take advantage of the available resources in both institutions, some of which may not be available in their smaller institutions.

Learning from peers was also one of the most common factors among respondents on why they collaborate in research. The results show that 43 (84 %) respondents collaborate in research to learn from their peers. This usually happens where two or more scholars with different expertise come together to solve a research problem. Each researcher brings a special skill that may not be known by the others and that brings an opportunity for all to learn from one another. There were mixed feelings among respondents when it came to having to collaborate to get incentives. In South Africa, a number of institutions usually attach incentives to publications published in selected peer reviewed journals, book chapters, peer reviewed conference proceedings and books that earn subsidy from the Department of Higher

Education and Technology (DoHET). Only 24 (47%) respondents indicated that incentives may influence them to collaborate with 21 (41%) saying incentives have very little influence on them when it comes to collaborating. It has been informally noted by researchers at some forums of discussion that some researchers at times choose not to collaborate so that they don't share incentives made available and opt to work alone. This can have serious implications because those who are skilled enough will work alone and continue getting incentives while they are not leaving anyone to take over from them when they retire which will create a knowledge gap. Having incentives for research in an academic setting is motivating and encouraging for researchers but it has negative implications for the future.

Reasons for collaborating

Respondents were requested to give specific reasons that are likely to foster collaborative initiatives with particular groups such as, students; mentors; mentees (other than students); colleagues in the same department; fellow researchers; and international researchers.

Reasons for collaborating with students and mentees (other than students)

The responses received for this question were not that surprising considering the population for this study. Respondents indicated that they collaborate with students to impart knowledge and help the latter to obtain their qualifications. Some respondents indicated that collaborating with students is part of their jobs. A number of promoters feel that it takes a lot of time to do postgraduate supervision and as a result, they make sure that they get an article out of the whole project so that their efforts do not go to waste. It was also interesting and encouraging to note that some supervisors feel that students bring fresh perspectives on themes and ideas that they may be having at the time. This means that such supervisors give students a platform and opportunity to participate in the whole project while taking their ideas into consideration. Furthermore, respondents indicated that they would like to share their experiences on a particular subject and help capacitate their mentees while strengthening their relationships with their students at the same time exploring areas outside their subject specialisation.

Reasons for collaborating with mentors and managers

There was a general consensus among those respondents, who are being mentored by senior colleagues, that it is important to tap into the mentor's experience and knowledge in order to develop skills and research avenues. Mentorship of young researchers where the latter learns from the senior and experienced colleagues is again at the centre stage. Field (2001:270) is of the opinion that a mentor should play an important role in the career development of mentees, by providing them with background information and support for individual growth, as well as making them aware of opportunities available.

The other important thing about having a mentor is the creation of an opportunity to connect with the mentor's professional networks. This allows the mentee to grow and expand his/her professional boundaries. Mentorship can either be formal or informal. The best example of a formal mentorship is that of a supervisor working with a post graduate student. Informal mentoring may happen between the experienced and the less experienced through a personal connection. One respondent mentioned that mentors know their mentees best, and it is advantageous to work with someone who knows and understands his/her mentee well. Having worked with someone before gives the mentee an advantage of knowing how the mentor does things and what the latter expects of him/her. This is important during collaboration where responsibilities are shared because it will be helpful in deciding which role should be played by whom. Other respondents indicated that a natural consequence of being a young researcher and wanting to learn definitely motivated them in the conduct of collaborative research with their mentors.

Reasons for collaborating with colleagues in the same department

Being in the same department will most likely mean that one knows and understands each other's strengths and weaknesses. Respondents indicated that they collaborate with colleagues with the aim of producing high quality papers in a short space of time to enhance their productivity. Some respondents mentioned a desire to pursue niche areas in their departments as a reason for collaborating with fellow researchers. They indicated that such collaborative research has the potential to generate income for them and increase their research output. Some respondents indicated that they work on departmental joint projects and they have no choice or can't avoid them as they are in the same department. This group may not yield desired results because collaboration is not conducted between willing partners who are committed to seeing the project through to the end.

Other respondents mentioned that co-supervision of students' work automatically gets them to work together and eventually they publish together with the students. In view of the fact that some LIS schools in South Africa have closed down or changed focus to non-LIS disciplines, the onus is left to the few available LIS schools to ensure the survival of the profession. The closing down of LIS schools has put too much pressure on the few academics left in LIS as they are expected to service the increasing student numbers and also conduct research so they stay relevant. This situation encourages collaboration where researchers will share responsibilities and reduce the time and effort required to complete a task.

Reasons for collaborating with colleagues from other departments

The respondents indicated that collaborating with someone from another department in the conduct of research widens their horizons. The respondents further mentioned that such collaboration is very important because it helps with the establishment of interdisciplinary networks and exposure to a wide variety of research methods. The other notable reason mentioned by the respondents is the cross-pollination of ideas that will result from collaborating with someone from a different department or discipline.

Reasons for collaboration with International Researchers

This type of collaboration as discussed in the sections above enables researchers to share international experiences, foster international networks, and can help researchers do comparative studies with peers from other countries. Respondents who indicated that they have collaborated at the international level believe that global perspective is key to providing comprehensive research studies. Researchers can never work in isolation and the same should happen in LIS. International collaboration according to some respondents can increase researchers' chances of accessing funds and publications as well as get international visibility.

Barriers to collaboration

This section explores the issues that LIS scholars perceive to hinder effective research collaboration in LIS schools in South Africa. Katz and Martin (1997) gave a summary of the following barriers to collaboration:

- Financial implications in the form of travel costs , moving of equipment's and so forth
- Increased administration resulting from more people/institutions involved,
- Lack of time from some collaborators, or additional time required as different parts of the research will be done in different locations
- Different management cultures, financial systems and rules on intellectual property rights

Table 4. Barriers to collaboration

	To a great extent	Somewhat	Very little	Not at all
Bureaucracy	42.2%	33.3%	22.2%	2.2%
Lack of funding	43.5%	28.3%	19.6%	8.7%
Intellectual property rights	9.1%	29.5%	36.4%	25.0%
Lack of time	43.5%	28.3%	15.2%	13.0%
Clash of values	9.1%	31.8%	34.1%	25.0%
Ethics	15.9%	18.2%	27.3%	38.6%
Distance between researchers	15.2%	19.6%	23.9%	41.3%

For this study, respondents were first asked to indicate the extent to which barriers such as bureaucracy, lack of funding, intellectual property rights, lack of time, clash of values, ethics, and distance between researchers may have prevented them or are likely to prevent them from engaging in collaborative research. Secondly respondents were requested to indicate the extent to which a number of personal traits and characteristics may be a barrier/s to research collaboration. Table 4 provides the extent to which some factors act as barriers to effective collaboration.

Table 5. Personal traits or characteristics that may be a barrier to research collaboration

	To a great extent	*Somewhat*	*Very little*	*Not at all*
Gender	6.7%	15.6%	20.0%	57.8%
Level of education	31.1%	44.4%	20.0%	4.40%
Competencies	70.5%	29.5%	0.0%	0.0%
Honesty	72.7%	13.6%	6.8%	6.8%
Respect	80.0%	11.1%	6.7%	2.2%
Self-discipline	72.1%	23.3%	4.7%	0.0%
Work Ethic	75%	20.50%	4.5%	0.0%
Mutual Intent	75%	20.50%	4.5%	0.0%
Attitude	70.5%	25.0%	4.5%	0.0%
Interpersonal skills	47.7%	45.5%	2.3%	4.5%
Reliability	74.4%	23.3%	0.0%	2.3%
Nationality	4.7%	2.3%	20.9%	72.1%

A good majority of respondents (i.e. 39 or 76%) indicated that bureaucracy may be a barrier to collaboration. We believe that academics work under tight deadlines and the pressure to deliver is high and therefore too much red tape may sometimes delay their progress. Again over 36 (71%) respondents indicated that lack of funding maybe a barrier to collaboration. It should be noted that many institutions make funds available for research but if access to those funds is a problem then little research will be done. If a project does not receive funds then it will never get off the ground. It was interesting and surprising to note that 34 (66%) respondents indicated that ethics has very little impact on whether they collaborate or not. We opine that ethics is very important in research and perhaps that is why institutions around the world have adopted specific ethical principles when it comes to research. Only 17 (34%) respondents indicated that ethics may be a great barrier and influence their decision to collaborate. The distance between researchers also seem not to be a problem among respondents with 33 (65%) respondents indicating that it will not stop them from collaborating. The latest computer technologies such as Skype make it possible to work with someone who is in another country as if one were in the same room, so the issue of distance is increasingly becoming a thing of the past.

The majority of the respondents (i.e. 29 or 57.8%) did not see gender as barrier to collaboration. However someone's level of education was considered very important by the respondents. Over 38 (75%) respondents indicated that someone's level of education may be a barrier to collaboration. This may be influenced by the fact that researchers collaborate to accomplish goals that they cannot accomplish on their own; as a result, someone who is not academically capable may not be a good partner to have especially when one is under pressure to deliver. This was supported by the fact that all respondents suggested that somebody's inadequate competencies is definitely a barrier to collaboration. Personal characteristics such as honesty, respect, self-discipline, as well as attitude had over 46 (90%) respondents strongly indicating that the attributes will definitely block them from collaborating. Everybody wants to be associated with a well-mannered and respected person as well as someone who is not troublesome.

Reasons for not collaborating

Just like in the study by Katz and Martin (1997), this study investigated those underlying reasons that may hinder collaboration in LIS in South Africa. Respondents were asked to provide reasons that best describe why they may not collaborate with the following groups: students, mentors, Mentees other than students, colleagues in the same department, fellow researchers, seniors or managers and international researchers. The following were results as obtained from the survey.

Reasons for not collaborating with students and mentees

There was a general feeling amongst respondents that they will never work with students who are lazy and not prepared to work. This factor cannot be overemphasized as respondents mentioned issues like, lack of competencies, poor work ethic, and not following instructions on the students' side as main reasons they may not collaborate with students. Students who are repeating the same mistakes or not considering any advice or guidance given to them may be left without mentors. The respondents feel that such students may delay them at times as they do not stick to deadlines and agreements. Senior researchers may want to share their knowledge and skills but if the partner is not willing to learn then it defeats the whole purpose. Senior researchers are rated and evaluated according to their output and therefore wasting time on someone who does not want to learn or not willing to learn may be costly for them. Other responses included lack of mutual understanding, lack of commitment, time constraints as well as if the two parties do not share common research goals.

Reasons for not collaborating with mentors and managers

There were no surprises when it came to reasons why researchers will not collaborate with their seniors or managers in the conduct of research. A number of respondents were concerned about the fact that their mentors or seniors make them do all the work but equally share the credit which is somehow discouraging to them. Even though this is obviously unethical, it is common knowledge that some mentors abuse their positions and take advantage of their mentees. Young researchers will be expected to do all the work with little contribution from their more senior collaborating partner. Respondents further mentioned that mentors always demonstrate authority, lack empathy and never listen to their suggestions. Ignoring the contribution made by the more junior researchers may be demoralising and may result in the young researchers losing interest in conducting research because of the lack of self believe. Managers or mentors have an obligation to build as any form of advice or feedback is supposed to build as opposed to being too harsh. Many masters and doctoral students never complete their studies as some mentors give poor feedback or criticism that is aimed at breaking the students. Some of the respondents mentioned a lack of work ethic, lack of time, and not getting valuable advice or input from their mentors as other reasons for not collaborating with their mentors. Mentors normally have a lot of commitments, and a

collaborative project with a student may not be a priority to them, while the student's development and growth will be depending on it. This can therefore discourage students from wanting to collaborate with mentors.

Reasons for not collaborating with colleagues in the same department

This was a very interesting question and some of the responses given were somehow unexpected. Respondents mentioned that some colleagues have drawn their own conclusions about others which affect or influence their decision to collaborate. This is again a question of underestimating others and having one's own biased perceptions of others before they get to know them. That is a personal problem and has to do with everybody's personality and can only be solved over time, even though it poses challenges. Other respondents indicated that they will never collaborate with colleagues in their department because some colleagues never give their ideas a chance. This is a problem everywhere; colleagues who are mostly quiet may keep their ideas to themselves in such partnerships. Others are not good in expressing themselves and will mostly keep to themselves. This may result in ideas that end up being used although they are not the best, just because they came from the most vocal participants. One respondent indicated that in some instances, the most vocal colleagues may have a good command of the English language, while their ideas lack substance. Some of the other reasons raised include selfish colleagues, clash of ideas, competencies, attitude; lack of work ethic, and professional jealousy which was really unexpected. Some colleagues may feel that involving others in projects and working together may improve their profile and maybe become a threat to them in the work environment. Such colleagues end up being selfish and holding on to information and blocking their fellow colleagues. Others indicated they are so busy to an extent that they do not have time to do any other extra work, including collaborative research. Issues relating to office politics and intellectual property rights were also highlighted as possible reasons why some respondents do not enter into collaborative initiatives with fellow colleagues in the same department.

Reasons for not collaborating with fellow researchers

This question aimed to get responses on why LIS researchers are not collaborating or may not collaborate with fellow researchers in other departments as well as those in other universities. Many responses given were similar to the ones given in the immediate question above. However the issue of different research interests came out ahead of others. Even though many universities encourage multi-disciplinary research, researchers seem to prefer working with scholars who understand their area of interest and methodologies involved in the research, just to name but a few. Other reasons included unethical behaviour, time and distance between researchers, and different agendas among collaborating researchers.

Reasons for not collaborating with international researchers

Most of the barriers already indicated in the preceding questions were also mentioned here. Other reasons which were given by respondents regarding this question and are worth mentioning include distance and logistical problems, lack of communication, and topical issues, just to list a few. There is a general feeling from many local researchers that it is really not easy to work with someone who is very far especially in another country, even though the technologies available today make this possible and better than before.

Conclusions

The study by Sooryamoorthy (2009) revealed that collaboration in research in South Africa has been growing steadily over the years. This implies that, even though there are difficulties and drawbacks associated with collaboration in research, LIS researchers are mainly focusing in all the benefits that come with such partnerships and therefore engaging in collaborative research. It is important to mention that, even though the benefits of collaboration are evident,

the drawbacks cannot be ignored. A re-look at the enhancers and inhibitors of research collaboration suggests that the distance between researchers, past relationships and the institution of affiliation most influenced who collaborated with whom. The results imply that LIS researchers prefer partnering with colleagues who are nearer, mainly from the same institution. The collaboration networks suggest that issues discussed above have had a major impact on the current status of collaboration in LIS research in South Africa.

Collaboration links between supervisors and students are very much evident and seem to be the most influencing factor on research collaboration among LIS researchers in South Africa. It is also very encouraging to see some partnerships between senior researchers from different schools which is crucial for the growth and development of research in the field. Ocholla (2008) has observed that collaboration of LIS schools is weak and largely informal. This was very evident in the current study, too. Collaboration mainly happened between individuals while departments rarely collaborate hence there is no evidence of students from a particular university collaborating with their peers from other universities. This finding concurs with the views of Ocholla & Bothma (2007) who indicated that collaboration among LIS schools and researchers in such areas as "teaching, research, student and staff exchange, conferences, workshops, curriculum development, publications, research supervision, examination is very important yet very minimal"**.**

Abstract
This paper assesses the diffusion of nanoscience and nanotechnology in Turkey in the last decade using bibliometric and Social Network Analysis (SNA) techniques. We extracted a total of 10,062 articles and reviews from Web of Science (WoS) authored by the Turkish scientists between 2000 and 2011. We divided the data set into two 6-year periods (2000-2005 and 2006-2011). Almost three quarters (7,398) of all papers were published between 2006 and 2011. For each period, we compared the number of nanotechnology papers, the universities' output along with their levels of collaboration with one another, the diffusion and adoption of nanotechnology, the most prolific authors and the nanotechnology research topics studied most often by the Turkish researchers. We found that nanotechnology research and development (R&D) in Turkey is on the rise and its diffusion and adoption has increased tremendously in the second period. This is due primarily to the fact that the government identified nanotechnology as a strategic field a decade ago and decided to provide constant support for nanotechnology R&D. Overlay maps showed that nanotechnology R&D in Turkey concentrated primarily in Materials Sciences, followed by Chemistry, Physics, Clinical Medicine and Biomedical Sciences.

Conference Topics
Country-level studies, Mapping and visualization

Introduction[1]

Nanoscience and Nanotechnology is the study of materials at atomic levels within the 1 to 100 nm range (i.e., at a magnitude of 10^{-9} of a meter) (Mehta, 2002). Although Nanotechnology has been introduced more than half a century ago by Feynman (1960), it took some time for the nanotechnology research to pick up. Many countries have invested heavily in nano-related technologies in the past two decades. The US government, for example, has allocated 1.74 billion US dollars to nano-related technologies in 2011 (Sargent, Jr., 2013). European countries under the 7th Framework Program have also heavily invested in joint projects among its members. Consequently, the number of scholarly publications in nano-related technologies in North America, Europe and Far Eastern countries has increased.

Turkey as a developed country prepared its strategic plan by taking nano-related research and development into account. Nanotechnology including nanophotonics, nanoelectronics, and nanoscale quantum computing is one of the eight strategic fields of research and technology mentioned in Turkey's "Vision 2023 Technology Foresight Study" that was prepared as part of the "National Science and Technology Policies 2003-2023 Strategy Document" by the Supreme Council of Science and Technology (SCST) more than a decade ago (Ulusal, 2004, pp. 19-20). Nanotechnology as a research field has been receiving state support since 2007 in Turkey (about one billion Turkish Lira, or circa 500 million USD). The Turkish Scientific and Technological Research Council (TUBITAK) and the Ministry of Development (MoD) support nanotechnology projects financially. For example, MoD continues for more than a decade to invest to improve the infrastructure of nanotechnology research facilities and

[1] This paper is based on the findings of first author's Ph.D. dissertation entitled "Assessing the diffusion of nanotechnology in Turkey: A Social Network Analysis approach." (Darvish, 2014).

supported the establishment of nanotechnology research centers. In addition, it supports several nanotechnology-related projects carried out by research institutes and universities.

Thanks to state support, nanotechnology has become a major field of research in Turkey. Universities invested heavily in nanotechnology in the last decade. More than 20 nanotechnology research centers were set up mostly in universities. Among them are Bilkent, Middle East Technical, Hacettepe, Sabancı, İstanbul Technical and Boğaziçi Universities. More than 10 universities are offering both undergraduate and graduate degrees in nanotechnology. More than 100 commercial companies and start-ups of various sizes have also invested in nanotechnology (e.g., Normtest, Arçelik, Yaşar Holding, Yeşim Textile and Zorlu Energy) and developed commercial nanotechnology products in a number of sectors including surface coating, textile, chemistry, automotive and construction industries, and polymer and composite materials. Turkey has been among the first three countries in terms of the growth of nanotechnology research with some 2,000 scientists working in this field (Bozkurt, 2015, p. 49; Denkbaş, 2015, p. 84; Özgüz, 2013). The number of nanotechnology related scientific papers published by Turkish researchers and listed in Web of Science (WoS) is ever increasing (more than 2,500 in 2014 alone).[2]

This paper aims to assess the diffusion of nanoscience and nanotechnology in Turkey between 2000 and 2011 using bibliometrics and Social Network Analysis (SNA) techniques. It identifies the total production of nano-related publications by Turkish researchers and the key fields in which nanotechnology is applied in Turkey (e.g., biomedicine, pharmacy, and metallurgy). The adoption of nanotechnology by the most prolific universities and the diffusion of nanotechnology knowledge through collaboration among them is also studied.

Literature Review

Scientists have investigated the diffusion of innovation and knowledge in societies from different perspectives. Rogers (2003, p. 5) defines the diffusion of an innovation as "the process by which an innovation is communicated through certain channels over time among the members of a social system." Social interactions between scientific domains and practitioners are instrumental to the diffusion of innovation and knowledge. According to Rogers, the key elements in the diffusion process are: innovation/knowledge, communication channels, time and social systems (p. 7). An innovation starts with a few people and has a few adopters, but eventually it gains the momentum until it reaches its peak. Rogers likens the diffusion process of an innovation to a mathematically-based bell curve (also known as "Rogers adoption/innovation curve") and categorizes the adopters accordingly (i.e., starting from the left tail of the curve to the right, 2.5% of the adopters are called "innovators", 13.5% "early adopters", 34% "early majority", 34% "late majority", and the remaining 16% on the right tail of the curve as "laggards").

Poire (2011) looks at the timeframe of the adoption of innovations along with the impact of innovations on the economy. He argues that "it takes about 28 years for a new technology to become widely accepted, followed by a period of rapid growth lasting about 56 years. Some 112 years after invention, the innovation reaches maturity and grows in-line with population increases" (Roy, 2005, p. 9). Using these yardsticks, he convincingly charted the adoption processes of textiles, railways, automobiles, computers and nanotechnology. He predicts that nanotechnology, which according to him came into being in 1997, will be more widely adopted by 2025, followed by a 56-year long rapid adoption period (until 2081) during which time nanotechnology products will become an integral part of our everyday life like computers.

[2] Search on WoS was carried out on January 11, 2015.

If an innovation is communicated among the members of a social system, as Rogers indicated, then studying social systems is important because scientists work and collaborate within such systems. Assessing social relations among scientists reveals how collaborative they are. Conventionally, Derek de Solla Price (1965) studied the scholarly communication process between scientists, thereby opening the door to the quantitative study of science.

Social Network Analysis is a paradigm in which relational interaction among members signifies the role of people in a network structure (Wellman & Berkowitz, 1997). The diffusion of knowledge in a network of people can thus be studied by exploring the social structure of the network along with the relations and collaboration (or lack thereof) among network members using SNA concepts such as density and centrality. For example, poorly connected "structural holes" in a densely connected network are crucial for connecting "clusters" (groups of people) in a network structure and for the diffusion of knowledge in the network (Burt, 1992). Newman (2000) referred to clustering as "community structure". The value of a person in a social network is therefore linked to his/her potential to establish connections between clusters that are separated by structural holes.

Scientific discovery comes with a group of specialized people who "attend, read and cite the same body of literature and attend the same conferences" (Chen et al., 2009, p. 192). Bibliometric methods such as co-citation (Crane, 1972) or co-author (Girman & Newman, 2002) analyses were used to study the diffusion of knowledge in the network of scientists as well as to track the level of collaboration among different partners along with the emergence of new research areas. As a collaborative model involving universities (research centers), funders and industries, the Triple Helix was proposed to streamline the diffusion of knowledge (Leydesdorff & Etzkowitz, 1998).

Scientometricians use visualizations in addition to other indicators to track or investigate new scientific developments over time. For example, science overlay maps were introduced as a novel approach to illustrate the bodies of research precisely surrounded by global scientific domains (Rafols, Porter & Leydesdorff, 2010). Science overlay maps can represent different types of data and large data sets such as network of authors, publications and universities succinctly and "help benchmark, explore collaborations, and track temporal changes" (Rafols, Porter & Leydesdorff, 2010, p. 1871).

Nanotechnology has been the subject of several studies in the past and reviewing them is beyond the scope of this paper. However, we should mention Milojević (2009, 2012) who studied the coginitive content of nanoscience and nanotechnology as well as its diffusion using SNA techniques and mapped the evolution and socio-cognitive structure of it. We should also mention one particular study that measured the growth and diffusion of nanotechnology on a global level on the basis of the number of publications produced by countries as well as the most prolific institutions and authors along with the most cited authors, papers and journals (Kostoff, Stump, Johnson, Murday, Lau & Tolls, 2006). China, Far Eastern countries, USA, Germany and France were among the most prolific ones.

As mentioned earlier, Turkey is among the first three countries based on the growth of nanotechnology research. Turkey's contribution to nanotechnology literature was also evident at the global level (Kostoff, Koytcheff & Lau, 2007). Recently, the state of nanotechnology centers and companies carrying out research and manufacturing nano-related technologies in Turkey was studied with a view to compare them quantitatively with their counterparts in China, India and Germany, for example (Aydoğan-Duda & Şener, 2010; Aydoğan-Duda, 2012). The present study attempts for the first time to map the nanotechnology output of Turkish universities and investigate the diffusion of nanoscience and nanotechnology knowledge in Turkey at the micro level by means of Social Network Analysis and bibliometrics. The results can be considered as a stepping stone for comparative studies for future studies.

Method

The aim of this research is to assess the diffusion of nano-related technology by mapping of collaborative social structure of scientists in Turkey between 2000 and 2011. We attempted to address the following issues: (a) the most prolific universities publishing nanotechnology research; (b) the rate of diffusion of nanotechnology knowledge and its adoption within universities between 2000 and 2011; and (c) key areas of nanotechnology research.

In order to answer the research issues, we used a compound textual query on nanotechnology modified from Kostoff's[3] and searched (WoS). We retrieved a total of 10,062 papers (with at least one author of each paper affiliated with a Turkish university or research institute) published between 2000 and 2011. We then divided the data set into two 6-year periods (2000- 2005 and 2006-2011) to further assess the diffusion of nano-related technology in Turkey.

We analyzed co-occurrences among universities to capture collaborations in network structures. VOSviewer was used to implement the method of "associative strength" that clustered bibliometric data based on their similarities and mapped the network structure. A geocoder[4] was used to get the geo-coordinates for each city and Google Maps was used to overlay the relationships among cities on a geographic map. Bibexcel was used to calculate the most frequent collaborators from selected universities in the research. The top ranked universities in each period (2000-2005 and 2006-2011) were selected on the basis of their co-occurrence in terms of scientific collaboration on nanotechnology. Gephi, VOSviewer and GoogleMaps were used to map the network structure.

Findings

The number of Turkey's scientific publications on nanotechnology increased from 215 papers in 2000 to 1,748 in 2011, more than an eight-fold increase (Fig. 1). Almost three quarters (7,398) of all papers (articles and reviews) were published between 2006 and 2011 while the rest (2,664) were between 2000 and 2005. This increase is mainly due to Turkey's making nanotechnology a priority field in its 2003-2023 strategic plan and providing state support to nanotechnology research and development starting from 2007. The number of newly-established universities, hence the number of researchers studying nanotechnology, has also increased tremendously in this period.

There are about 180 universities in Turkey, two-thirds being state-funded. Using the fractional counting method, Figure 2 shows the top ranked universities based on the number of nanotechnology papers they published between 2000 and 2011. The Middle East Technical, Hacettepe, İstanbul Technical, Gazi and Bilkent Universities are the top ranking ones. All but four (Bilkent, Koç, Fatih and Sabancı) universities in Figure 2 are state funded.

[3] Personal communication with Prof. Ronald N. Kostoff (20 April 2012). Search query is available from the authors upon request.

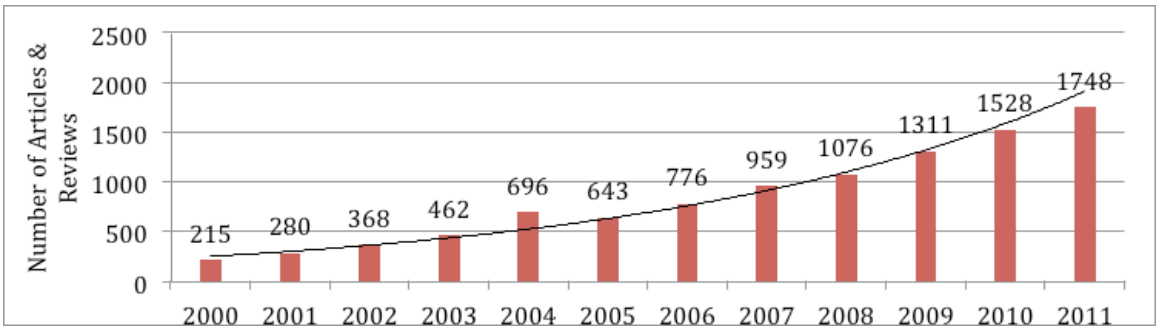

Figure 1. Number of nano-related technologies publications in Turkey: 2000-2011 Source: Thomson's ISI Web of Science as of November 2013.

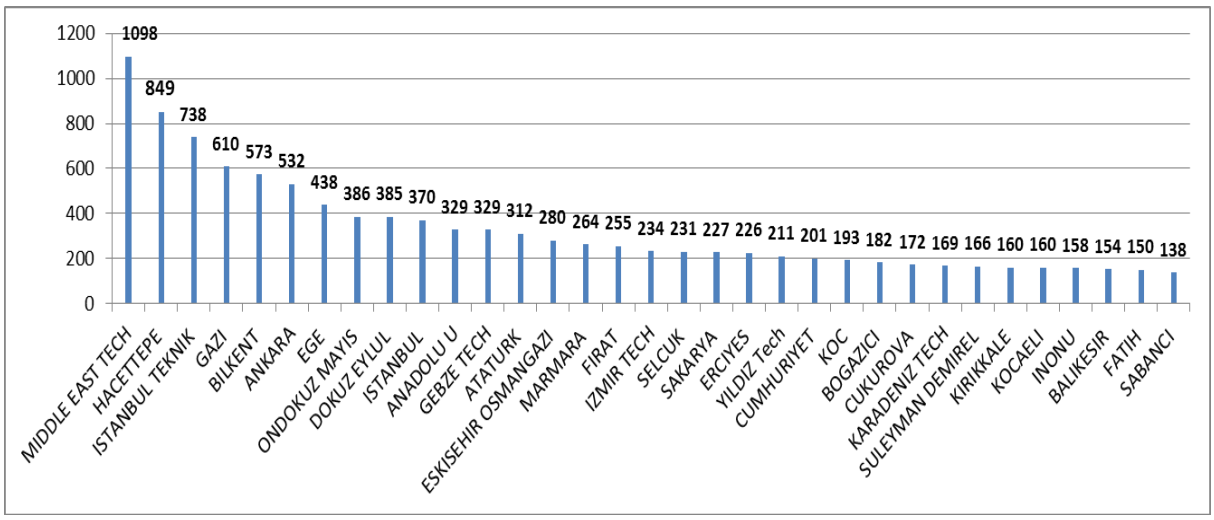

Figure 2. Number of nanotechnology papers of the top Turkish universities between 2000 and 2011 Source: Web of Science as of November 2013.

To assess the level of collaboration and the diffusion of nanotechnology knowledge among universities, we examined the average co-occurrence frequencies of all universities in published papers and created separate networks for the periods of 2000-2005 and 2006-2011 (Fig. 3). The collaboration network was much sparser in the first period with a few universities such as Hacettepe and METU acting as hubs of research on nanotechnology and cooperating with others. The network was much denser in the second period with more universities both acting as hubs of nanotechnology research and collaborating with their counterparts. This is an indication of an increasing level of collaboration among universities in carrying out nanotechnology research within a relatively short period of time.

The diffusion of nanotechnology knowledge in Turkey can be examined from a somewhat different angle by looking at the number of provinces where nanotechnology research took place. Turkey is divided into 81 administrative provinces. The information presented in Figure 4 is less granular than that in Figure 3 due to a few provinces such as İstanbul, Ankara and İzmir having several universities (both old and new). Nevertheless, the number of provinces where nanotechnology research is carried out went up from 40 in the first period (2000-2005) to 72 in the second period (2006-2011). The geographical spread is due to new universities being established in some provinces for the first time and to the government support that enabled researchers both in new and old universities to collaborate further.

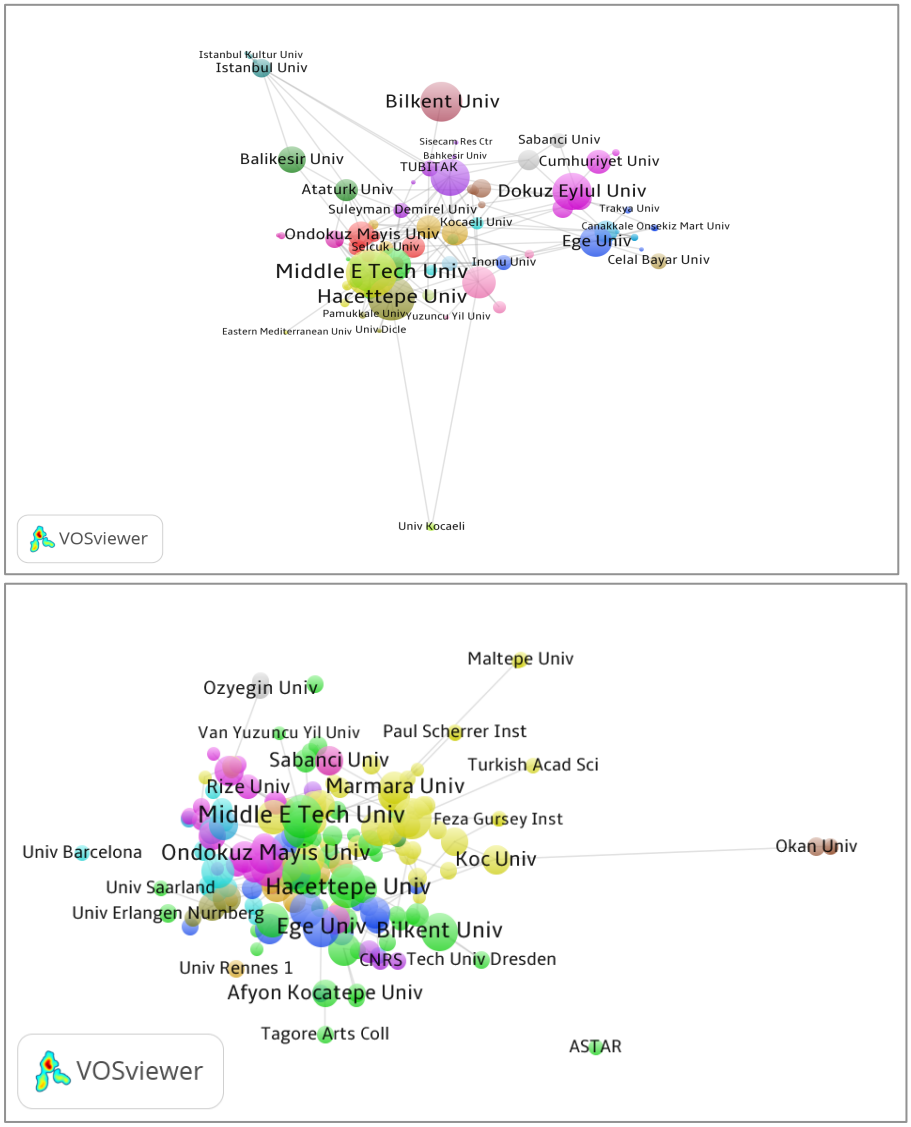

Figure 3. Collaboration of Turkish universities on nanotechnology (top) 2000-2005; (bottom) 2006-2011.

Table 1 shows the top 15 universities with the highest co-occurrence frequencies in both periods. The average co-occurrence frequency for the top 15 universities has almost tripled from 17 in 2000-2005 to 46 in 2006-2011. Note that the top 15 universities in the second period are slightly different from the ones in the first period, as some of the more prolific and more collaborative universities with higher frequencies of co-occurrence replaced the previous ones. We used the fractional counting method and found that the average number of nanotechnology papers published by the top 15 universities in the first period increased from 9 in 2000 to 27 in 2005, and from 35 in 2006 to 77 in 2011 in the second period, indicating more than an eight-fold increase (Table 2).

Next, we examined the diffusion of nanotechnology knowledge in Turkey using a more refined approach and identified the new authors collaborating each year in order to find out the adoption rate of nanotechnology research. Regardless of whether they appeared in the same paper or not, each new collaboration between any two authors was counted as one and considered a new adoption. The number of collaborating authors was just 214 at the beginning (2000) whereas it rose to 2,989 in 2011 (Table 3 and Figure 5). The number of new adopters was rather slow in the first period (2000-2005) with an average of 216 collaborations per year but the "tipping point" seems to have been reached in 2006 when the number of new adopters jumped from 282 in 2005 to 1622, an almost six-fold increase. The average number of new adopters in the second period (2006-2011) rose to 1868, more than eight times of what it was in the first period. Altogether, the number of cumulative new adopters soared in 12 years and was 13,692 in 2011. The annual rate of cumulative increase in percentages ranged between 11% (2004) and 54% (2006). Needless to say, the increase in the number of new adopters is primarily due to nanotechnology becoming a major research field in Turkey and nanotechnology research being supported by government funds.

Table 3. Number of new and cumulative adopters between 2000 and 2011

Year	# of new adopters	# of cumulative adopters	Rate of cumulative increase (%)
2000	214	214	0
2001	177	391	45

2003	381	965	39
2004	115	1080	11
2005	282	1362	21
2006	1622	2948	54
2007	1668	4652	37
2008	1907	6559	29
2009	1919	8478	23
2010	2225	10703	21
2011	2989	13692	22

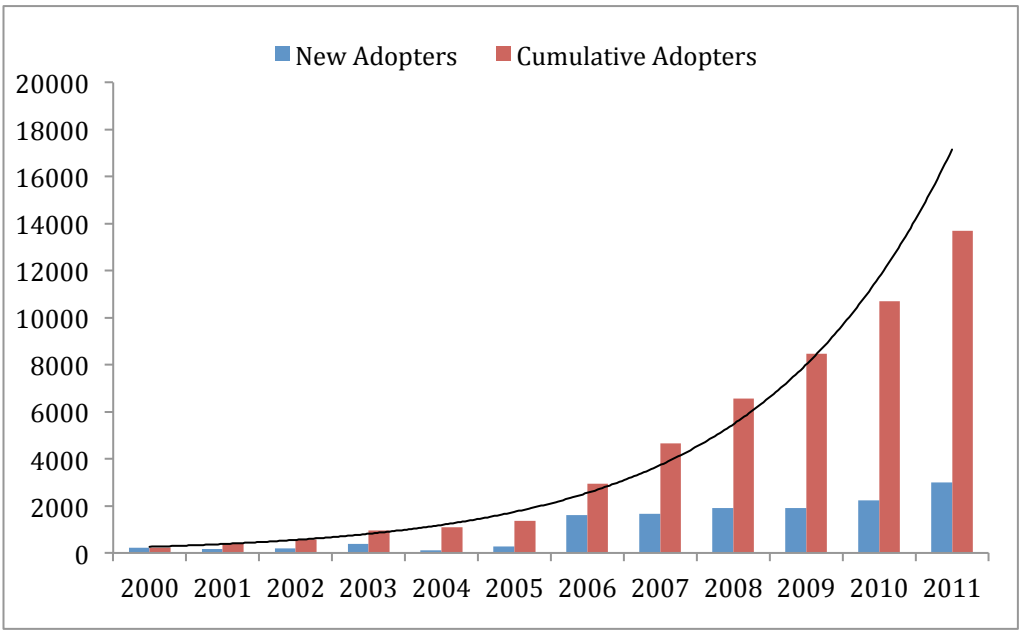

Figure 5. The growth of adoption of nanotechnology knowledge based on the number of collaborating authors (2000-2011).

Next, we identified the most prolific Turkish researchers in nanotechnology between 2000 and 2011 based on the number of papers they authored or co-authored. The fractional counting method was used for co-authored papers. Table 4 shows the top 20 researchers in both periods along with their total number of co-authors. The total number of papers authored or co-authored by the top 20 researchers almost doubled in the second period (from 645 to 1,189). Nine researchers appeared in both periods (italicized in the table) with different ranks. This means that 11 new researchers became more productive than they were in the first period and replaced the less productive ones in the second period or they entered the field anew. O. Buyukgungor of Ondokuz Mayis University, for instance, is at the top of the second period with 149 papers to his credit even though he did not appear in the top 20 of the first period. The top 20 most prolific researchers co-authored more papers with their colleagues in the second period (216 and 315, respectively). The number of co-authors of nine researchers who appeared in both periods increased 42% in the second period, indicating that they were influential in diffusing the nanotechnology knowledge to their colleagues. The same can probably be said for the remaining 11 researchers who appeared in the top 20 list in the second period.

Finally, we identified the research topics in nanotechnology that were studied more often by the Turkish scientists. We created separate overlay maps of research topics for both periods using ISI's 224 Subject Categories listed in WoS records. Both co-authorship networks and overlay maps were shared with five senior and five junior experts in nanoscience whose publications appeared in leading journals and their comments with respect to their places in the network were recorded (not reported here) (Darvish, 2014).

Each color in the map represents a subject category and the node size is proportional to its co-occurrence frequency with other nodes (Fig. 6). It appears that the nanotechnology papers authored by Turkish researchers in both periods were primarily related with Materials Science

(black) followed by Chemistry (blue), Physics (purple), Clinical Medicine (red), Biomedical Sciences (light green), Environmental Science and Technology (orange), and Computer Science (fuchsia). Subject categories appeared in overlay maps clearly show the priorities of Turkey in nanotechnology research and development and are commensurate with the nanotechnology products developed by commercial companies based in Turkey.

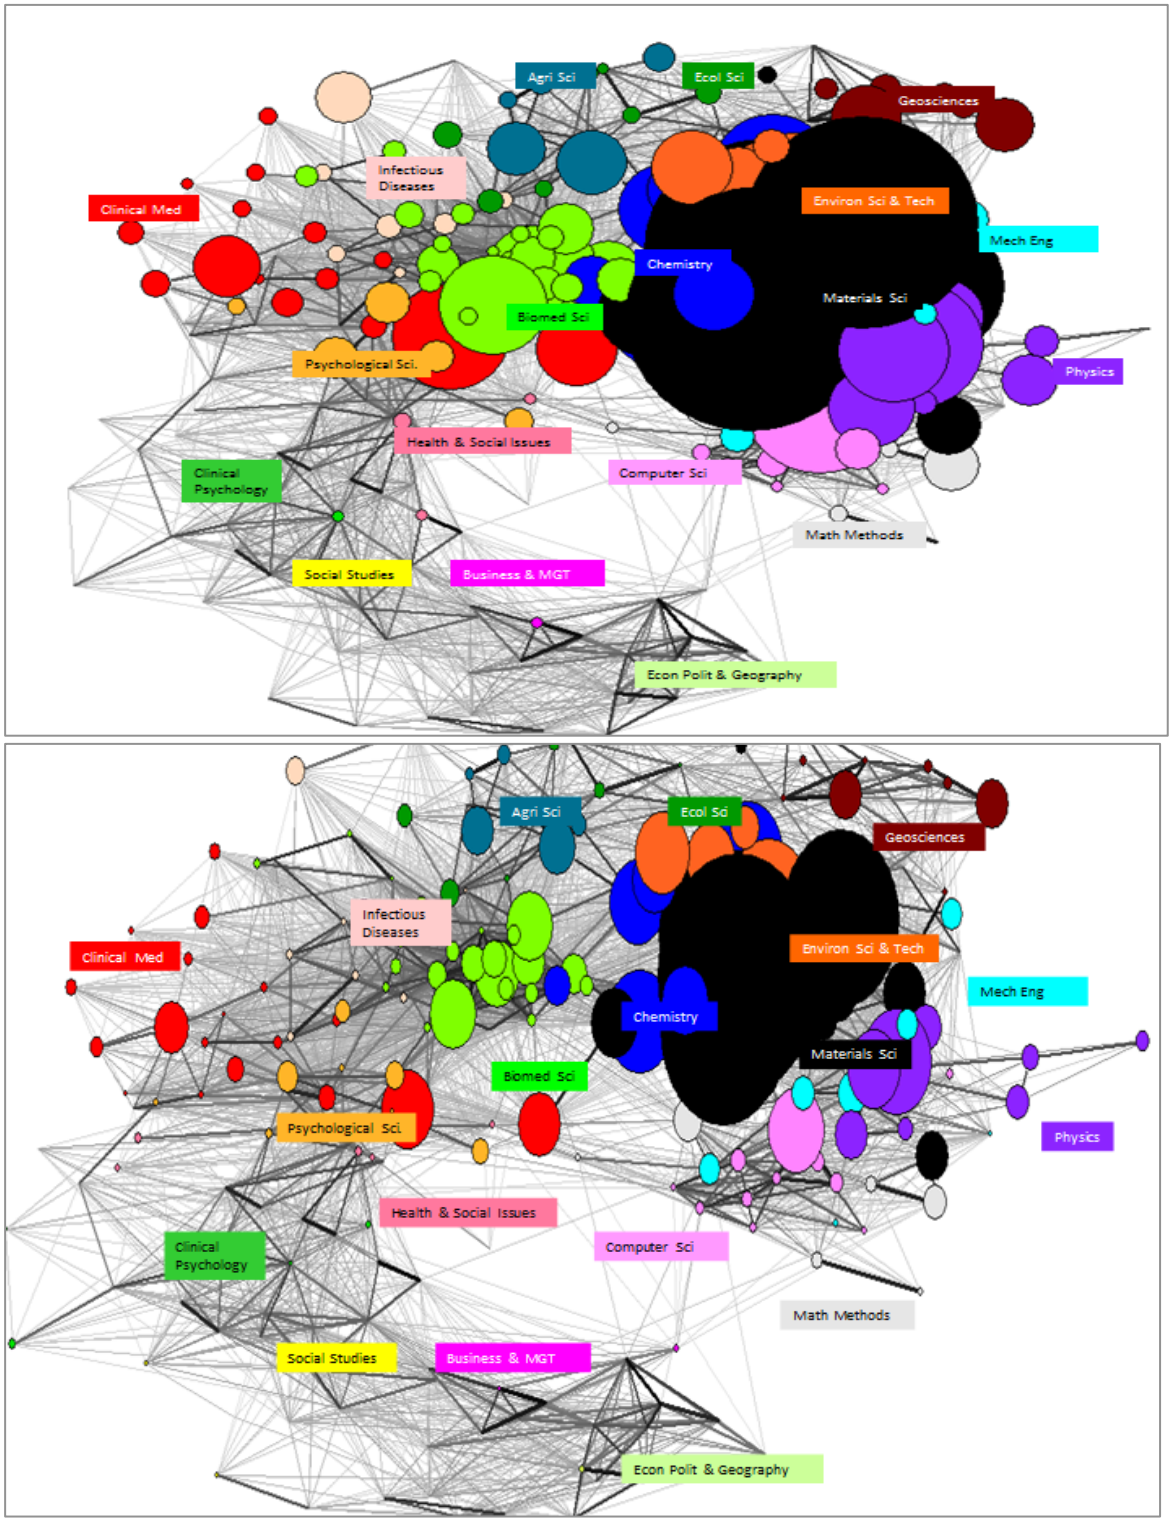

Figure 6. Overlay maps of subject categories of nanotechnology papers authored by Turkish scientists (top) 2000-2005; (bottom) 2006-2011.

Conclusion

Our analysis clearly shows that nanotechnology R&D in Turkey is flourishing. The number of nanotechnology papers published by Turkish scientists has tripled once the Turkish government has identified nanotechnology as one of the eight strategic fields in its national science and technology policy of 2003-2023 and decided to invest in nanotechnology accordingly. This decision has tremendously increased the diffusion and adoption of nanotechnology as a research field. Nanoscientists became more collaborative and more prolific in their research. This is somewhat similar to the experience of India, China, Iran and Latin American countries in that the importance of nanotechnology has increased once they identified it as a promising technology in their national development plans (Aydoğan-Duda, 2012).

The key areas of nanotechnology research and applications in Turkey are primarily in Materials Science, Chemistry, Physics, Clinical Medicine and Biomedical Sciences. All but Clinical Medicine appear in Milojević's list of areas as having the highest number of nanoscience and nanotechnology papers published in the literature (Milojević, 2012). The diversity of nanotechnology research shows that Turkish scientists are well aware of the trans- and interdisciplinary nature of nanotechnology as a discipline, although collaborative nanotechnology research in some areas such as Mathematics, Computer Science and Social Sciences seems to be currently lacking in Turkey.

Nanoscience stimulates scientific research in Physics, Chemistry, Biology and Medicine. Results revealed that notably well-established universities are instrumental in nanoscience research and newer universities are catching up. Turkey recognized the importance of nanotechnology as a strategic field relatively early. Based on Poire's timeframe of innovations becoming the drivers of economy, we can say that the diffusion of nanotechnology and its widespread adoption in Turkey will likely continue to accelerate until early 2030s.

Abstract
This paper aims to assess the diffusion of nanotechnology knowledge within the Turkish scientific community using co-citation and co-word analysis techniques. We retrieved a total of 10,062 records of nanotechnology papers authored by Turkish researchers between 2000 and 2011 from Web of Science (WoS) and divided the data set into two 6-year periods. We identified the most prolific and collaborative top 15 universities in each period based on their network properties. We then created co-authorship networks of Turkish nanotechnology researchers in each period and identified the most prolific and collaborative top 15 authors on the basis of network centrality coefficients. Finally, we used co-word analysis to identify the major nanotechnology research fields in Turkey on the basis of the co-occurrence of words in the titles of papers. Findings show that nanotechnology research in Turkey continues to increase due to researchers collaborating with their colleagues. Turkish researchers tend to collaborate within their own groups or universities and the overall connectedness of the network is thus low. Their publication and collaboration patterns conform to Lotka's law. They work mainly on nanotechnology applications in Materials Sciences, Chemistry and Physics, among others. This is commensurate, more or less, with the global trends in nanotechnology research and development.

Conference Topic
Country-level studies, Mapping and visualization

Introduction
Nanotechnology is a relatively new field studying materials at atomic levels within the 1 to 100 nanometer (nm) range (one nm is equal to one billionth of a meter, or, 10^{-9}) (Nanotechnology, 2015). It involves physics, chemistry, medicine, and biotechnology, among others, and promises a great deal of innovation for, and benefit to, society as a whole. Turkey identified nanotechnology early on (2003) as one of the eight strategic fields to support and invested considerably in nanotechnology infrastructure and education. It set up several "centers of excellence" in universities for nanotechnology research and development (R&D). Among them are the Research Center for Nanotechnology and Biotechnology of the Middle East Technical University (METU) and the National Nanotechnology Center in Bilkent University. The former is the first such center established with 15M USD government support while the latter is the first largest multi-purpose nanotechnology center established with 70M USD investment. Universities themselves also invested in nanotechnology. Altogether, there are currently more than 20 nanotechnology research centers in Turkey (Bozkurt, 2015;

[1] This paper is based on the findings of first author's PhD dissertation entitled "Assessing the diffusion of nanotechnology in Turkey: A Social Network Analysis approach." (Darvish, 2014).

Denkbaş, 2015; Özgüz, 2013). The private sector has also invested in nanotechnology in Turkey. Currently, more than 100 companies working in this field and they already developed several nanotechnology products and commoditized them.

In parallel with both government's and private sector's financing of nanotechnology research, several universities initiated multidisciplinary nanotechnology degree programs both at undergraduate and graduate levels (MSc and PhD). The undergraduate and graduate programs of Bilkent University's "Material Science and Nanotechnology", METU's "Micro and Nanotechnology" and Hacettepe University's "Nanotechnology and Nanomedicine" are among them.

The substantial interest and investment in nanotechnology triggered nanotechnology research in Turkey. In fact, Turkey is among the top three countries in the world in terms of the growth rate of nanotechnology research. More than 2,000 researchers are active in this field producing some 2,500 papers in 2014 alone[2] (Bozkurt, 2015, p. 49; Denkbaş, 2015, p. 84; Özgüz, 2013). In this paper, we investigate the development of nanotechnology research in Turkey using bibliometric and Social Network Analysis (SNA) techniques to study the network characteristics of more than 10,000 papers authored by Turkish researchers between 2000 and 2011. We compare the diffusion of nanotechnology research between 2000-2005 and 2006-2011 by measuring the network properties such as degree, betweenness and closeness centrality coefficients of the most prolific and collaborative universities and researchers for each period. We also identify the major nanotechnology research strands in Turkey using co-word analysis.

Literature Review

Information scientists have studied the growth of science and communication using bibliometrics and Social Network Analysis (SNA). While the former deals mainly with the effects of scientific productivity using citation analysis, the latter mainly focuses on the pattern of relationships among scientists. The network composed of co-authorship among scientists is a true indication of their cooperation in research activity.

The "small world" effect is a phenomenon that has been studied by scientists in different fields. This phenomenon conjectures that each member (node) in a society is linked to others (edges) through friends. Literally, every node in a small world is connected through an acquaintance. Newman (2000) found out that average distance from one person to the other by an acquaintance is proportional to the logarithm of the size of the community, implying one of the small world properties. Moreover, he found out that traversing between the two randomly selected nodes of a network takes an average of six steps.

In social contexts, Moody (2004) analyzed the structure of a social science collaboration network over a period. He discovered that collaboration between graduate students in a specific topic creates a small world of scientists and removes restrictions between them. Small world networks may manifest themselves in several shapes and models. Therefore, a good understanding of small world models helps us understand the network characteristics, too. For example, according to Watts (2003) a social network can be categorized as active or passive. Granovetter (1974) studied an active social network from the perspective of finding a job while Burt (1992) looked at such a network as social capital preluding the "rich get richer" phenomenon. In this study, the co-authorship network of structure is represented in a passive sense where the nodes and the edges connecting them are treated as actors and their relationships. Small world models are comprised of clusters or components. Clusters embedded in a network structure reveal a property called "clustering coefficient". According to Watts and Strogatz (1998), one can define a clustering coefficient *C*, which is the average

[2] Search on WoS was carried out on January 11, 2015.

fraction of pairs of neighbors of a node which are also neighbors. That is to say, if node *A* neighbors with node *B* and node *B* is a neighbor of node *C*, then there is a probability that node *A* is also a neighbor of node *C*.

According to Otte and Rousseau (2002, p. 443), betweenness, closeness and degree centrality are well known measures used in analyzing networks. Betweenness centrality is defined as the number of shortest paths going through a node. Thus, a node with high betweenness centrality will have a large impact on the diffusion of knowledge in the network (assuming that knowledge diffusion follows the shortest paths). Centrality is the total number of links that a node has. Degree centrality identifies the most influential node in the diffusion of knowledge in the social network. Closeness measures how far a node is from other nodes in the network structure. Closeness centrality is a measure of how long it will take to diffuse knowledge in a network (Centrality, 2015).

Betweenness centrality plays an important role in the structures of social networks. According to Freeman (2004), the discovery of the structural properties of scientific papers is measured by the betweenness centrality. Actors with a high level of betweenness centrality play a pivotal role in connecting different groups within the network. Betweenness centrality characterizes preferential attachments, cliques, or brokers. Preferential attachments play an important role in network development (Barabasi & Albert, 1999, p. 509). In other words, people in social networks tend to work with well-known people that lead to the concept of "strong and weak ties", characterizing a group of people attached to one node with high centrality. This is called the "star network model" (Moody, 2004; Scott, 2000).

Newman (2000) stated that collaboration among scientists in networks is a good example of showing preferential attachment. As mentioned earlier, if two nodes have high degrees of centrality, the probability of being acquainted with a mutual friend gets higher. Only a small percentage of people in a social network are well connected while the rest are loosely connected (Lotka's law). The productivity of authors in a network resembles Lotka's law in that a small number of researchers publish the majority of papers while large numbers of researchers publish one or two papers (Martin, Ball, Karrer & Newman, 2013). Each group of authors creates a community in which a node with a high degree of centrality is the central node. Therefore, collaboration networks consist of separate clusters representing different scientific fields where they may connect through lower degree connectors. Each community comprises several star networks and these clusters may be connected by a node of lesser degree. Newman (2000) referred to clustering as "community structure".

Co-authorship analysis is used by bibliometricians to track temporal and topological diffusion of scientific publications. Co-authorship stimulates the knowledge diffusion in scientific communities (Chen et al., 2009, p. 192). Thus, co-authorship analysis is used quite often to study the diffusion of innovation and knowledge. For example, Özel (2010) assessed the diffusion of knowledge in business management among academia in Turkey from 1928 to 2010 by studying the co-authorship relationships of academics in business management.

Co-word analysis of texts helps map scientific fields and reveals the cognitive structure of the scientific domain (Chen, 2004). Callon, Courtial, Turner, and Bauin (1983) used the co-word analysis to study the literature over time in terms of the frequencies or co-occurrences of words in titles, abstracts, or more generally, in text. PageRank measuring the popularity of web pages is a similar metric (Page & Brin, 1989). For example, the appearance of a certain author in the references of a corpus of articles reflects the prestige of that author in the network structure.

As we mentioned earlier, the growth rate of nanotechnology research in Turkey is quite encouraging and researchers contribute to the global nanotechnology literature (Kostoff et al., 2006; Kostoff, Koytcheff & Lau, 2007). Although the state of the art of nanotechnology centers and companies has been studied quantitatively (Aydoğan-Duda & Şener, 2010;

Aydoğan-Duda, 2012), their research output in terms of scientific papers has yet to be studied in detail. This is the first such study to investigate the diffusion of nanotechnology in Turkey and the level of collaboration among the most prolific universities and researchers using co-authorship and co-word analysis.

Method

This paper aims to depict the development of nanotechnology in Turkey between 2000 and 2011 by identifying the network structure of nanotechnology papers authored by Turkish researchers and finding out the most productive universities and researchers who help diffuse the nanotechnology knowledge by collaborating with their peers. Social network analysis, co-authorship and co-word analysis tools were used to map the nanotechnology network structure and the collaboration patterns. We attempt to answer the following research questions:

1) Which universities and researchers contribute most to the diffusion of nanotechnology research in Turkey by collaboration?
2) Do co-authorship networks in nanotechnology literature exhibit a "small world" network structure?
3) What are the main nanotechnology research interests of Turkish scholars?

To answer these questions, we retrieved a total of 10,062 records of nanotechnology papers (articles and reviews) from Web of Science (WoS) published between 2000 and 2011 by Turkish authors. We divided the data set into two equal periods (2000-2005 and 2006-2011) to better identify the trends. Almost three quarters of papers (7,398 papers or 73.5%) were published in the second period. Elsewhere, we presented the descriptive statistics for each period on the number of nanotechnology papers published by universities and analyzed the diffusion and adoption of nanotechnology in Turkey by means of the output of the most prolific authors (Darvish & Tonta, 2015). In this paper, we investigate the diffusion of nanotechnology in Turkey by studying the network properties of nanotechnology literature. We first identified the top 15 most prolific universities and authors by means of social network analysis tools. We then identified the scientists with the highest coefficients of centrality in the network structure. We used co-authorship, co-word[3] and factor analyses to track the collaboration patterns and research interests of Turkish nanotechnology scholars between the two periods. We used Bibexcel, VOSviewer, Pajek and Gephi to create files and map the bibliometric data, calculate the properties of the social network structure (e.g., the betweenness, closeness, and degree centralities and the PageRank of each node) and depict the network's features visually.

Findings

Table 1 shows the network properties of the top 15 selected universities in each period (2000-2005 and 2006-2011) ranked by the degree centrality coefficients of their nanotechnology papers. Middle East Technical (METU), Bilkent and Hacettepe Universities are at the pinnacle of the list and they contributed to the network with the highest number of nanotechnology papers. İstanbul Technical (İTU), Erciyes and Kocaeli Universities are at the bottom of the list with the lowest degree centrality coefficients in the 2000-2005 period. Nodes with higher degree centralities participate more in the network than that with the lower ones and the network structure adheres to the small world phenomenon.

[3]The co-word analysis was conducted based on software: http://www.leydesdorff.net/software/fulltext/index.htm

Table 1. Centrality coefficients of nanotechnology papers of the top 15 universities between 2000-2005 and 2006-2011

2000-2005					2006-2011

Avg		**0.296**	**0.425**	**0.141**	**Avg**		**0.446**	**0.439**	**0.055**

The average degree centrality for the top 15 universities rose from 0.296 in the first period to 0.466 in the second period, indicating an almost 60% increase. Istanbul Technical University's degree centrality increased five times between the two periods, making it one of the top nodes in the second period. Kırıkkale, Abant İzzet Baysal, Marmara and Kocaeli Universities with relatively fewer number of papers did not make it to the top 15 universities in the 2006-2011 period and were replaced by Anadolu, İstanbul, Fırat and Atatürk Universities.

Bilkent University is at the top of the 2006-2011 list with the highest closeness centrality coefficient (0.588) followed by Gebze Institute of Technology (0.541) (which was in the 6th place in the first period). Their high closeness centrality coefficients indicate that sub-networks within the whole network are almost 60% connected. However, their betweenness centrality coefficients are relatively low, which means that the flow of information among sub-clsuters within the whole network is slow. Hacettepe and Middle East Technical Universities are also at the top of the 2006-2011 list. These four universities form a cohesive network structure in 2006-2011. However, the average closeness centrality coefficient stayed almost the same for both periods (0.425 and 0.439, respectively). In other words, it took equally long to spread nanotechnology knowledge for the top 15 universities in each period.

In general, betweenness centrality coefficients are much lower for all universities. In fact, the average betweenness centrality has decreased from 0.141 to 0.055 in the second period, indicating that sub-clusters in the network structure became less connected in the second period for the top 15 universities. Atatürk, Ankara, Gazi, Bilkent, Gebze Institute of Technology and Ondokuz Mayıs Universities have the highest betweenness centrality coefficients in the second period, an indication of relatively higher flow of information among sub-clusters within the network than the rest. Dokuz Eylül, Hacettepe and Ankara Universities

have the lowest betweenness centrality coefficients in the first period and Hacettepe, İstanbul Technical and Ege Universities in the second period.

Next, we studied the co-authorship network structures in both periods using social network analysis (SNA) techniques (Fig. 1). SNA enabled us to discern the nodes that might be crucial to the diffusion of nanotechnology knowledge. The network consists of 470 nodes and 1,042 edges in 2000-2005 and 945 nodes and 4,915 edges in 2006-2011. The rates of growth for nodes and edges (ties) increased two- and four-folds, respectively, between the two periods. However, the level of collaboration has not changed so much. There is a minimal change in density (from 0.009 to 0.011) between the two periods, but the network is still quite sparse. Nonetheless, the average degree and clustering coefficients show that clusters within the network are somehow connected for both periods. For example, the average clustering coefficient for 2000-2005 is 0.75, indicating that 75% of the nodes were connected. Since the network has grown in the second period, the rate of connectedness has decreased (0.51), indicating that newly formed clusters were not that cohesive yet.

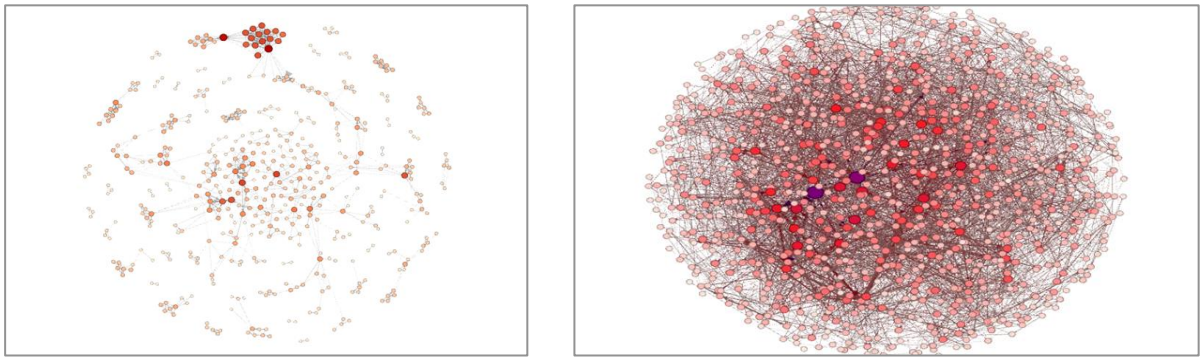

Figure 1. Co-authorship network of scientists working on nanotechnology between: (1) 2005-2011and (r) 2006-2011

The network in the second period adheres to the transitivity relations, indicating that the network at meso level is well connected even though the sub-clusters are not that well connected (especially in the periphery of the network) (Fig. 1). That is to say that there has been some progress in terms of creating new sub-clusters in the co-authorship network, although links among sub-clusters have yet to be formed. In other words, almost all scientists have co-authored with one or more authors in their own cluster but not beyond.

Table 2 shows the top 15 Turkish authors and their affiliations with the highest centrality coefficients (closeness, betweenness, degree, and PageRank) between 2000 and 2005 who contributed to the diffusion of nanotechnology with their scientific papers. Some scientists appear in more than one columns of centrality due to their high collaboration level in the network structure. For example, Yakuphanoğlu F (Fırat University), Yağcı Y and Öveçoğlu MN (İTU), Çelik E (Dokuz Eylül) and Denizli A (Hacettepe) appeared in three columns with high degree (collaborator), betweenness (broker and gatekeeper), and PageRank coefficients (prolific author) while Yılmaz F and Toppare L (METU), Morkoç H (Atatürk), Özdemir I (Dokuz Eylül) and Pişkin E (Hacettepe) appeared at least in two columns out of four (degree, betweenness, closeness and PageRank centralities). They were highly influential in the diffusion of nanotechnology in Turkey between 2000 and 2005.

Table 2. Network properties of the top 15 Turkish authors based on co-authorship degree centralities: 2000-2005.

Rank	Degree centrality	Betweenness centrality	Closeness centrality	PageRank
1	Balkan N (Fatih)	Yilmaz F (METU)	Sarı H (Bilkent)	Ovecoğlu MN (ITU)
2	Teke A (Balıkesir)	Gencer A (Hacettepe)	Sökmen I (Dokuz Eylül)	Çelik E (Dokuz Eylül)
3	Yağci Y (ITU)	Koralay H (Firat)	Kasapoğlu E (Cumhuriyet)	Denizli A (Hacettepe)
4	Yakuphanoğlu F (Firat)	Okur S (Izmir Inst Tech)	Çiraci S (Bilkent)	Hasçiçek YS (Gazi)
5	Ovecoğlu MN (ITU)	Denizli A (Hacettepe)	Aytor O (Bilkent)	Yağci Y (ITU)
6	Çelik E (Dokuz Eylül)	Yavuz H (Hacettepe)	Biyikli N (METU)	Yakuphanoğlu F(Firat)
7	Yilmaz F (METU)	Güneş M (Kirikkale)	Özbay E (Bilkent)	Toppare L (METU)
8	Toppare L (METU)	Yakuphanoğlu F (Firat)	Doğan S (Bilkent)	Yilmaz VT (Ondokuz Mayıs)
9	Doğan S (Bilkent)	Balkan N (Fatih)	Morkoç H (Atatürk)	Pişkin E (Hacettepe)
10	Morkoç H (Atatürk)	Çelik E (Dokuz Eylül)	Sari B (Gazi)	Erkoç Ş (METU)
11	Denizli A (Hacettepe)	Pişkin E (Hacettepe)	Talu M (Gazi)	Kurt A (Koç)
12	Erol A (Istanbul)	Güven K (Erciyes)	Kartaloğlu (Bilkent)	Elmali A (Ankara)
13	Özdemir I (Dokuz Eylül)	Yağci Y (ITU)	Yilgor E (Koç)	Hincal AA (Hacettepe)
14	Turan R (METU)	Ovecoğlu MN (ITU)	Yilgor I (Koç)	Ozdemir I (Dokuz Eylül)
15	Dag O (Bilkent)	Menceloğlu YZ (Sabancı)	Andaç O (Ondokuz Mayıs)	Oral A (Sabancı)

Co-authorship map of the first authors for the first period is shown on the left-hand side of Figure 2. Most of the authors listed in Table 2 are also on the map. Although most authors were from universities with high degree centralities, other authors whose universities did not have high degree centralities were also instrumental in the diffusion of nanotechnology knowledge in the network during the 2000-2005 period (e.g., Yilgor E and Yilgor I from Koç, Koralay H and Yakuphanoğlu E from Fırat, and Kasapoğlu E from Cumhuriyet Universities).

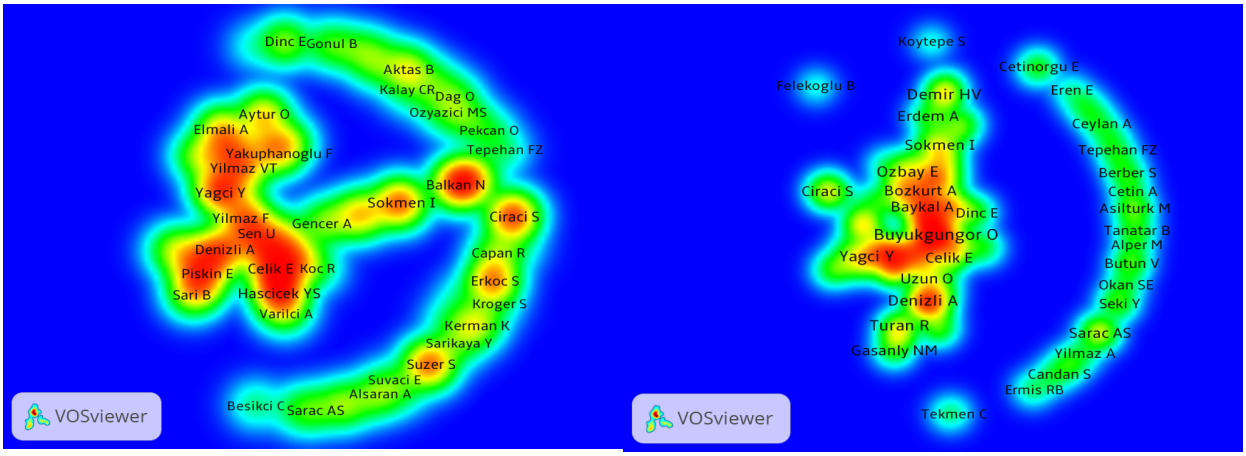

Figure 2. Co-authorship map of Turkish nanotechnology scientists between: (l) 2000-2005 and (r) 2006-2011.

Table 3 shows the top 15 authors who were influential in the diffusion of nanotechnology in Turkey between 2006 and 2011. Interestingly, Büyükgüngör O of Ondokuz Mayıs University has the highest centrality coefficients in all four categories but one (the betweenness centrality) even though he was not in the top 15 authors in the first period. His name appears in the center of the 2006-2011 network of Figure 2 as a prestigious researcher playing an important role in the dissemination of nanotechnology knowledge in the network structure. (His research field is Crystallography.) Similarly, Özçelik S of Gazi University is at the top 15 in all four categories. Six authors appear in at least three columns: Denizli A (Hacettepe), Şahin E (Gazi), Yağcı Y (İTU) and Toppare L (METU) in degree, betweenness and PageRank columns, and Özbay E and Çıracı S (Bilkent) in degree, closeness and PageRank columns. An

additional six authors appear in at least two columns: Yeşilel ÖZ (Osmangazi) and Baykal A (Fatih) in closeness and PageRank columns; Yıldız A (Fatih) and Yılmaz F (METU) in degree and betweenness columns; Çakmak M (Koç) in betweenness and PageRank columns; and Turan R (Ege) in degree and PageRank columns.4 It should be pointed out that even though Fatih and Karadeniz Technical Universities failed to have the highest degree centrality coefficients in neither period, some of their scientists (e.g., Yildiz A and Bacaksız E, respectively) played an important role nonetheless in the diffusion of nanotechnology knowledge in the network.

The centrality coefficients of four authors were high in both periods: Yağcı Y (İTU), Denizli A (Hacettepe), and Toppare L and Yılmaz F (METU). They were highly active in spreading the nanotechnology knowledge in Turkey between 2000 and 2011 as prolific authors, collaborators, brokers and gatekeepers, and diffusers.

Table 3. Network properties of the top 15 authors based on co-authorship degree centralities: 2006-2011.

Rank	Degree centrality	Betweenness centrality	Closeness centrality	Page Rank
1	Büyükgüngör O (Ondokuz Mayis)	Yilmaz F (METU)	Büyükgüngör O (Ondokuz Mayis)	Büyükgüngör O (Ondokuz Mayis)
2	Şahin E (Gazi)	Büyükgüngör O (Ondokuz Mayis)	Yeşilel ÖZ (Osmangazi)	Özbay E (Bilkent)
3	Toppare L (METU)	Özçelik S (Gazi)	Demir HV (Bilkent)	Özçelik S (Gazi)
4	Yilmaz F (METU)	Toppare L (METU)	Nizamoğlu S (Bilkent)	Toppare L (METU)
5	Özçelik S (Gazi)	Yağcı Y (ITU)	Çağlar Y (Anadolu)	Denizli A (Hacettepe)
6	Yağci Y(ITU)	Şahin E (Gazi)	İlican S (Anadolu)	Turan R (Ege)
7	Özbay E (Bilkent)	Yildiz A (Fatih)	Çağlar M (Anadolu)	Şahin E (Gazi)
8	Turan R (Ege)	Çakmak M (Koç)	Özbay (Bilkent)	Çıracı S (Bilkent)
9	Çakmak M (Kirikkale)	Şahin O (Dokuz Eylül)	Özçelik S (Gazi)	Yeşilel ÖZ (Osmangazi)
10	Yerli A (Sakarya)	Yilmaz M (Istanbul)	Baykal A (Fatih)	Yağci Y (ITU)
11	Yildiz A(Fatih)	Turan R (METU)	Köseoğlu Y(Fatih)	Sökmen I (Dokuz Eylül)
12	Çetin K (Ege)	Bacaksiz E (Karadeniz Technical)	Toprak MS (Fatih)	Arslan H (Hacettepe)
13	Çiraci S (Bilkent)	Denizli A (Hacettepe)	Çiraci S (Bilkent)	Oskar S (METU)
14	Denizli A (Hacettepe)	Şen S (Yalova)	Durgun E (Bilkent)	Çakmak M (Koç)
15	Sari H (ITU)	Balkan A (Fatih)	Akgol S (Adnan Menderes)	Baykal A (Fatih)

The collaboration network of Turkish scientists who work on nanotechnology seems to be well connected at the micro level but not so much at the macro level. In other words, researchers tend to collaborate within their own sub-clusters (i.e., groups or universities) more often. The frequencies of the total number of publications that first authors contributed to adhere to Lotka's law:

$$f(y) = .2459 \div y^{1.2881} \quad (1)$$

where *f(y)* denotes the relative number of authors with *y* publications (the K-S DMAX = 0.6323) (Rousseau, 1997), indicating that a small number of well-known scientists have stronger positions in the network. As mentioned earlier, although some scientists from smaller universities with the lower degree centrality coefficients have appeared in the network structure as a turning point, one can call them as non-elite authors. However, their impact on knowledge diffusion is remarkable.

[4] Note that some author names with the same initials are affiliated with two different universities in this period (e.g., Çakmak M at both Koç and Kırıkkale Universities and Turan R at both Ege and Middle East Technical Universities). They may well be the same authors who may have moved from one university to the other during this period.

We also carried out a co-word analysis on the words that appear in the titles of articles extracted from WoS to find out the most frequently used terms between 2000 and 2005, and between 2006 and 2010. The first 75 most frequently occurring words in each period were collected, processed and compiled by the software.5 Non-trivial words were eliminated. In order to analyse the word/document occurrence matrix in terms of its latent structure, SPSS software version 16.0 was used to factor analyse the co-occurrence of words. Factor analysis maps each word to a different component (research strand) with the highest factor loading. SPSS created two factors from the list of the co-words. Table 4 and 5 show the output of factors for the periods of 2000-2005 and 2006-2011 along with the loadings of different words in each factor (not all 75 words listed in the tables). According to eigenvalues, the first factor explains 56% of the variance in the entire data set for the period of 2000-2005 while the second one explains the rest of the variance (44%). For the 2006-2011 period, the first factor explains 35% of the variance in the entire data set while the second and third ones explain 33% and 32% of the variance, respectively.

Table 4. Factor analysis of co-words in the titles of nanotechnology papers (2000 and 2005).

Rotated component matrix[a]

Words	Factor 1	Words	Factor 2
CHEMICAL	.999	PLASMA	.999
QUANTUM	.999	TREATMENT	.999
STEEL	.998	CONDUCTING	.990
HYDROGEN	.997	CERAMIC	.982
COPOLYMER	.992	SOL-GEL	.982
FIELD	.992	LAYER	.945
PROPERTIES	.984	OPTICAL	.945
ELECTRICAL	.973	SURFACE	.945

Extraction Method: Principal Component Analysis. Rotation Method: Varimax with Kaiser Normalization.
a. Rotation converged in 8 iterations.

We then produced a normalized cosine extraction of the words and mapped the network structure of co-word analysis in each period using Kamada & Kawai algorithm embedded in Pajek (Fig. 3). Words that appear in both periods belong mainly to Multidisciplinary Science and Materials Science. Represented fields in both periods are as follows: Surface Materials ("Doped", "Alloy", and "Plasma"); Chemistry and its subfields ("Coating", "Crystal" "Catalyst", and "Sol-Gel"); and Physics ("Quantum", "Dot" and "Nanotube"). It appears that Turkish nanoscientists work primarily in Material Sciences, followed by Physics and, to some extent, Biotechnology.

[5] We used the software available at http://www.leydesdorff.net/software/fulltext/index.htm to create a normalized cosine symmetric co-occurrence matrix of labels.

Table 5. Factor analysis of co-words in titles of nanotechnology papers (2006 and 2011).

Rotated component matrix[a]

Words	Factor 1	Words	Factor 2	Words	Factor 3
COPOLYMER	.766	STEEL	.673	DOT	.687
COMPLEXES	.697	WELL	.655	MORPHOLOGY	.676

METAL	.636	CELL	.618	MODIFIED	.610

Extraction Method: Principal Component Analysis. Rotation Method: Varimax with Kaiser Normalization.
a. Rotation converged in 3 iterations.

Discussion and Conclusion

In this paper, we assessed the network structure of nanotechnology papers authored by Turkish scientists between 2000 and 2011. We used the social network analysis techniques and studied the network properties from different perspectives. We first identified the top 15 universities for each period (2000-2005 and 2006-2011) on the basis of centrality coefficients. They played pivotal roles in the dissemination of nanotechnology knowledge in Turkey. We then created the co-authorship network of nanotechnology scientists and analyzed the network properties (coefficients of degree, betweenness, closeness centralities and PageRank) of the top 15 authors in each period. We also used the co-word analysis to identify the major nanotechnology research fields in Turkey on the basis of the co-occurrence of words in the titles of papers.

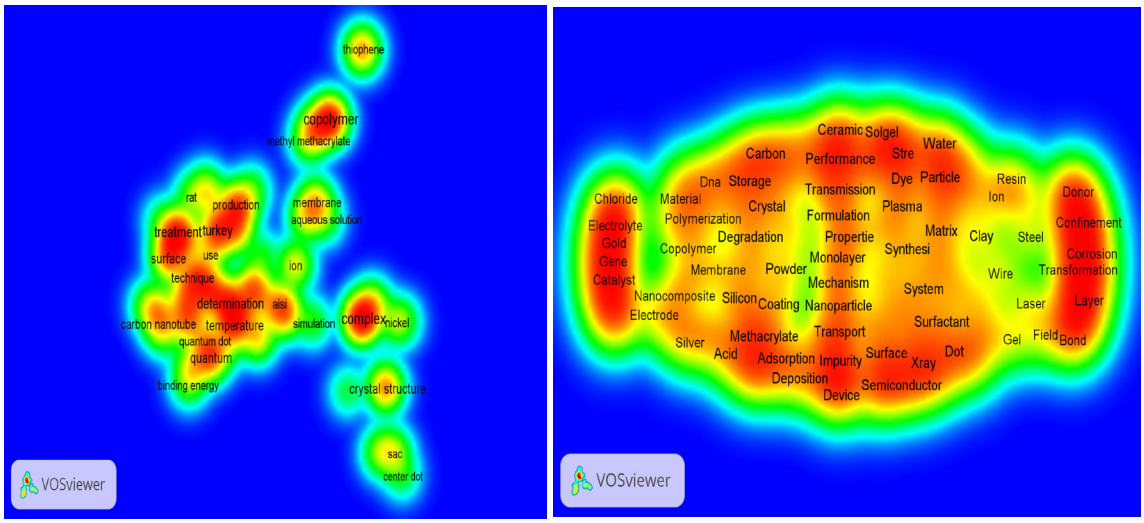

Figure 3. Network of co-word analysis in nanotechnology in Turkey: (l) 2000-2005 and (r) 2006-2011.

Although the number of nodes in the network has increased in the second period (2006-2011), the overall connectedness of the network structures is low. The centrality coefficients of the network structure of the top 15 universities revealed that the social network structure is denser

at the micro level than that at the macro level. While the betweenness centrality remained low and the closeness centrality did not change much, the degree centrality increased almost 60% in the second period, which is an indication of the small world phenomenon in the network structure.

The research output of Turkish nanoscientists and collaboration among them conform to some extent to Lotka's law in that a few researchers tend to publish the bulk of nanotechnology papers while the rest are less prolific. This indicates that Turkish scientists tend to work with prolific authors. The taxonomy identified by the co-word analysis shows that Turkish nanoscientists mainly work in Materials Sciences, Chemistry and Physics. Nanotechnology research continues to flourish due to collaborations at the micro level within the Turkish scientific community and the diffusion of nanotechnology knowledge is accelerating. Bibliometric indicators and network properties reported in this research may help policy-makers to understand the interdisciplinary character of nanoscience and nanotechnology better and develop funding mechanisms accordingly.

Abstract
The purpose of this paper is to analyse the evolutionary pattern of international research collaborations. Using publication data from 1997 to 2012, this study decomposes international collaborations into two complementary types, intra-collaboration (within the same geographical area) and inter-collaboration (across different geographical areas). Our results show that the geographical concentration of international research collaborations is reducing. The formation of new network structure of international research collaborations is driven by the increase of inter-research collaborations of countries across different geographical areas rather than intra-collaborations of countries within the same geographical area.

Conference Topic
International collaboration

Introduction
Scientific collaborations have been widely acknowledged to be efficient in managing time and labour in research labs (Coccia, 2014; Solla Price & Beaver, 1966), improving research quality (Presser, 1980; Narin et al., 1991; Katz & Hicks, 1997) and spurring the breakthroughs of scientific research for supporting competitiveness (Coccia, 2012). A number of factors have contributed to the continuous increase of international research collaborations and co-authored papers (Beaver & Rosen, 1978; Frame & Carpenter, 1979; Katz & Martin, 1997). Along with the steady rise of international scientific collaborations, a better understanding on the structure of the global research network across geo-economic areas and its evolutionary pattern are needed for scholars and policy makers.

The high heterogeneity across countries – in terms of size, scientific capacity of the national system of innovation, etc. – generates a variety of patterns of the international research collaborations (Melin, 1999; Narin et al., 1991; Ozcan & Islam, 2014). A main issue in economics of science is to determine how and to which extent countries are engaged in international research collaborations so as to understand the behaviour of knowledge flows and to design research policies for improving the scientific research production which will in turn to enhance national competitiveness.

Luukkonen et al. (1992) maintain that the map of collaborative connections between countries corresponds to a geographical map. Frame et al. (1977, p. 502), considering data of 1973, claim that: "the production of mainstream science is more heavily concentrated in the hands of a few countries". Hoekman et al. (2010), using data on co-publications in European countries, show that research collaborations are geographically localized and despite a research heterogeneity in European countries in terms of research collaboration patterns, there

[1] Mario Coccia gratefully acknowledges financial support from United Nations University -The Maastricht Economic and Social Research Institute on Innovation and Technology (Contract ID 606U U-04 76) where this joint research was conducted while he was a visiting researcher.

is “a gradual convergence is taking place toward a more integrated interconnected European science system” (Hoekman et al., 2010, p. 672).

The purpose of this research is to investigate the evolutionary pattern of international research collaborations across countries. Emphasis is placed on two complementary collaboration types, i.e. intra- and inter-collaborations. The former refers to research collaborations conducted by countries within the same geographical area; the latter refers to research collaborations engaged by countries from different geographical areas.[2] Increase of intra-collaborations indicates that cooperation is more and more bounded within certain geographical territories, while increase of inter-collaborations signals the fade of geographical limit.

The main research questions of this paper are:

- How does the distribution of international collaborations across countries evolve over time?
- What type of research collaborations (inter- or intra-) plays a more important role in reshaping the global collaborative scientific network across geo-economic areas?
- How do inter- and intra- connections change in the global collective network?

The analysis of the temporal and spatial evolution of these patterns is of great scientific interest for researchers and policy makers in order to better master knowledge flow and optimize collaborative research output across countries.

Data and methodology

The data of this study are collected from publications in academic journals covered by the Science Citation Index (SCI) and Social Sciences Citation Index (SSCI). In particular, this study refers to dataset by National Science Foundation (2014)-National Center for Science and Engineering Statistics, special tabulations from Thomson Reuters (2013), SCI and SSCI. Collaboration data cover two years 1997 and 2012 and 40 countries (see the list in Appendix A). These 40 countries produce about 97% of the global total articles over 1997-2012. The 40 countries are classified into eight geographical areas: North America, South America, Europe Union, Other Europe, Middle East, Africa, Asia and Australia/Oceania (see Appendix A).

The analysis consists of the following steps:

- Firstly, to analyse the worldwide distribution of international collaborations, this study uses Lorenz curves and Gini coefficient. Lorenz curve is indicated by $L(X)$, then Gini coefficient can be derived as follows:

$$Gini\ coefficient\ (G) = 1 - 2\int_0^1 L(X)dX \quad (1)$$

  G is main indicator of concentration of the distribution of data.
- Secondly, to map the research connections between countries, both absolute collaborative output (number of articles) and collaboration intensity are considered. The former data set demonstrates the major players in the global collaboration research network while the latter puts all countries into one comparable framework. Although the matrix of co-authored papers between countries provides us main information concerning the output co-occurrence, the number of collaborated output might have different meanings for the collaborating country pair due to their different research capacity. For instance, suppose that a research collaborative pair is formed by Country A (of which the number of total publications is 1000) and Country B (of which the number of total publications in 10,000). Collaboration intensity (the ratio of collaborative output to national total publications) presents a stronger collaboration

[2] The under studied geographical areas are: North America, South America, Europe Union, Other Europe, Middle East, Africa, Asia and Australia/Oceania.

link for country A than B. Therefore, extra caution should be exercised when analysing the collaborative connections between research partners.

Based on eight geographical groups, this study disentangles intra-collaborations (between countries located in the same geographical area) from inter-collaborations (between countries of different geographical areas).[3]

Salton and Jaccard indexes are both valuable in measuring relative collaboration intensity (cf. Luukkonen et al., 1993). The collaboration index by Salton's measure (CSI) is

$$CSI = \frac{CO_{ij}}{\sqrt{P_i * P_j}} \quad (2)$$

whereas, the Jaccard's measure (CJI) is given by:

$$CJI = \frac{CO_{ij}}{P_i + P_j - CO_{ij}} \quad (3)$$

Where $\boldsymbol{CO_{ij}}$ is the number of co-authored papers between country *i* and country *j*

$\boldsymbol{P_i}$ is the total publication number by country *i*

$\boldsymbol{P_j}$ is the total publication number by country *j*

In addition, to understand the intra- and inter- collaborations by Salton and Jaccard indices (equations (2) and (3)), the adapted intra- and inter- collaboration intensities are

- $\mathrm{CSI}_{\mathrm{intra}} = \frac{\mathrm{CO_{ij}}}{\sqrt{\mathrm{P_i * P_j}}}$ (*i* & *j* ∈ same geographical area) (4)
- $CSI_{inter} = \frac{CO_{ij}}{\sqrt{P_i * P_j}}$ (*i* & *j* ∈ different geographical areas) (5)
- $CJI_{intra} = \frac{CO_{ij}}{P_i + P_j - CO_{ij}}$ (*i* & *j* ∈ same geographical area) (6)
- $CJI_{inter} = \frac{CO_{ij}}{P_i + P_j - CO_{ij}}$ (*i* & *j* ∈ different geographical areas) (7)

Coefficient of variation is also applied to assess the dispersion of data.

- Thirdly, from a dynamic perspective, this study applies network analysis to explore the structure of international collaborations and its changes from 1997 to 2012. In particular, intra- and inter- scientific ties across countries are distinguished from each other in the networks.

Empirical analysis

Global distribution of scientific research and collaborations

It has been well recognized that research capability and resources are unevenly distributed in the world, and hence scientific research output is concentrated in certain countries which are scientifically strong (Frame et al., 1977). By measuring the statistical dispersion of total publications and international collaborations, Table 1 shows that the Gini coefficient of internationally co-authored papers is lower than that of total publications, which means the former is distributed more evenly across countries than the latter. Most importantly, the Gini coefficients for both types of scientific outputs are decreasing over years. This means that the distributions of total publications and internationally co-authored papers both became less geographically concentrated in the later years.

[3] Refer to Appendix A for detailed group information.

Table 1. Gini Coefficient over years

	1997	*2002*	*2007*	*2012*
Total publications	0.67	0.63	0.61	0.59
Internationally co-authored papers	0.60	0.58	0.56	0.54

Dynamics of international collaborations

Salton and Jaccard measures are considered for estimating the collaboration intensity (Figure B1 and B2, in the Appendix B). The arithmetic mean of Salton measure is as twice as that of Jaccard measure, which is in line with Hamers, et al. (1989). However, the coefficient of variation in Jaccard is somewhat higher than that of Salton (see Fig. B1 and B2), indicating a greater dispersion of collaboration intensities is measured by Jaccard index. As the aim of this study is to analyse collaborative research variability between countries, intensities derived from Jaccard index seem to be more suitable.[4]

At the level of geographical groups, Figure 1 shows the relationship of the intra- and inter-collaboration intensities between 1997 and 2012. Red dots represent the inter-collaboration intensity and green ones represent intra-collaboration intensities. A dot being above diagonal line indicates that the collaboration intensity of this observed unit has increased in 2012 in contrast to that of 1997. Likewise, a dot underneath the diagonal indicates that the international collaboration intensity has decreased in 2012 compared to that of 1997. The fact that all the dots lying above the diagonal line suggests that both intra- and inter- collaboration intensities in all geographical areas have improved over years. On the other hand, by comparing the red and green dots, it is of great interest to observe that inter-collaborations in all geographical areas have increased dramatically while intra-collaborations stay mostly low and close to the diagonal line. The intra-collaboration intensity in the European Union (EU) is the only exception with high level of intra-collaborations in both 1997 and 2012, which is a phenomenon of "Europeanisation" as discussed by Mattsson et al. (2008). In general, this figure shows that intra-collaborations tend to be static while inter-collaborations exhibit high dynamics of growth.

[4] In the rest of the paper, we present only results calculated based on Jaccard measure. Similar results using Salton measure are available upon request.

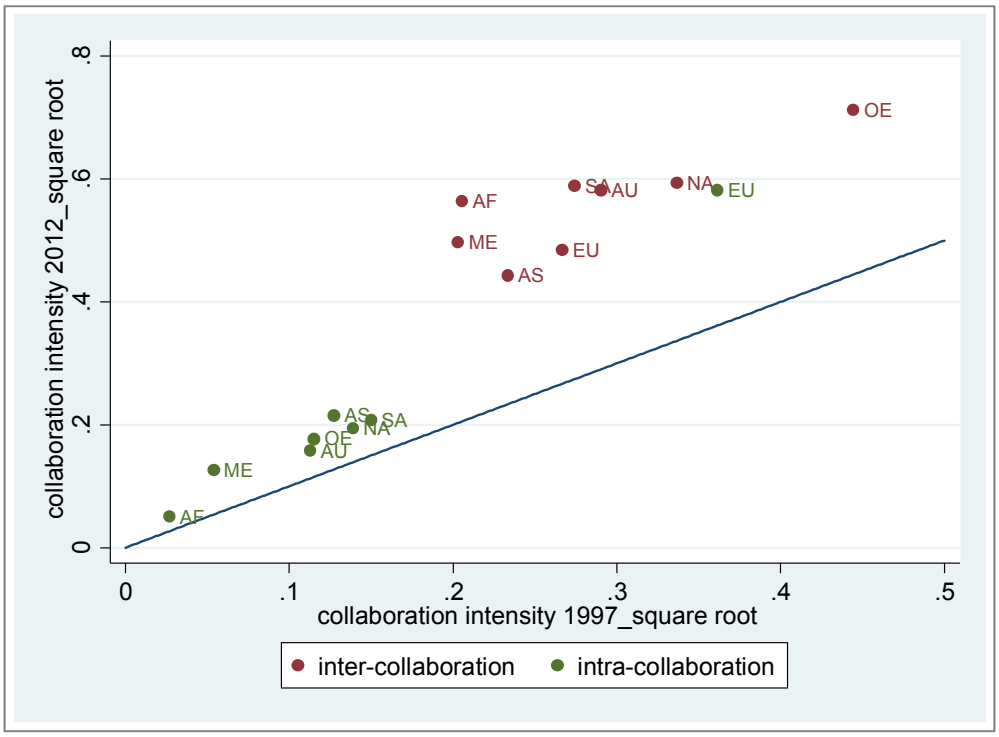

Figure 1. Comparison of international collaboration intensity (inter vs. intra)

Note: 1) The eight geographical areas are: North America (NA), South America (SA), European Union (EU), Other Europe (OE), Middle East (ME), Africa (AF), Asia (AS) and Australia/Oceania (AU). 2) Collaboration intensity is measured by Jaccard index.

To further understand the changes of collaborative performance in individual countries, Figure 2 presents the intra- and inter-collaboration intensity in the 40 under studied countries. Countries in European Union are the only ones showing growth of both intra- and inter-collaborations. This can be the result of European Commission's policy which stimulates cooperation between European countries. In the rest countries, the intra-collaboration performance looks all static, while inter-collaborations have risen obviously. Among all the countries, a group of Asian countries (China, India, Japan, Singapore, and South Korea) show relatively slow growth in inter-collaborations.

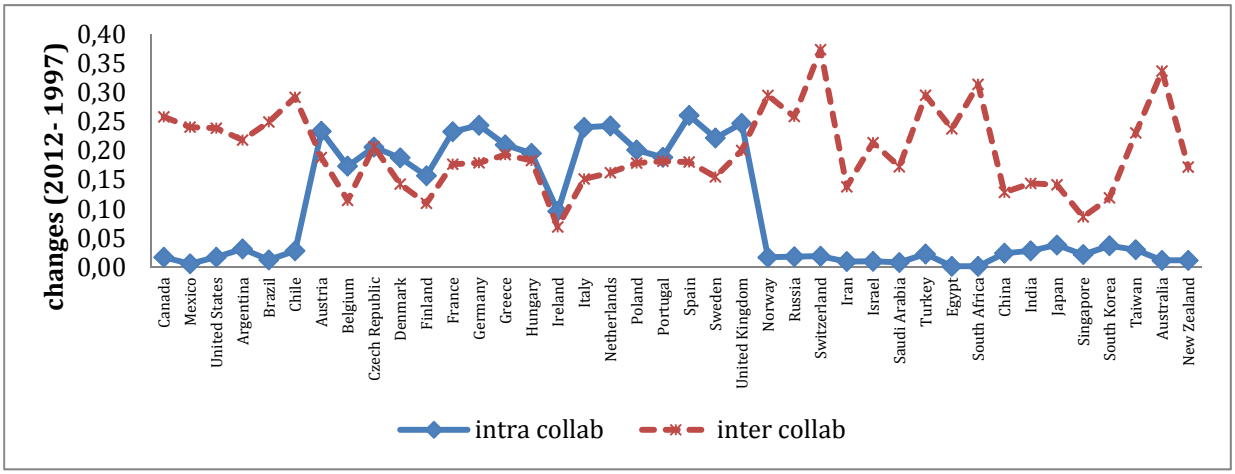

Figure 2. Changes of international collaboration intensity by country (inter vs. intra)

Note: 1) Collaboration intensity is measured by Jaccard index. 2) The value of y-axis is calculated by the collaboration intensity in 2012 minus that in 1997.

Networks of research collaborations

Based on Jaccard collaboration intensity, collaborative networks across 40 countries in 1997 and 2012 are provided in Figure 3 and 4. The thickness of each edge between two nodes reflects the strength of their collaborative relationship. The higher collaboration intensity one country pair has, the thicker their connection line is. In order to distinguish between intra- and inter-collaborations, geographical areas are presented in different colours.[5] Lines connecting nodes in different colours represent inter-collaborations, while those between nodes in same colours represent intra-collaborations. The size of each node embodies its aggregated collaboration intensity (including both intra- and inter- collaborations).

Figure 3 shows that scientific collaboration networks have been, to some degree, formed by geographic ties. Apart from the intensive connections between European countries (intra-collaborations), there are a few geographically biased small clusters are of great interest. The rectangular cluster in Nordic countries (formed by Denmark, Sweden, Norway and Finland) and the triangular cluster in South America (formed by Chile, Brazil and Argentina) both indicate that scientific collaborations are geographically localized. Besides these small clusters, in North America, a strong tie is observed between United States and Canada. In Asia, China is mainly connected with Japan. In Australia/Oceania, New Zealand has a strong connection only with Australia.

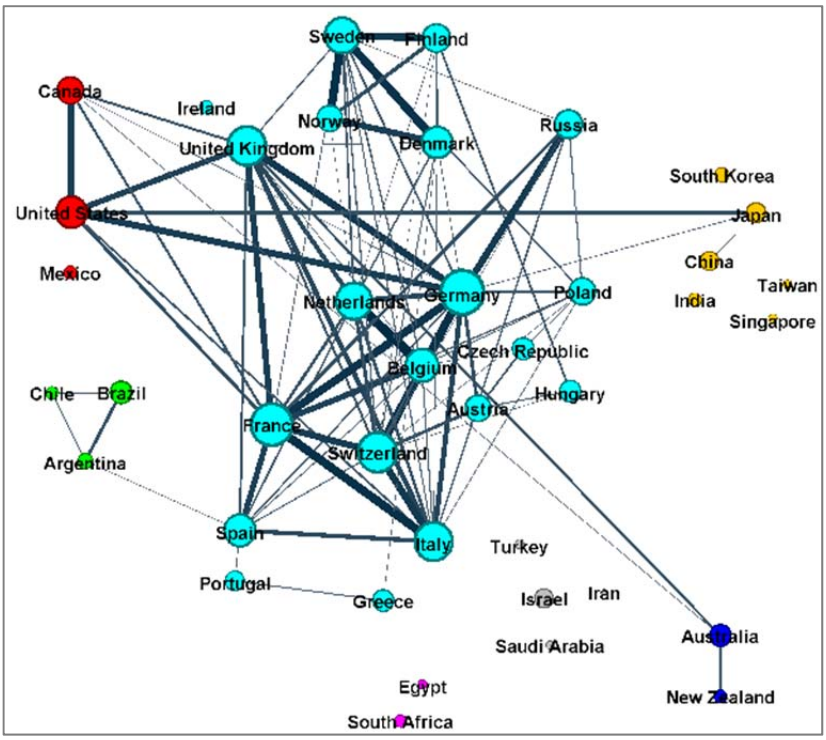

Figure 3. Network of global research connections in 1997.

Note: 1) A filter of 0.0083 is applied in this figure, which means that edges with collaboration intensity less than 0.0083 are omitted. 2) The thickness of each edge between two nodes reflects the strength of their collaborative relationship. 3) The size of each node embodies its aggregated collaboration intensity.

[5] To emphasize the effect of geographical locations, *European Union* and *Other Europe* are regarded as one group in the network figures (Fig. 3 and 4).

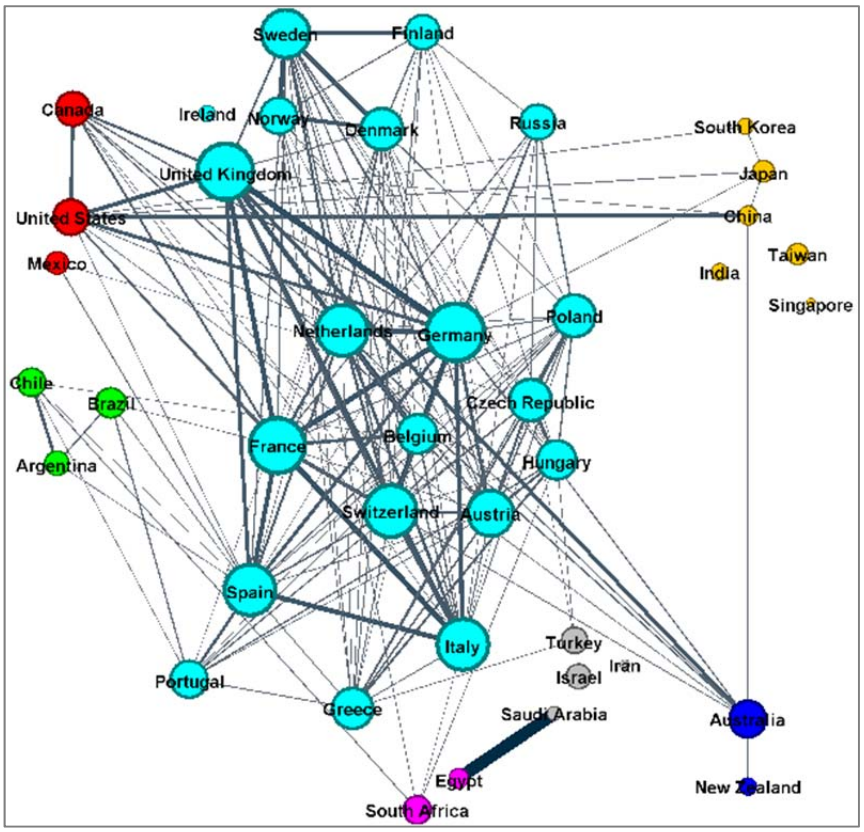

Figure 4. Network of global research connections in 2012.

Note: 1) The network in 2012 is much denser than that of 1997. In order to keep the visualization compact and readable, filter applied in this figure is as twice high as the 1997 figure. Edges with collaboration intensity less than 0.016 are omitted. 2) The thickness of each edge between two nodes reflects the strength of their collaborative relationship. 3) The size of each node embodies its aggregated collaboration intensity.

In order to understand the dynamics of international collaborations, it is necessary to compare the structure of networks in the earlier year 1997 (Fig. 3) with that of the later year 2012 (Fig. 4). In contrast with 1997, the aggregated collaboration intensity (embodied by the circle size of each node) for most countries has increased in 2012. In particular, an important observation is that, the variety of inter-collaborations (lines between different coloured nodes) has grown significantly in 2012, while the connection strength between major intra-collaborative partners (nodes with the same colours) stayed roughly at original level of 1997.

In contrast with the structure in 1997 (Fig. 3), the rectangular Nordic cluster and triangular South American cluster in 2012 have both increased their inter-connections with countries beyond their geographic neighbours (see Fig. 4). The strong tie between Chile and Brazil (i.e. intra-collaboration) has been weakened while both Chile and Brazil developed new inter-collaborative partnerships with countries from other geographical areas. Similarly, the tie between Finland and Denmark became relatively weaker, whereas both of them established more connections with various countries. Due to the effect of "Europeanisation" of this geo-economic area, the new major collaboration partners are still within Europe, but far beyond the old Nordic limit in the later year.

Asian countries, though still with relatively low collaboration intensity, have increased scientific cooperation with the United States (i.e. known as type of inter-collaborations). In particular, China has developed a very strong collaborative tie with the United States and a reasonable partnership with Australia, which are both inter-collaborations. Yet as the second

largest producer of scientific publications, China did not develop any new strong collaborative ties (i.e. intra-collaborations) within its own geographical area.

Located in North America, Mexico seemed to have developed new collaborative research partners only beyond its own geographical area (i.e. inter-collaborations). As one of the most dynamic countries regarding international research collaborations, South Africa seemed to have built inter-collaborative relationships mainly in Europe and South America. Different from the isolated situation in the earlier stage (1997), Egypt and Saudi Arabia developed an extremely strong research partnership in 2012.[6] Their connection with each other was so strong that they hardly had any cooperation with any third countries.

Conclusions

The main lessons learned of this research can synthetized as follows:

1) The Gini coefficients for total publications and collaborations were both smaller in 2012 than 1997, indicating that the distribution among the under studied 40 countries became more and more balanced. Nevertheless, it is worthwhile to note that the distribution of total publications was more divergent than that of internationally co-authored papers.
2) In the process of evolution of international collaborations, evidence shows significant difference between intra- and inter- collaborations. In all geographical areas, except European Union, the intra collaboration performances exhibited a steady-state pattern, whereas inter-collaborations in the global network research structure have risen dramatically.
3) From a dynamic point of view, the comparison of 1997 and 2012 networks shows that inter-collaborations (between countries from different geographical areas) have grown significantly in the later stage, while the connection strength between major intra-collaborative partners stayed mostly unchanged. This finding indicates that recent research network across countries has a higher global inter-connection beyond geographical territorials, which is likely driven by advances of ICT and transportation new technologies and improvement of socio-economic systems.

In short, the increase of research collaborations between countries from different geographical areas has reshaped the global structure of international scientific collaborations. In the modern process of knowledge production, countries seem to be looking for more diverse collaborative partners worldwide.

Nanotechnology Research in Post-Soviet Russia: Science System Path-Dependencies and their Influences

Maria Karaulova[1], Oliver Shackleton[1], Abdullah Gök[1] and Philip Shapira[1,2]
[1] Manchester Institute of Innovation Research, Manchester Business School, University of Manchester (United Kingdom)
[2] School of Public Policy, Georgia Institute of Technology (USA)

Abstract
This paper contributes to the analysis of Russian research dynamics and output in nanotechnology. The paper presents an analysis of Russian nanotechnology research outputs during the period of 1990-2012. By examining general outputs, publication paths and collaboration patterns, the paper identifies a series of quantified factors that help to explain Russia's limited success in leveraging its ambitious national nanotechnology initiative. Attention is given to path-dependent institutionalised practices, such as established publication pathways that are dominated by the Academy of Sciences, the high centralisation of the entire research system, and issues of internal collaborations of actors within the domestic research system.

Conference Topic
Country-level Studies

Introduction
Nanotechnology has been an interest of bibliometric research since the early 2000s after the United States and China adopted large-scale policy and funding programmes to stimulate scientific development by massively investing in this interdisciplinary research area. China has been among the countries with a large increase in research outputs in nanotechnology, and is the emerging economy that is frequently the focus of researchers (Appelbaum et al., 2011; Bhattacharya & Bhati, 2011; Liu et al., 2009).

Other emerging and transitional economies have also invested in nanotechnology development. Russia is a particular case among these countries, because the National Nanotechnology Initiative that was adopted in 2007 was a political as well an economic, scientific and technological project. The Russian government picked up on global trends and invested greatly in development of nanotechnology. On a purchasing power basis, it is suggested that public investment in Russian nanotechnology has rivalled that of the US and China (Schiermeier, 2007). Lux Research (2013) estimates that Russian nanotechnology investment has consistently been the third largest in the world after the US and China: Russia invested over $1 bln in 2010 and 2011 in nanotechnology projects, and just under $1 bln in 2012. However, with lower than anticipated results in nanotechnology, the Russian government has decreased its investment programme and the share of Russia in world nanotechnology funding dropped from 15% to 13% in 2013. It is anticipated to continue decreasing.

Important changes and structural reforms of Russian science (including nanoscience) have been implemented only relatively recently, in the mid- to late-2000s, almost two decades after the dissolution of the Soviet Union in 1991. Until then, Russian science was relatively unchanged from rules and institutional developed during the Soviet era. The Academy of Sciences of Russia maintained its Soviet-style organisation up until 2013 when it was subjected to a radical reform. Universities were reformed in 2008 and 2009 to move them away from mainly teaching and to develop research capabilities and to try to emulate US research clusters. The funding structure for Russian science was tied to four-year umbrella research programmes accompanied by small-scale research foundations until 2013, when decisions were made to reform Russia's Federal Targeted Programmes and Grant

Programmes towards more grant-based system. Importantly, the Russian National Nanotechnology Initiative and the associated surges in interest and investment pioneered the system-wide initiatives that started several years before other large-scale top-down changes.

Existing literature on nanotechnology research and innovation in Russia is less prodigious than for other "Rising Powers" countries, particularly China but also including Brazil and India. Scientometric analyses often examine Russian nanotechnology development as a benchmark for other emerging economies, mainly China and India (Liu et al., 2011, 2009) rather than deeply probing within the Russian system. At the same time, there is an important strand of scientometric work on Russian science and technology (including nanotechnology) produced by the Russian research community itself. In these cases, research is often descriptive or addresses internal debates within Russia (Terekhov, 2012, 2011), and sometimes lacks a critical approach. Additionally, most of these studies remain mostly background reference country reports (and are frequently only available in Russian).

There are, of course, some exceptions. For example, Klochikhin (2012) contextualised Russian nanotechnology policy in terms of post-Soviet path-dependencies and asked whether it was possible to break out from technological inertia to a new development trajectory. There are other studies of Russian nanotechnology that pose similar questions, be it from the industry and market formation perspective (Ananyan, 2005), or regulation (Gokhberg et al., 2012). A recent overview of the Russian Science, Technology and Innovation system (Karaulova et al., 2014) provides background for discussion of persisting path-dependencies. In the present paper, we build on, and extend, this prior work to examine Russia's technology development policies and to reflect on the challenges posed by its persistent and deeply-embedded path-dependent practices.

Data and Methodology

The dataset for our research covers the time period from 1990 to 2012, which includes the transitional period after the breakup of the Soviet Union, the Russian Nanotechnology Initiative (NNI) development (2004 – 2007) and the post-NNI period of nanotechnology research. We first provide an updated profile of nanotechnology research in Russia since the breakup of the Soviet Union until 2012. Second, we investigate the possible emergence of new trends of research of Russian nanotechnology after the adoption of large-scale policy programs. Third, we use self-reported publication data in order to illustrate the path-dependent nature of Russian nanotechnology research.

The bibliometric analysis draws on datasets of nanotechnology publications and patents developed by researchers at Georgia Institute of Technology and the Manchester Institute of Innovation Research. Two data sources are used: the Web of Science (scientific publications) (WoS) and Derwent Innovations (patents). Both data sources are published and made available in the Web of Knowledge by Thomson Reuters. Nanotechnology records in the databases are identified using the two-stage search strategy detailed in Porter et al. (2008), and updated in Arora et al. (2012). A keyword search based on a Boolean query is applied. Unrelated records are then removed by applying exclusion terms.

The defining characteristic that we used to identify Russian publications was that at least one author of each included publication had to have a Russian affiliation address (Soviet Union in 1990-1992; Russia subsequently). The primary language of publications in the dataset is English, but specialised editions that include translated articles originally published in Russian are included as well. In total 33,538 Russian nanotechnology publication records were identified in 1990-2012. We acknowledge that there are limitations in using WoS for capturing the totality of Russian science activity (but see also subsequent discussion in this paper of Russian journal publishing strategies).

A feature of the Soviet Union, carried over into the Russian Federation, is that science was and is developed in parallel – but not always in cooperation – with researchers elsewhere in the world. This influences the choice of terminology used by Russian researchers. For example, it has been observed that there is a rich tradition of nanotechnology research in Russia. Alexander Terekhov traces the technological development of Russian nanotechnology back to 1980s when the understanding of the physical properties of ultra-dispersed states enabled Soviet researchers to construct the first lasers and to conduct experiments at the nano-scale (Terekhov, 2013). But the term nanotechnology was not necessarily used at that time. A simple search strategy would not pick up on many Russian nanotechnology publications, especially in earlier years, which are crucial to understand trends of overall growth and development. We judge that the more complex and nuanced approach we apply is better able to capture the emergence and development of the Russia nanotechnology field.

After the publication data was collected and cleaned from unrelated records, further data cleaning to remove duplicates and consolidate organizational and author names was undertaken using VantagePoint text mining software. Cleaning is a large part of our methodology. One of the biggest problems of country report studies that use bibliometric analysis is the issue of varied affiliation reporting. We have addressed various problems through intense cleaning of the data. One problem of aggregation relates to affiliation (location, funding source, author) categories that the database recognizes as separate, but are actually the same. This is an issue that occurs in the self-reported semi-structured publication data. There are variations in reporting of affiliation data, different ways to spell the name of the organization, abbreviations and others. If left unchallenged, the data may be potentially distorted: the contributions of certain actors may appear as less than it reality, which can be misleading. Another major cleaning issue is disambiguating terms that were lumped together. For example, the process of disambiguation of the "Tech Univ" field and further aggregation of the items highlighted that the original very general field contained mainly records published in three large technical universities, and in a number of smaller ones. Table 1 illustrates examples of the data cleaning strategy.

Table 1. Affiliation Cleaning Strategy Examples.

	Original Record	*Cleaned Record*
Reporting Style	1. RAS, AM Prokhorov Gen Phys Inst; 2. Russian Acad Sci IOF RAN, Prokhorov Gen Phys Inst;	RAS Inst Gen Phys Prokhorov

Disambiguation	Tech Univ	1. St Petersburg Tech Univ 2. Tech Univ Moscow Inst Elect Technol 3. Tech Univ Berlin

Excessive aggregation of the data may lead to the loss of informative value. The Russian Academy of Sciences (RAS) presents the greatest challenge here. RAS is a large research

organisation that possesses more than 500 research institutes. However, the reported RAS affiliations are disordered, because research institutes often have long names and some of them do not issue guidelines for official English versions. Aggregating all these institutes under the domain of the "Russian Academy of Sciences" would yield analytical benefits in some circumstances, such as broad benchmarking. However, such a large agglomeration is not useful for detailed analysis. In our analyses of nanotechnology publications associated with RAS, we undertook disambiguation and identified 263 distinct affiliations, including research institutes of RAS, scientific centres and observatories.

We further grouped the data according to country, region, and type of affiliation. *Academy of Science* organisations are specific research entities that have wide government affiliations and heavily rely on government funding, that have a wide regional structure and hierarchical administrative division. We separately distinguished *Universities*. *Public Research Organisations* are private and state-owned research institutes that are neither academy of science institutions, nor universities. These also include research foundations and ministries. *Corporate actors* are privately and state-owned company affiliations. Organisations were usually labelled as 'corporate' actors if they had a distinctive property type word in their names (LLC, Ltd, GmbH, ZAO etc). *Other* included all other organisations that could not be attributed to any other category

In order to examine the internationalisation of Russian science we also separated publications into nationally collaborated publications (NCP) and internationally collaborated publications (ICP). The two groups are mutually exclusive and highlight the degree to which research produced in Russia only involves domestic actors (NCP), or there are also international partners (ICP).

Table 2. Grouping Results, number of publications.

Results

The annual output of Russian nanotechnology publications steadily increased between 1990 and 2012. In 1998, there was a considerable jump in the number of publications; this probably reflects the fresh inclusion of a series of Russian journals within the WoS. Growth rates for domestic and international publications are almost identical starting from 1999 until 2012 and are about 1.1% per year. On average, domestic publications grow 2% faster than internationally collaborated publications.

The Academy of Sciences, 15 universities and four State Research Institutes are the leading organisations in terms of publication output. Some 68% of domestic publications are produced by the Russian Academy of Sciences and another 12% by Moscow State University. The top five organisations produced together 80% of all publications in 1990-2012 (Table 3). The top three organisations (RAS, MSU and St Petersburg State University) produced 78% of all publications. RAS is the dominant actor in producing nanoscience publications. However, in terms of annual publication outputs, university researchers have been catching up with RAS in the past decade.

Table 3. Biggest Publishers in Russian Nanoscience, 1990-2012.

	Organisation name	*Publications*	*Share*
1	Russian Academy of Sciences	22794	68.12%
2	Moscow MV Lomonosov State University	4007	11.98%
3	St Petersburg State University	1208	3.61%
4	Russian Research Centre Kurchatov Instute	613	1.83%
5	Nizhnii Novgorod State University	496	1.48%

Disambiguated, the bibliometric map of Russian science demonstrates a more nuanced picture of interactions in the nanotechnology research (Figure 1). One major research organisation, RAS Institute of Physics and Technology n.a. Ioffe, is a focal point for connecting various regional groupings of research centres, such as a cluster of four RAS institutes on Siberia that closely collaborate with one another, but do not have strong external links.

In terms of research performance, nanotechnology publications that only have Russian authors are cited on average 2.5 times per publication. Out of all domestic actors Russian Academy of Sciences publications collect the highest number of citations: 4.55 p/p. PRO publications, albeit being much smaller in number, collect 3.86 citations p/p. Universities collect on average 3.24 citations p/p, and publications produced by corporate actors collect 2.44 citations p/p.

Table 4. Shares of ICP and Average Citation Rate of Russia's Main Collaboration Partner Countries, 1990-2012.

Country	*Germany*	*USA*	*France*	*UK*	*Japan*	*Sweden*	*Italy*
ICP %	12.3%	8.2%	5.04%	3.4%	2.9%	2.08%	1.9%
Avg Cit	7.7	9.2	5.8	12.2	6.9	6.04	5.3
	Ukraine	*Poland*	*Spain*	*Netherlands*	*Belarus*	*Finland*	*South Korea*
ICP %	1.8%	1.5%	1.5%	1.4%	1.3%	1.1%	0.9%
Avg Cit	2.4	3.9	5.1	18.9	3.8	4.05	3.9

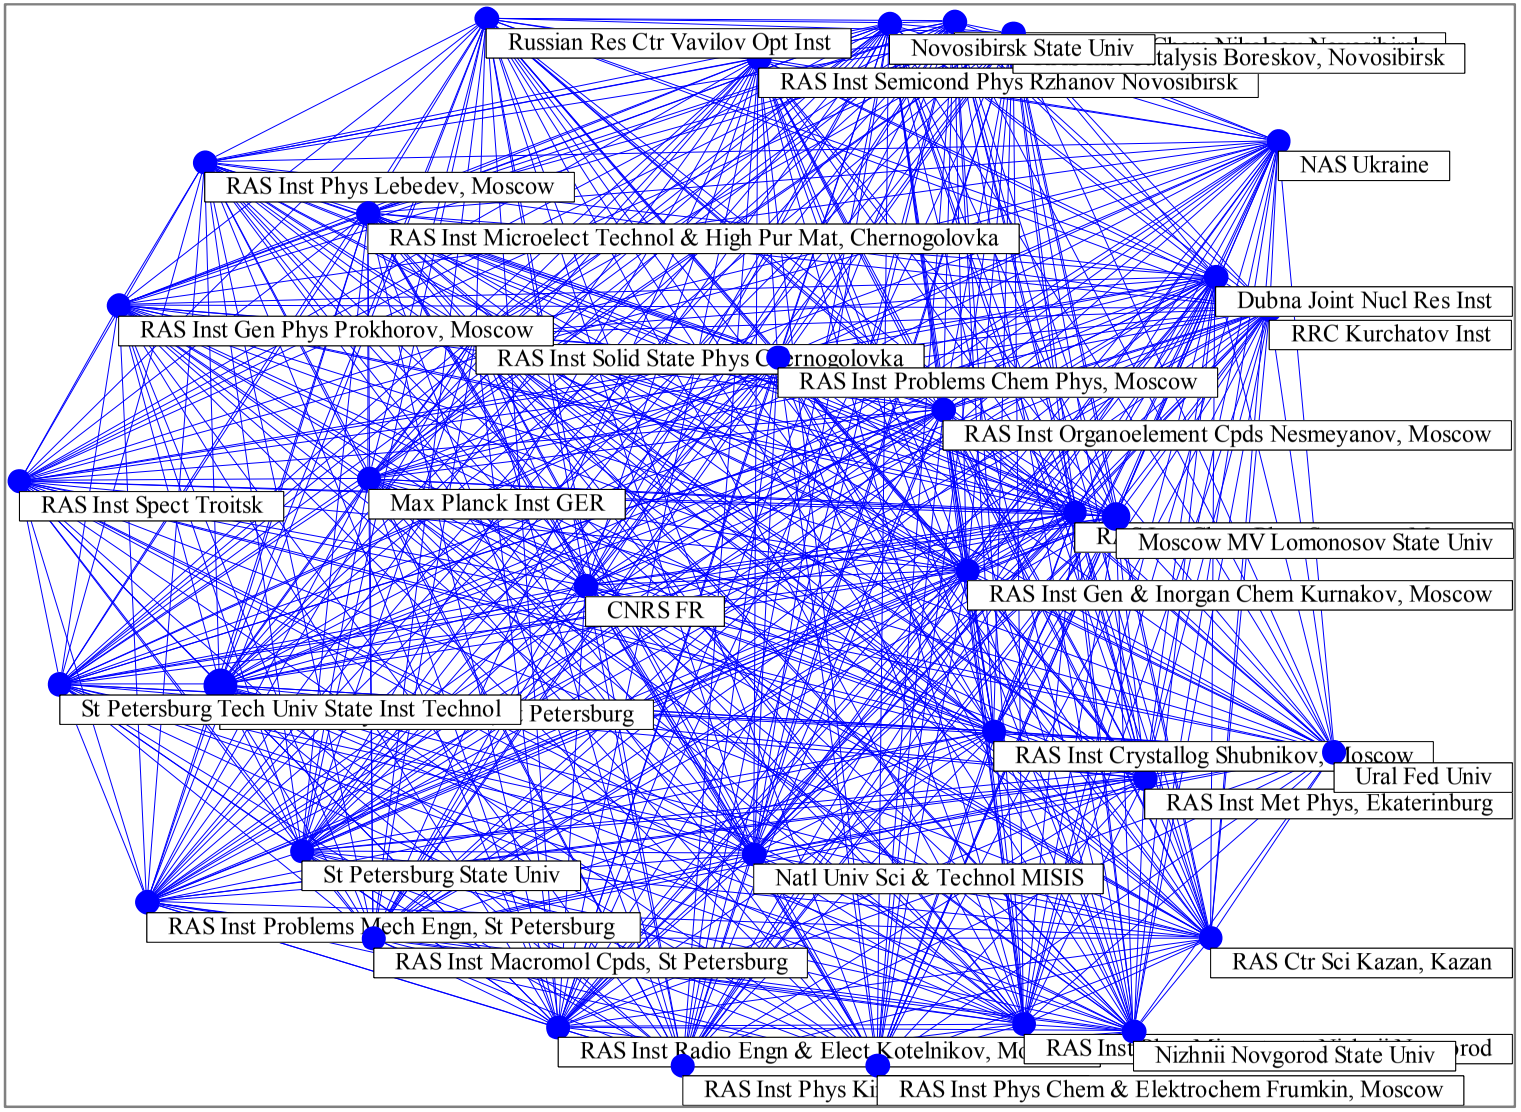

Figure 1. Bibliometric Map of Top 35 Publishers of Russian Nanoscience, 1990-2012.

Patterns of international collaboration seem to be connected to these structural differences. The average number of internationally cited publications is 4.33 times: international collaboration increases average citation by 1.7. There are, however, some regional variations in international collaboration performance outputs (Table 4). Russian international collaborations have strong European orientation, and there is evidence of recurrent path-dependent practices. It is noticeable that former Soviet states and influenced territories, such as Ukraine, Poland and Belarus factor highly in collaborative research. It implies research links are built on the older networks than the current political system and research takes place through these interactions. An impeding factor may be than average citation rates for these countries are significantly lower than for other countries with the same collaboration intensity (refer to Table 4). These 8.3% of CIS-collaborated ICPs represent collaboration patterns that may be detrimental to Russian science.

In the next section we pay particular attention to three elements of nanotechnology research that can highlight path-dependent dynamics of scientific knowledge production in Russia. We define them as journal gatekeepers, centralisation, and institutional diffusion. These all relate to structural features of the Russian science system that have persisted even after the Soviet Union broke apart.

Journal Gatekeepers

The data for journals in which Russian co-authored publications can be found, is available for 32844 publications, which constitutes 97% of the data. The majority of Russian publications in English were published in translated journals. Out of the top-10 journals with the biggest number of Russian publications, 7 are translated versions of Russian journals (refer to Table 5).

Translated versions of Russian journals are identified not by the publishing body (the rights to publish in most cases are owned by Springer), but by the contents of the journal and the editorial board. For example, Springer publishes *The Physics of the Solid State*. The description on the website says "The journal Physics of the Solid State presents the latest results from Russia's leading researchers in condensed matter physics at the Russian Academy of Sciences and other prestigious institutions" (Springer, n.d.). An analogous journal, called *Phyzika Tvyordogo Tela* (*The Physics of the Solid State*) is published in Russian by the Ioffe Institute in St.Petersburg (Ioffe Physical Technical Institute, n.d.). The Chief Editor of both journals is A.A. Kaplyanskii, and the editorial board matches both journal records. Tables of contents of issues match as well. Based on these we drew a conclusion that *The Physics of the Solid State* is a translated version of *Phyzika Tvyordogo Tela*, and the 'publishing body' is therefore an Institute within the Russian Academy of Sciences (the publishing body of the original), not Springer (the publishing body of the translated version). By doing manual analysis of the top journals in which Russian scientists publish we have identified that at least 25% of the entire publication volume was published in this manner (input of the Russian translated journals in the top-20 journal contributions). The overall contribution of the top-20 journals was 25%.

A paper is first published in a Russian peer-reviewed journal, and subsequently translated and published in the English version without an additional peer review. But it would also depend on the domestic peer reviewer whether a submitted article would be considered for publication and further translation for a WoS-indexed version of a journal. The publisher and the editorial board become important. As Table 5 demonstrates, vast majority of the translated Russian journals are published by the Russian Academy of Sciences and editorial boards mainly consist of members of RAS. This *status quo* is grounded in history: many of them were founded during the Soviet Union to inform the world about achievements of Soviet science.

Table 5. Top 20 Journals of Russian Nanotechnology.

	Journal	*Publishing Body*	*Records*	*Share*
1	Physical Review B	APS	1595	4.86%
2	Physics of the Solid State	RAS	1412	4.30%
3	Semiconductors	RAS	1255	3.82%
4	Technical Physics Letters	RAS	848	2.58%
5	JETP Letters	RAS	828	2.52%
6	Inorganic Materials	RAS	511	1.56%
7	Applied Physics Letters	American Institute of Physics	510	1.55%
8	Journal of Applied Physics	AIP Publishing	505	1.54%
9	Journal of Experimental & Theoretical Physics	RAS	490	1.49%
10	Russian Chemical Bulletin	RAS	411	1.25%

After the breakup of the Soviet Union, these established publication pathways and journals have been maintained and there has not been much impetus for change. Although an opportunity opened for Russian researchers to submit research publications to leading international journals, existing publication practices have persisted. Moreover, temporal dynamics highlight an increasing gap between publications submitted to translated Russian journals and international journals: the difference rose from twice as many translated journal publications as international journal publications in 2000 to 2.67 times in 2005 and to 3.8 times in 2011. In the earlier period this could have been explained by the lack of experience of researchers to publish abroad, or by poor knowledge of English. In the later period the English language problem continues, but it also has become prominent that internal domestic recognition for a Russian researcher can be even more important than international recognition in order to develop and continue a research career in Russia. Therefore, publishing in top domestic journals becomes a priority, and the English translation of these papers in journals that collect few citations is a by-product rather than the goal, because this research is anchored in Russian scientific discourse and debates.

RAS maintains the monopoly over acceptance of research outputs to the leading domestic journals, thus acting as a quality control body. It is also a gatekeeper in the Russian research system as to which domestic researchers are highlighted for international recognition. The domination of the Academy of Sciences constrains other research performers, such as universities and PROs, to develop and take advantage of publicly-provided research resources, for example through the Russian NNI. As a comparison, in their study of Chinese publication patterns Zhou and Leydesdorff (2006) recognised this 'gatekeeping' role as one of the main barriers to internationalisation of Chinese science in the early 2000s. However, this pattern has now changed with the emphasis in China in publishing directly in WoS journals.

Centralisation and the Academy

In our analysis, we observe two centralisation trends in publications within the Russian Academy of Sciences. These first of these is *geographical centralisation*. RAS has institutes in all 83 regions of Russia, but four regions (Moscow, St Petersburg, Novosibirsk, and the Moscow Region) produced the largest shares of publications in 1990-2012, contributing over 80% of the total amount. Moscow is the leader with almost 35% of all publications, together with the Moscow Region the agglomeration produced 45.2% of all Academy of Sciences publications. Previously, the high concentration of research in a limited geographical area and

with a large network of ineffective and low-performing institutes has been suggested to be one of the main reasons for the persistent problems of RAS (Graham, 1998).

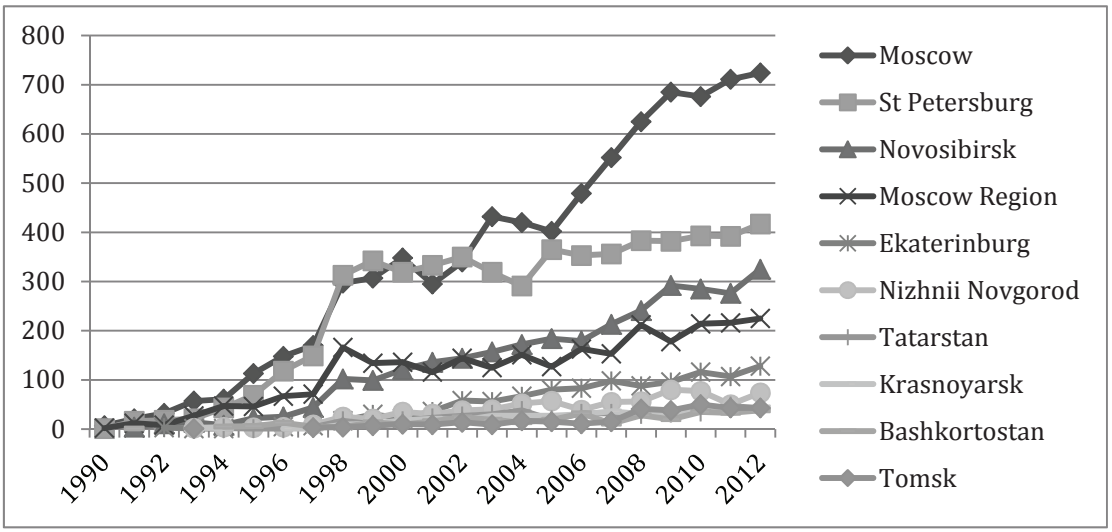

Figure 2. Temporal Dynamics of Geography of Nanoscience in Russia, 1990-2012.

Yet, while problems of RAS centralisation have long been observed, it seems that these trends have intensified in recent years: Academy research is becoming even more centralised (Figure 2). In nanotechnology, RAS institutes in Moscow surged upwards in the mid-2000s, producing almost twice as many publications in 2012 as the research cluster in St Petersburg. Many of these institutes have benefited from recent government science and innovation funding programmes, including specific nanoscience and nanotechnology funding programmes.

The *centralisation of high quality research* is a second persistent trend in Russian nanoscience. RAS has consistently contributed about 70% of the Russian annual publication output. In order to investigate whether quantity translates into quality, we assessed the performance of Russian domestic research system according to the criteria of (1) what affiliations of 10 top-cited ("star") scientists are, and (2) what affiliations of 100 top-cited publications are.

The top 10 most productive researchers coincide with the most cited researchers, with slight reversal in rank.[1] The majority of these "star" scientists are affiliated with RAS Ioffe Physical Technical Institute in St. Petersburg (Table 6). The Institute itself contributed about 14% of all publications and has an average citation of 6.13. The peak publication activity of all of the most productive scientists was between 1998-2000 after which the decline started. The most productive periods of the most productive Russian nanoscientists coincide with the most productive periods of Russian nanoscience: the contribution of "star" scientists was above 9% in 1996-2001, reaching a peak of 11.5% in 1998. A second, smaller, peak is reached in 2006, after which further decline occurs.

[1] The most highly cited Russian scientists are the ones who collaborated with colleagues at the University of Manchester in a paper in *Science* (Novoselov et al., 2005) that contributed to the award of the 2010 Nobel Prize in Physics to two Manchester researchers. This publication has 3541 citations. To include this exceptionally highly cited publication into the data would overshadow the underlying pattern of Russian nanotechnology performance, so this publication is not included in this part of the citation analysis.

Table 6. "Star" Scientists of Russian Nanoscience.

Rank	*Author Name*	*Affiliations*	*Times Cited*
1	Ledentsov, N	RAS Ioffe Physical Technical Institute	6033

9	Maximov, M	RAS Ioffe Physical Technical Institute	1909
10	Ruvimov, S	RAS Ioffe Physical Technical Institute	1812

The Post-Soviet period saw the rise and the peak of careers of scientists trained in the latter years of the Soviet Union. A drop in productivity coincides with the completion of the active research phase of their careers. There are few new 'rising stars' in the system, which explains the overall decline in performance. This data reinforces concerns about the 'generation gap' in nanotechnology where the average age of researchers is now in the mid-50s (Terekhov, 2011). RAS co-authored 81 out of the 100 most highly cited publications in Russian nanoscience.

Overall, it is notable that RAS dominates in quality as well as the quantity of research in Russian nanoscience. The productivity of RAS reached its peak in the late 1990s and has since then been in decline. The Russian government's support of the development of research universities and RAS reform in 2013 are expected to further contribute to decentralisation of the national research system and to the emergence of new centres of excellence. The trend towards concentration of research in the two capitals – Moscow and St Petersburg – is also a concern as government support to develop scientific research in other regions is limited.

Institutional Diffusion

The third and the final collaboration trend reflects the institutional diffusion of the Russian research system. Institutional theory proponents argue that institutions last and prosper when other elements of the system are dependent on them, e.g. when institutions are diffused well with other institutions (Clemens & Cook, 1999). In a research system this mainly takes form of inter-institutional collaborations. In order to examine the institutional relationships of the Russian research system we investigated (1) whether each organisation preferred to publish on its own; (2) if research was done through the collaboration of authors in one organisation; (3) whether the organisation engaged in collaborative activities with other organisations of the same type; (4) if organisations collaborated nationally; and (5) whether organisations collaborated internationally.

The results of this analysis demonstrate various patterns of domestic collaboration (Figure 3). For instance, corporate publishers have to rely heavily on collaborations, so they have higher rate of collaborations with all types of actors than the average. An asymmetric relationship among the system actors reflects institutional domination of the Academy of Sciences of Russia. The analysis of institutional collaboration patterns demonstrates that there are very weak collaboration links between the Academy of Sciences and other system actors.

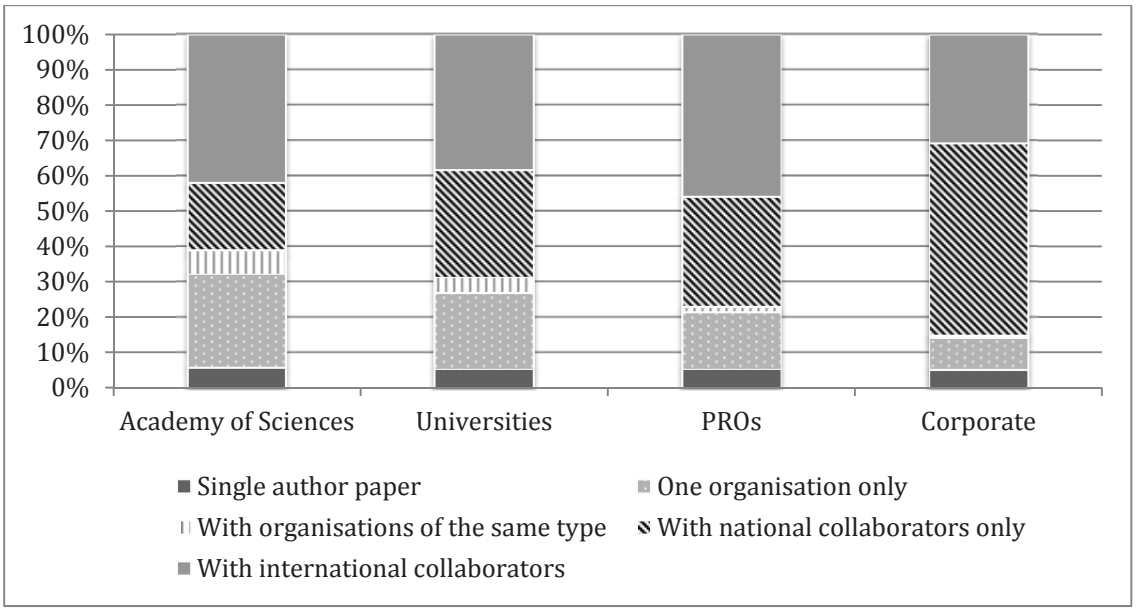

Figure 3. Institutional Diffusion of Russian Research System.

About two-fifths of academic publications are written either by a single author, or by a group of authors within RAS, and only 19% are collaborated with other Russian organisations. An international orientation is evident for PROs: over 46% of publications are internationally collaborated, but only 1.5% of publications are collaborated with other PROs. University organisations stand in the middle and have larger share of nationally collaborated publications than the Academy or PROs.

Weaknesses in international orientation and a reluctance to engage in national collaborative research projects is a particular concern for the Russian Academy of Sciences given that it dominates much of the Russian research system. In some RAS institutes, domestic collaboration rates with others outside of the home institute are noticeably low, for example just 11.6% in the Institute of Theoretical Physics RAS n.a. the Landau Institute of Theoretical Physics.

Conclusion

This exploratory study highlights three major path-dependent structural features of the Russian research system that are evident in Russia's nanotechnology research and publication activities. These structural features tend to be under-emphasized in other quantitative and qualitative studies, including those undertaken from within Russia itself. The available studies tend to focus on underfunding, deteriorating equipment, brain drain and other factors that, without a doubt, are very important in understanding the position of Russian science. In this research note, using bibliometric analysis in the case of nanotechnology, we draw attention to other less explicit but nonetheless important underpinning factors that frustrate the successful implementation of science and innovation policies and which may weaken returns on research investment. Reflecting upon and revising institutional practices of research that have remain largely unchanged since the breakup of the Soviet Union is an important challenge for Russian science policy. Some reform efforts have begun, but much more is likely to be needed to support the next generation of researchers.

Support Programs to Increase the Number of Scientific Publications Using Bibliometric Measures: The Turkish Case

Yaşar Tonta[1]

Hacettepe University Department of Information Management, 06800 Beytepe, Ankara (Turkey)

"*Not everything that counts can be counted, and not everything that can be counted counts*." – William Bruce Cameron

Abstract
Bibliometric measures for scientific journals such as journal impact factor, cited half-life, and article influence score are readily available through commercial companies such as Thomson Reuters, among others. These metrics were originally developed to help librarians in collection building and are based on the citation rates of published papers. Yet, they are increasingly being used, albeit undeservedly, as proxies for peer review to assess the quality of individual papers; and research funding, hiring, academic promotion and publication support policies are developed accordingly. This paper reviews the use of such metrics by the Turkish Scientific and Technological Research Council (TUBITAK) in its Support Program of International Scholarly Publications and concentrates on the most recent policy changes. A sample of 228 journals was selected on the basis of stratified sampling method to study the impact of changing algorithms on the level of support that journals received in 2013 and 2014. Findings are discussed and some recommendations are offered to improve the existing algorithm.

Conference Topic
Country level studies

Introduction
Bibliometric measures such as journal impact factor (JIF) and cited-half life are based on citation rates of published papers in the literature and their aging. They were originally developed to help librarians in collection building and in making decisions as to how long the back issues of journals should be kept in stacks (San Francisco, 2012). Yet, such bibliometric measures are often used to assess the quality of individual papers, authors, and institutions. They are increasingly being used, albeit undeservedly, as proxies for peer review to assess the quality of individual papers; and research funding, hiring, academic promotion and publication support policies are developed accordingly. Algorithms used to rank authors, institutions or even countries are primarily based on such bibliometric measures as JIF and h index (Simons, 2008). This paper reviews the use of such metrics by the Turkish Scientific and Technological Research Council (TUBITAK) in its Support Program of International Scholarly Publications and concentrates on the most recent policy changes.

Literature Review
The drawbacks of citation-based metrics, especially JIF, for research assessment is well documented in the literature (e.g., Seglen, 1997; Guerrero, 2001; Simons, 2008; Browman & Stergiou, 2008; Lawrence, 2008; Todd & Ladle, 2008; Balarama, 2013; Kotur, 2013; Marks, Marsh, Schroer & Stevens, 2013; Marx & Bornmann, 2013; Casadevall & Fang, 2014; Jawaid, 2014). Convincing arguments supported by empirical data were brought forward as to why such measures should not be used to evaluate research (e.g., skewed citation distributions, different publication and citation practices in Science vs. Social sciences, and the manipulation of JIFs by editorial policies). Some researchers stressed the hidden dangers

of a "citation culture" (Todd & Ladle, 2008) while others drew attention to how measurement and "bean counting" harms science (Lawrence, 2008), as such metrics can easily be "gamed" (Marks et al., 2013). The title of the editorial of the special issue on "the use and misuse of bibliometric indices in evaluating scholarly performance" of the journal *Ethics in Science and Environmental Politics* says it all: "Factors and indices are one thing, deciding who is scholarly, why they are scholarly, and the relative value of their scholarship is something else entirely" (Browman & Stergiou, 2008).

The San Francisco Declaration on Research Assessment (DORA), signed by researchers, journal editors and publishers alike, strongly recommends not to use "journal-based metrics, such as Journal Impact Factors, as a surrogate measure of the quality of individual research articles, to assess an individual scientist's contributions or in hiring, promotion, or funding decisions" (San Francisco, 2012). "[M]ost experts agree that the JIF is a far from perfect measure of scientific impact" (Bollen, Van de Sompel, Hagberg & Chute, 2009). Even Thomson Reuters, the publisher of such metrics through its Journal Citation Reports (JCR), is against using JIF to measure the quality of scientific papers (Marx & Bornmann, 2013, pp. 62-63). Yet, its use as "a tool of research assessment has reached epidemic proportions worldwide, with countries like India, China and the countries of Southern Europe being among the hardest hit" (Balaram, 2013, p. 1268). Some declared war on the impact factor (Balaram, 2013) and advised that its use should be abolished (Hecht, Hecht & Sandberg, 1998). Nonetheless, it is believed that, despite its misuse and abuse, JIF "will retain its impact and won't fade away" (Jawaid, 2014).

Consequently, policies developed for hiring, academic promotion, research funding, and monetary support to scientific publications in different countries tend to rely increasingly on metrics based on citation rates of published papers. Turkey is no exception (Tonta, 2014). The Higher Education Council of Turkey (YÖK) and the Turkish Scientific and Technological Research Council (TUBITAK) have been using journal impact factors for almost two decades in their academic promotion policies and incentive programs to support scientific papers, respectively.

The use of bibliometric measures for research assessment in Turkey along with their suitability as criteria to evaluate research quality has recently been reviewed (Tonta, 2014). This paper examines the most recent algorithmic changes introduced in 2013 and 2014 to rank the journals in the Support Program of International Scholarly Publications (UBYT) of TUBITAK and compares them with the earlier one (2012). The effects of year-to-year changes on the consistency of the ranks of journals are also studied. Note that, as the timeframe is short (2012-2014), we do not intend to study the impact of such changes on the authors' behaviour in terms of which journals they prefer to submit their papers to, journals' acceptance rates or the length of time it takes to publish therein. Rather, we try to understand the motives behind changes along with their effects on journal scores, which in turn determine the rank of each journal and thus the amount of monetary support that TUBITAK provides to the authors of papers that appeared in a specific journal.

TUBITAK's Support Program of International Scholarly Publications

Since 1993, TUBITAK provides monetary support to the authors of scholarly papers that appear in journals indexed by Thomson Reuters as an incentive to increase the number of such publications. The journal impact factor (JIF) was the sole criterion for support until 2013. As is well known, the impact factor (IF) of a journal is measured by the number of citations it gets in a given year to the papers published in it in the previous two years. Thomson Reuters publishes JCRs annually in which journals in each subject discipline covered by Science Citation Index (SCI) and Social Sciences Citation Index (SSCI) are ranked according to their JIFs. TUBITAK used JCRs to determine the eligible journals and

categorized the top 25% of journals in each subject discipline as Group "A", the next 25% of journals as Group "B" and the remaining 50% of journals as Group "C" (and "Group D" for social science journals—the bottom 10% of the remaining 50% of journals) (UBYT Programı, 2012).[1]

In 2013, TUBITAK has almost quadrupled the amount of support per paper. In parallel with this decision, TUBITAK also changed the rules to further classify journals with high IFs by developing its own "journal impact factor". Rather than simply classifying journals as A, B, C, and D on the basis of JCR's two-year JIF data, TUBITAK decided to use JCR's five-year JIFs and cited half-lives of journals in each discipline and multiplied the two figures to come up with its own JIF and ranked journals accordingly. (Cited half-life of a journal is the median—in years—of citations to papers published in it in a given year and depends on how fast the literature obsolesces in subject disciplines.) TUBITAK then took the average TUBITAK JIF of ranked journals and identified the journals with 2 standard deviations (SD) above and below the average to award them the maximum (5,000.00 Turkish Lira[2]) and minimum (500.00 TL) amount of support, respectively. Journals in between were awarded on the basis of a linear transformation formula taking the number of journals in each JCR discipline into account. This formula was criticized by some (Batmaz, 2013) as it happened to downgrade the ranks of some "A class" Archaeology journals considerably, thereby making them least supported ones. Similarly, the 2013 algorithm ranked 56% of Geology journals lower, including *Tectonics*, one of the most prestigious journals in this discipline (Yaltırak, 2014, p. 18).

Apparently, the new algorithm did not fulfill its objectives and TUBITAK, after using it for only one year, quickly replaced it in 2014 with the one that is based on JCR's article influence score. The 2013 transformation formula was used in 2014 to determine the exact amount to be paid to each journal (TUBITAK, 2013; 2014 Yılı, 2014). Comparable to IF, average influence score (AIS) is "a measure of the average influence, per article, of the papers in a journal" (Bergstrom, West & Wiseman, 2008) and is similar to Google's PageRank algorithm in that citations coming from papers in highly cited journals are weighted more heavily (Franceschet, 2010; Arendt, 2010). It is based on the number of citations, nonetheless. AIS is "the most stable indicator across different disciplines" (Franceschet, 2010) and can therefore be used for interdisciplinary comparisons (Arendt, 2010).

The drawbacks of metrics used by TUBITAK (JIF, TUBITAK's own JIF consisting of JCR's five-year IF and cited-half life and AIS) were discussed in detail elsewhere (Tonta, 2014). What follows is a survey based on a sample of 228 journals supported by TUBITAK to see the impact of changes introduced in 2013 and 2014.

Method

In order to find out the impact of most recent changes introduced in 2013 and 2014, we used TUBITAK's list of journals supported in 2012[3] to draw a sample. The list has a total of 11,562 journals. As explained earlier, TUBITAK categorized these journals in 2012 under Groups A, B, C and D according to JIFs reported in Thomson Reuters' JCR. The distribution of 11,562 journals under categories is as follows: Group A: 4,205 (or 36%) journals; Group B: 2,446 (or 21%) journals; Group C: 4,711 (or 41%) journals; and Group D: 200 (or 2%) journals. Social sciences journals constituted about one third of all journals. We selected a sample 232 journals (or 2% of the population) using stratified sampling method. Journals under Groups A, B, C and D formed the four strata. Two numbers between 1 and 100 were

[1] For more detail on TUBITAK's classification of journals, see Tonta (2014).

[2] *Circa* 2,000.00 USD.

[3] Available at http://ulakbim.tubitak.gov.tr/tr/hizmetlerimiz/ubyt-yayin-tesvik-programi.

identified (37 and 54) randomly and every 37th and 54th journal titles were selected. Table 1 provides population parameters and sample statistics.

The distribution of Science and Social science journals in the sample is quite similar to that of population. This can be interpreted as an indication of the generalizability of findings to the population with a calculated margin of error. The original sample size was 232 but 4 journals under Group D were later discarded to simplify the comparisons. Journals supported in 2013 and 2014 are not available as single lists but can be searched using a search engine available at the site.[4] All 228 journal titles in the sample were searched and their journal scores as well as the amount of support they would get were recorded. Six journals[5] in the 2012 list were no longer available in 2013 and 2014 among the supported journals and they were replaced with the next ones (e.g., 38th or 55th record) provided they were in the same category of Science and Social Science journals (e.g., Groups A, B, and C).

Table 1. Population parameters and sample statistics.

	Population parameters						*Sample statistics*					
	Science		*Social Science*		*Total*		*Science*		*Social Science*		*Total*	
Group	*N*	*%*	*N*	*%*	*N*	*%*	*N*	*%*	*N*	*%*	*N*	*%*
A	2037	48	2168	52	4205	100	40	48	44	52	84	100
B	1824	75	622	25	2446	100	36	72	14	28	50	100
C	3763	80	948	20	4711	100	77	82	17	18	94	100
D	--	--	200	100	200	100	--	--	4	100	4	100
Total	7624	100	3938	100	11562		153		79		232	

It should be noted that the minimum and maximum amounts for 2012, 2013 and 2014 were fixed (433.00 TL and 1,300.00 TL for 2012 and 500.00 TL and 5,000.00 TL for 2013 and 2014). As journals in 2012 were awarded fixed amounts of support depending on which group they belonged to, the figure for each journal was obtained by checking its group (e.g., A, B, C) as well as its being a Science or Social science journal. Social science journals were paid twice the amount of what is determined for each group (e.g., the author of a paper published in a Social science journal under group A was awarded 2,600.00 TL instead of 1,300.00 TL).

Findings

Table 2 below provides descriptive statistics for 228 journal titles including the quartiles. Despite the fact that the amount of support was increased in 2013 to 5,000.00 TL, the mean and median values do not seem to be affected much from this increase. The percentage of increase for the journals in the 3rd quartile is noticeable (19%), the reasons for which will be discussed shortly.

Figure 1 provides the scatter graph of the amount of support given by TUBITAK in 2012, 2013 and 2014 to the authors of papers that appeared in 228 journals sampled. Note that the blue line represents the 2012 figures and ranked in descending order by the amount of support. The amount was fixed depending on which group the journal belonged to. The authors of articles that appeared in Groups A, B, and C journals were paid 1,300.00, 867.00, and 433.00 Turkish Lira (TL), respectively.[6] If the paper appeared in a Social science journal,

[4] http:// http://www.ulakbim.gov.tr/

[5] Or, they might have been discontinued or their names might have changed. Replaced journal titles are: *Journal of Dental Research, Tulsa Studies in Women's Literature, Journal of Electronic Imaging, Plasma Physics Reports, and Vie et Milieu – Life and Environment*.

[6] The authors of case studies, technical communications, letters to the editors, etc. received half this amount.

the amount of support is doubled so that the authors of Social science papers will be further encouraged. Therefore, the solid blue line at 2,600.00 TL and 1,733.00 TL represent both 43 Group A and 14 Group B Social science journals, respectively, whereas the blue line at 1,300.00 TL represents 41 Group A Science journals. The 867.00 TL band represents both 35 Group B Science journals and 17 Group C Social science journals. The 433.00 TL band represents 78 Group C Science journals.

Table 2. The amount of support (in Turkish Lira*).

	2012	*2013*	*2014*	*Increase 2013-2014 (%)*
Mean	1176	1317	1403	7
Minimum	433	500	500	0
1st quartile	433	533	558	5

3rd quartile	1408	1518	1806	19
Maximum	2600	5000	5000	0

*Rounded to the nearest whole number.

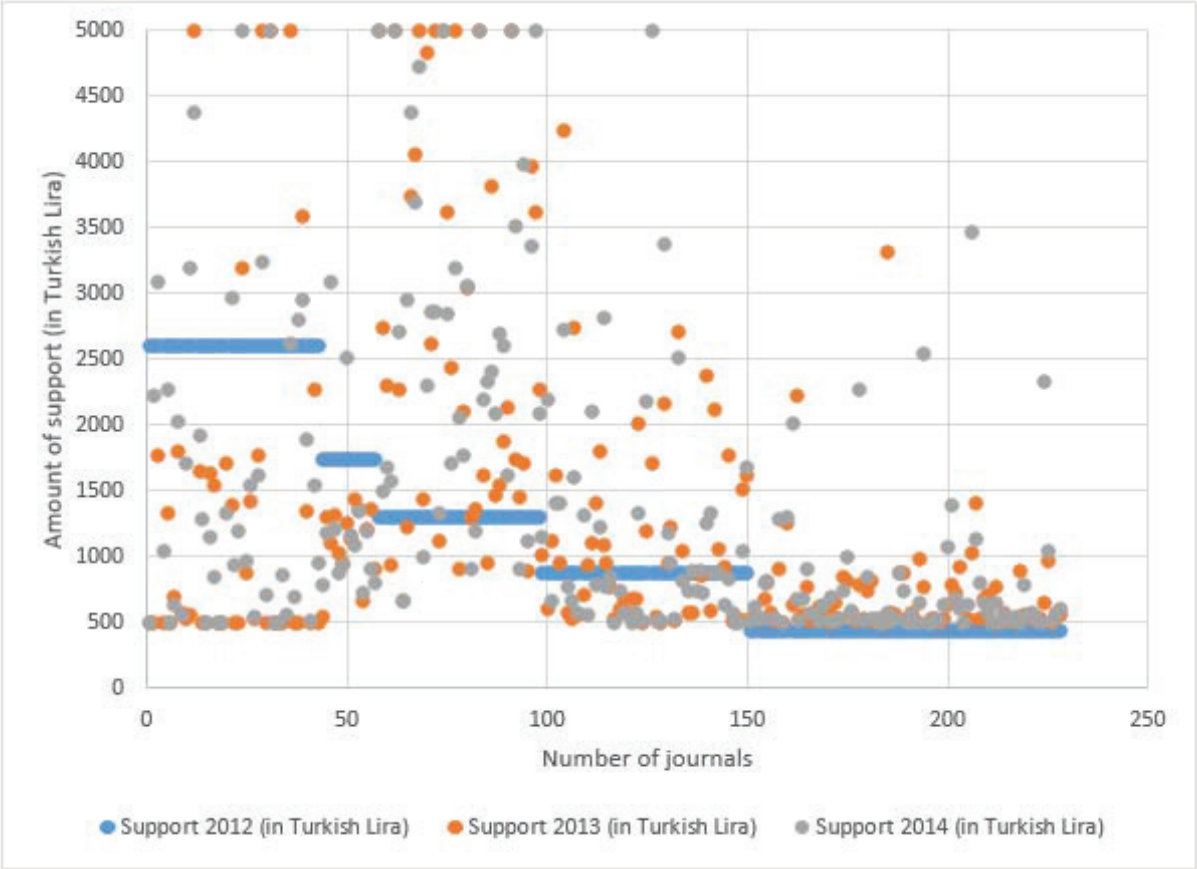

Figure 1. The scatter of journals by the amount of support in 2012, 2013 and 2014 (N = 228).

As indicated earlier, the maximum amount of support in 2013 was increased to 5,000.00 TL (the minimum being 500.00 TL). Note that the Group A journals of 2012 received relatively less support in 2013 and 2014. Out of 84 journals classified under Group A in 2012, only 15 (18%) maintained their top positions in the following years.[7] However, the positions of Social

[7] The amount between 500.00 TL and 5,000.00 TL was divided into three equal groups and the ones that were awarded between 3,500.00 TL and 5,000.00 TL are considered as top journals.

science journals classified under Group A fluctuated more than that of Science journals. Only 3 out of 43 Social science journals (7%) maintained their top positions as opposed to 12 out of 41 Science journals (29%).

Note that 2013 and 2014 figures are scattered without seemingly any discernible pattern (Fig. 1), as the 2012 figures are ranked in descending order by the amount of support and they do not necessarily correspond with the amounts in 2013 and 2014. Although statistically significant, the correlation between the amount of support to journals in 2012 and 2013 and that in 2012 and 2014 was rather low (Pearson's r = .289 and .231, p = .000, respectively). The correlation between the 2013 and 2014 journals was moderate (Pearson's r = .767, p = .000) (see Fig. 2).

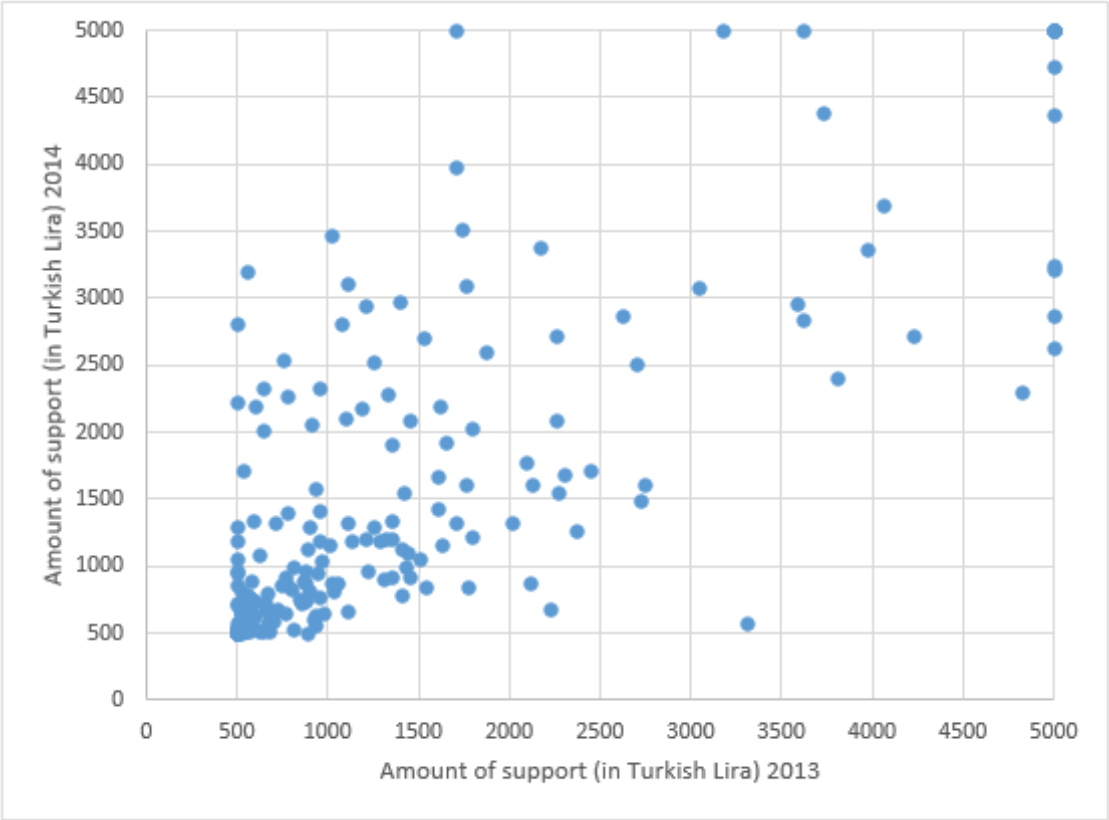

Figure 2. The scatter of journals by the amount of support in 2013 and 2014 (N = 228).

It is estimated that some 30,000 scholarly journals are published in the world. Thomson Reuters indexes about 12,000 of them and TUBITAK supports almost all of them (TUBITAK's 2012 journal list had 11,562 journal titles). It should be pointed out that TUBITAK's threshold for support is rather low. As Figures 3 and 4 below show, about one third of journals barely meet the minimum criteria and get the minimum amount of support (500.00 TL). It is reasonable to suggest that after careful consideration support to more than 3,000 journals can easily be discontinued.

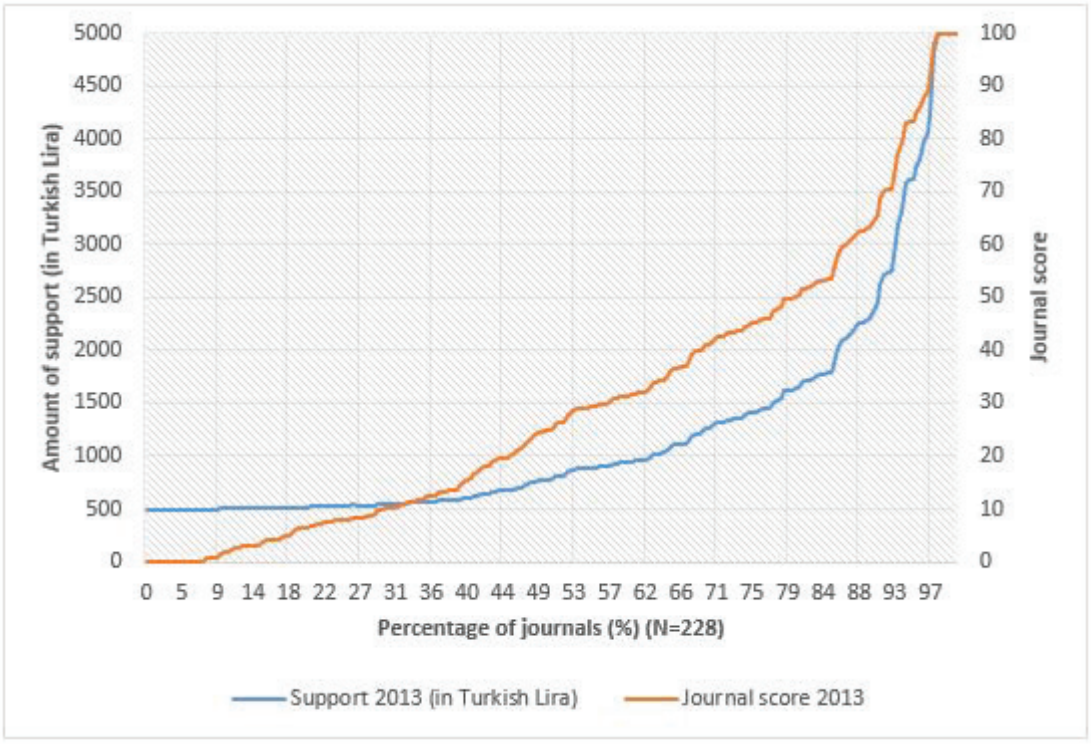

Figure 3. Relationship between journal score and the amount of support in 2013.

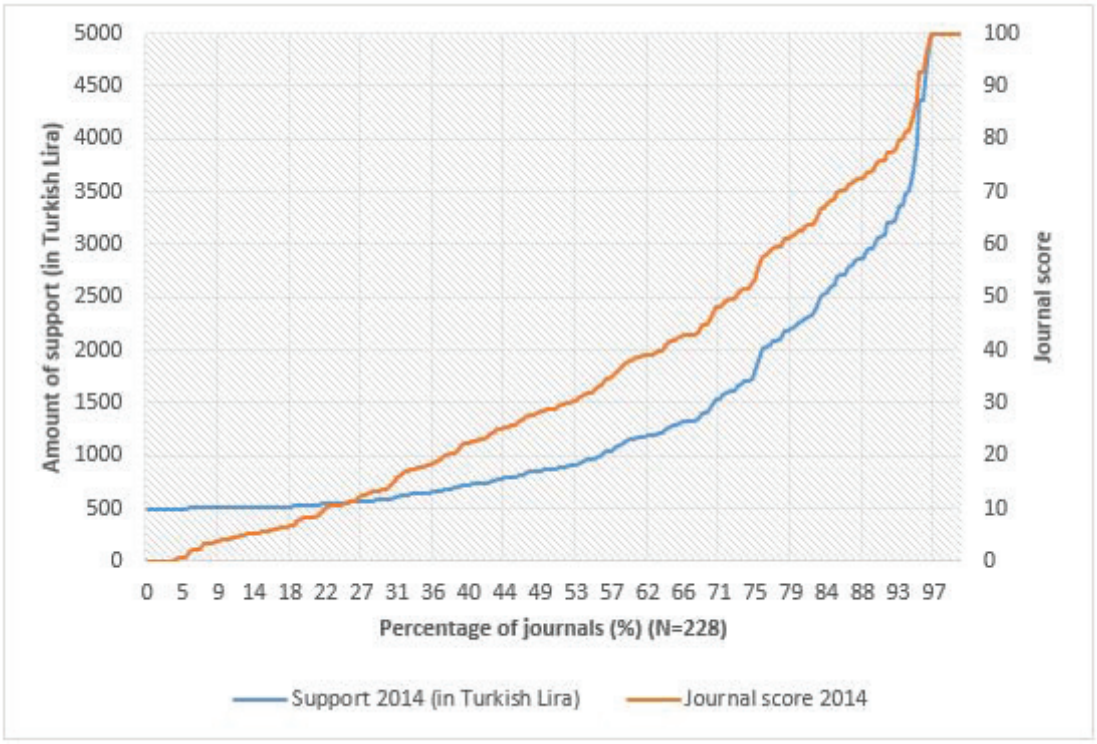

Figure 4. Relationship between journal score and the amount of support in 2014.

It should also be pointed out that the new policy discourages the authors of papers that appear in journals with low Article Influence Scores to seek support. As Figure 3 and 4 show, the gap between the journal scores and the amount of support starting from about 27%-35% gets widened. In other words, the amount of support is not that high for journals with relatively

lower AISs. More than 90% and 80% of journals received less than 2,500.00 TL (half the full amount of 5,000.00 TL) in 2013 and in 2014, respectively. Journals that received more than 4,000.00 TL support were about 5% of all journals in both 2013 and 2014. The situation was even worse for Social science journals (Fig. 5). This trend can also be followed from the last column of Table 2. The percentage of increase for the journals in the third quartile between 2013 and 2014 was 19% while it was only 5% for the journals in the first and second quartiles. This could be interpreted as a positive sign to encourage the authors to publish in more prestigious journals with higher AISs. Note that if the amount was less than 100.00 TL per co-author for papers with multiple authors, no support is provided. This is a further disincentive for authors not to claim the TUBITAK support for papers that appear in journals with low impact factors or article influence scores.

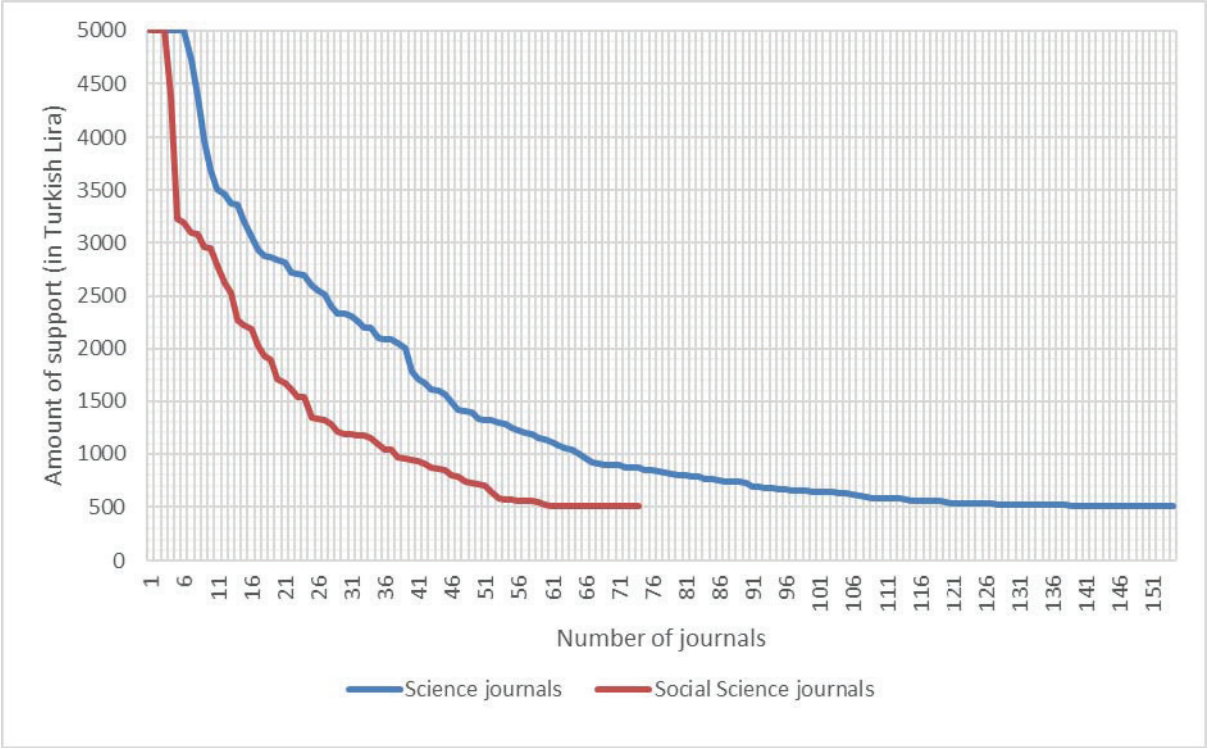

Figure 5. The amount of TUBITAK support for Science and Social science journals in 2014.

As we explained earlier, TUBITAK classified the second half of journals in Science disciplines listed in JCR under Group "C" and provided minimum support (433.00 TL per article) for these journals. (For Social Science disciplines, the second half of journals were divided into two: the top 40% of them being labeled as Group "C" and the remaining 10% as Group "D". Later, TUBITAK stopped supporting the authors of papers publishing in journals under Group "C" in Sciences (i.e., the last 50% of journals) and Group "D" in Social Sciences (i.e., the last 10% of journals) (UBYT Uygulama, 2012). As Group C Science journals constituted about one third of all journals supported in 2012, we wanted to see if they get supported after the policy changes in 2013 and 2014. Our sample included 77 Group C Science journals (one third of all sampled journals) (Table 1). It appears that all of them got supported both in 2013 and 2014. However, the overwhelming majority of them received very little support. As mentioned earlier, the 2013 algorithm was based on five-year JIFs and cited half-lives whereas the 2014 algorithm was based on article influence scores. Recall that the amount of support was increased almost four times starting from 2013. If TUBITAK were to continue supporting Group C Science journals, the amount would have been equal to 1,665.00 TL. Yet, the number of Group C Science journals receiving 1,665.00 TL (or higher) support

was only 2 in 2013 and 5 in 2014. The average amount of support in 2013 and 2014 were 701.00 TL (median=564.00 TL) and 770.00 TL (median=577.00 TL), respectively.

As JIFs and article influence scores are both based on the number of citations, it is not that surprising to see that journals that performed poorly in 2012 did so, too, in 2013 and 2014. What is surprising to see though is that TUBITAK seems to have nullified its earlier decision of not supporting Group C Science journals. A very few of those journals performed differently in 2013 and 2014 when new algorithms were used.

Discussion and Conclusion

It appears that the two algorithms used by TUBITAK in 2013 and 2014 are not that different from each other after all, even though the former was based on Thomson Reuters' JIFs and cited half-lives and the latter on article influence scores (AIS). However, as mentioned earlier, AIS is the most stable indicator and the average influence of journals can therefore be comparable across disciplines (Franceschet, 2010; Arendt, 2010). JIFs and AISs are highly correlated with each other and papers published in high impact journals usually have high AISs (Arendt, 2010; Rousseau & STIMULATE 8 Group, 2009). Arendt (2010) examined the relationship between the two metrics using 5,900 journals listed in JCR Science Edition (2007) and found that both JIFs and AISs vary by discipline. Moreover, the correlation between the two metrics was quite high (Pearson's r (172) = .896) and statistically significant ($p < .001$). Arendt (2010) cautioned that these two metrics should not be used formulaically for research assessment and for ranking scientific papers, authors or institutions.

This advice should be taken into account by TUBITAK as well. As the algorithm based on AIS is more stable and does not vary that much by scientific disciplines (Arendt, 2010; Franceschet, 2010), its use should be monitored closely by TUBITAK to see if it merits further refinement.

The support to journals in the lower end of the scale should be discontinued. Having decided in 2012 to discontinue support to Group C Science journals, it is not clear why TUBITAK reversed its decision the following year without monitoring how these journals performed with the new algorithms used in 2013 and 2014. In fact, the performance of all journals should be monitored to fine-tune the algorithms used.

TUBITAK is of the opinion that its support program caused to increase the number of scientific publications over the years. Turkey has indeed performed very well and became the 18th country in the world in terms of the number of scholarly papers published in ISI-indexed journals. However, the positive correlation between the amount of support provided by TUBITAK and the number of papers with Turkish affiliations is not a strong argument in and of itself[8] to justify the continuance of the support program because correlation does not necessarily mean causation. The existing support to papers published in low impact journals could very well be the main cause of this positive correlation. This merits further research because TUBITAK support does not seem to have encouraged the authors to publish in more prestigious journals.

In conclusion, bibliometric performance measures alone are not the sole criteria for research assessment and, as the Board of Directors of IEEE recently recommended, they "**should be applied only as a collective group (and not individually)**" (IEEE, 2013, original emphasis).

What's Special about Book Editors? A Bibliometric Comparison of Book Editors and other Flemish Researchers in the Social Sciences and Humanities

Truyken L.B. Ossenblok[1] and Mike Thelwall[2]

Abstract
This paper examines the bibliometric characteristics of book editors and non-editors, focussing on gender, career stage, number of publications and collaboration practices. The data consist of 8970 Flemish affiliated researchers with at least one publication between 2000 and 2011 in the comprehensive Flemish academic bibliometric database (VABB-SHW). The analysis shows that most book editors are established male researchers while most non-editors are non-established male researchers. Moreover, males are more likely to be editors than are females. Half of the established editors edit more than 1 book, in contrast to only a small number of non-established editors. Overall, book editors publish more than non-editors, but, when controlling for career stage, book editors publish even more book chapters and monographs than do non-editors. Although editors are highly collaborative while editing a book, no significant differences were found in the number of collaborative articles, monographs, book chapters and proceedings written by editors and non-editors.

Conference Topic
Country-level studies

Introduction
Bibliometric studies have demonstrated the importance of books to many disciplines belonging to the Social Sciences and Humanities (SSH). There is a growing consensus among researchers and policy-makers that scholarly publication patterns and their underlying research cultures cannot be adequately analyzed without the inclusion of books (Hicks, 2004; Nederhof, 2006; Sivertsen, 2009). So far, this insight has resulted in a limited number of studies on books in the SSH, mostly focused on scholarly monographs. A book publication type that has received far less attention is the edited book. Editing a book often appears to be undervalued for academic careers (Edwards, 2012) but, in Flanders, from 2010 onwards, edited books are included in the funding system (Ossenblok & Engels, 2015) which gives incentives to individual researchers to take on book editorships (Gläser & Laudel, 2007).

We define an edited book here as a collection of chapters written by different authors, gathered and harmonized by one or more editors (Ossenblok & Engels, 2015) and identifiable by the presence of an ISBN. Edited books have been shown to comprise a sizeable share of the publication output of many SSH disciplines, especially in the humanities (Leydesdorff & Felt, 2012; Nederhof, 2006). In Flanders, the Northern Dutch-speaking part of Belgium, about 2% of all peer reviewed publications in the SSH are edited books, with up to 6% in Linguistics, Literature and Theology (Engels, Ossenblok, & Spruyt, 2012). Compared to monographs, edited books have significantly higher citation rates, especially in social science disciplines (Torres-Salinas, Robinson-Garcia, Cabezas-Clavijo, & Jiménez-Contreras, 2013).

This paper presents a bibliometric case study of the characteristics of book editors, for which, to the best of our knowledge, no previous studies exist. We analyse comprehensive

publication data and present four elements of a general profile of these scholars: career stage; gender; number of publications; and collaboration practices. We hypothesise that scholars tend to edit books only when they are established researchers that are at the forefront of scholarly collaboration.

Data and methods

The data set consists of 8970 authors affiliated with one of the five Flemish universities and who have published a minimum of one peer reviewed publication in the period 2000-2011: a journal article, monograph, edited book, book chapter and/or proceedings paper included in the VABB-SHW (for a full account see: Engels et al., 2012). Because of the use of this database for funding in Flanders, this database appears to be close to exhaustive in its coverage of Flemish research. In addition to the data found in the VABB-SHW, we also determined the gender of all authors. For this, two researchers independently divided all unambiguous first names into two groups: male names and female names. The remaining authors were looked up on the internet, resulting in an additional 1462 gender matches.

A comparison was made between two subsets: book editors (researchers who have published a minimum of 1 peer reviewed edited book in the period under study); and all other researchers, called here non-editors although they may be journal editors or may have edited books during other periods of time. Furthermore, we differentiated between established and non-established researchers. Established researchers are defined in this study as having a total of 12 publications or more and at least one publication in a minimum of 6 different years in the period 2000-2011. These heuristics were chosen after inspection of typical properties of authors in the database. Of course, non-established researchers may have many publications within up to five years, may have a prolific consistent set of outputs before or after the period analysed, or may have many outputs of a type not recorded in the database (e.g., book reviews, performances). Nevertheless, the criteria seem to be effective at differentiating between two sets of researchers, the first of which contains researchers that can reasonably be thought of as being established and the second of which probably contains a much lower proportion of established researchers. Cramer's V was used to measure the strength of the correlation between the different subsets, resulting in a number between 0 (no association) and 1 (maximum association). In addition the Mann-Whitney U test, a rank-based nonparametric test, was used to determine whether there were differences between the subsets on the different characteristics under study, using $p=0.05$ as the threshold for statistical significance.

Results

Career stage and gender

Figure 1 shows the proportion and number of established and non-established, male and female editors and non-editors in our study. In total, 676 (7.5%) researchers had published one or more edited books (i.e., editors), and 8970 (92.5%) researchers had not published an edited book (i.e., non-editors). Figure 1 demonstrates that 55.9% (n=378) of editors are established researchers whereas 13.3% (n=1102) of non-editors are established researchers. Furthermore, 74.3% (n=502) of editors are male whereas to 58.9% (n=4883) of non-editors are male. In addition, 9.3% of all male researchers are editors and 4.9% of all female researchers are editors. Furthermore, 25.5% of all established researchers are editors, whereas only 4% of all non-established researchers are editors. Altogether, 43.5% (n=294) are male established editors, 30.8% (n=208) are male non-established editors, 13.3% (n=90) are female non-established editors and 12.4% (n=84) are female established editors. Different proportions occur in the subgroup of the non-editors where 49.1% (n=4070) are male non-

established researchers, 37.6% (n=3122) are female non-established researchers, 9.8% (n=813) are male established researchers and 3.5% (n=289) are female established researchers.

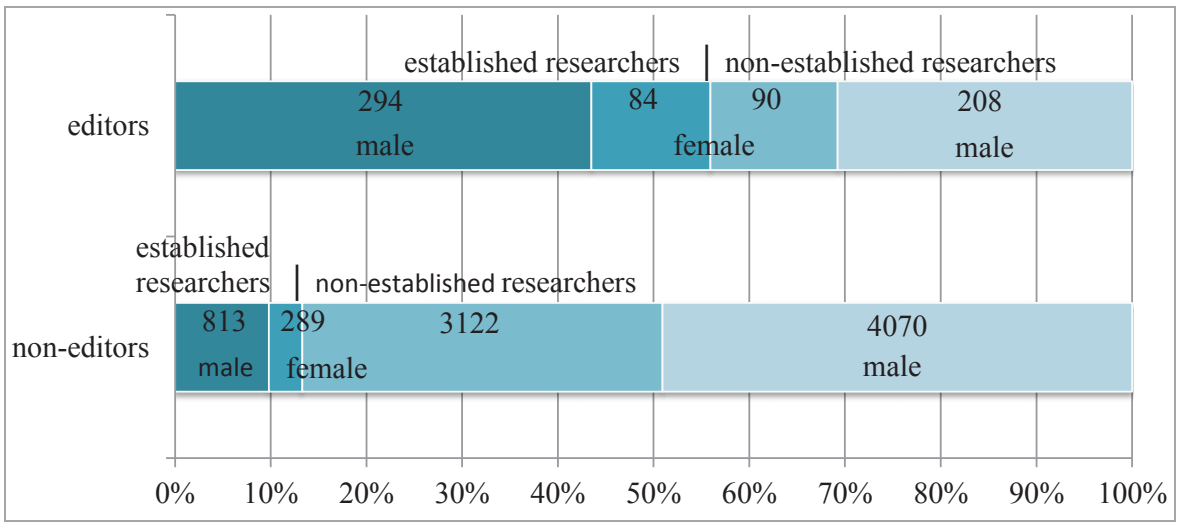

Figure 1: Share and number of established and non-established, male and female editors and non-editors (2000-2011).

There is a moderate association (Cramer's V=0.134; p=.000) between gender and career status overall (see also Figure 1). However, when looking at the different subsets, the correlation between gender and career status is stronger within the subset of non-editors (Cramer's V=0.119; p=.000) than within the subset of editors (Cramer's V=0.091; p=.000). Overall, though, career status has a stronger association with editorship than with gender (resp. Cramer's V=0.304; p=.000 and Cramer's V=0.083; p=.000). Therefore in the rest of this study we will focus on differences in career status rather than gender.

Number of publications

Table 1 shows the mean and median number of edited books, articles, book chapters, monographs and proceedings for all editors and non-editors. In addition, the table displays the difference between non-established and established researchers. Overall, editors publish on average a greater number of all publication types than do non-editors. However, established non-editors publish on average more articles than do established editors. Mann-Whitney U tests were run to test for differences in numbers of publications between editors and non-editors for all publication types except edited books. The distributions of all the publication types for editors and non-editors and for established and non-established researchers were visually similar. The differences between editors and non-editors are statistically significant for all publication types (all p=.000). When comparing established editors and established non-editors, all differences are significantly different (p=.000) except for the numbers of proceedings (p=.138). When comparing non-established editors with non-established non-editors, the differences for articles (p=.119) and proceedings (p=.911) were not significantly different, whereas the differences for book chapters and monographs were (both p=.000).

Furthermore, Table 1 shows that the median of numbers of edited books differ between established and non-established editors. Non-established editors are more likely to have (co−)edited one book whereas established editors are more likely to have more than 1 edited book. More specifically, 83.2% of all non-established editors have one edited book, whereas 48.4% of all established editors have one edited book, 24.3% have two edited books and 27.2% have three or more edited books.

Table 1: The mean and median (med) number of edited books, articles, book chapters, monographs and proceedings for all established and non-established editors and non-editors (2000-2011).

		edited books		*articles*		*book chapters*		*monographs*		*proceedings*	
		mean	*med*	*mean*	*med*	*mean*	*med*	*mean*	*med*	*mean*	*med*
Editor	established researcher	2.17	2	20.62	14	7.92	6	0.59	0	0.97	0
	non-established researcher	1.22	1	2.93	2	2.31	2	0.16	0	0.17	0
	total	1.76	1	12.82	7	5.44	4	0.40	0	0.62	0
non-editor	established researcher	-	-	26.00	18	1.57	1	0.22	0	0.82	0
	non-established researcher	-	-	3.00	2	0.29	0	0.03	0	0.16	0
	total	-	-	6.06	2	0.46	0	0.05	0	0.24	0

Collaboration practices

For both editors and non-editors, Figure 2 shows the proportion of their edited books, articles, book chapters, monographs and proceedings that have been published in collaboration (i.e., multiple authored versus single authored publications). Editors collaborate the most while editing a book (90.3%; n=1827), which is in agreement with previous research demonstrating that most edited books are co-edited (Ossenblok & Engels, 2015). Furthermore, established editors collaborate more than non-established editors for all publication types under study (p=.000). Altogether, though, non-editors seem to collaborate more for articles, book chapters, monographs and proceedings than do editors. Mann-Whitney U tests were run to determine if editors and non-editors differ significantly in their numbers of collaborative publications. The different distributions of all the publication types, except edited books, were visually similar. The numbers of collaborative publications of editors and non-editors were statistically significantly different for book chapters and monographs (both p=.000) but not for articles (p=.282) and proceedings (p=.116). Thus, non-editors collaborate significantly more in book chapters and in monographs than do editors. In addition, when comparing non-established editors with non-established non-editors, no significant difference in the number of collaborative publications was found for all publication types separately (but p=.000 for articles, monographs and book chapters; p=.005 for proceedings). However, when distinguishing between established editors and non-editors, the differences are significant for all publication types separately (p=.000) except for proceedings (p=.208). In sum, established non-editors collaborate more than do established editors for articles, monographs and book chapters.

Discussion and conclusions

Within a comprehensive collection of Flemish affiliated authors' publications for 2000-2011, this paper demonstrates that 7.5% of the authors have edited one or more books, that more than half of the book editors are established researchers, and that 3 in 4 editors are male.

Female researchers are less likely to be established than are male researchers and this difference is more pronounced for non-editor than for editors. As career status in this study is defined through numbers of publications and publication years, these findings confirm previous findings that male researchers are often more productive than are their female colleagues (Larivière et al., 2013; Puuska, 2010).

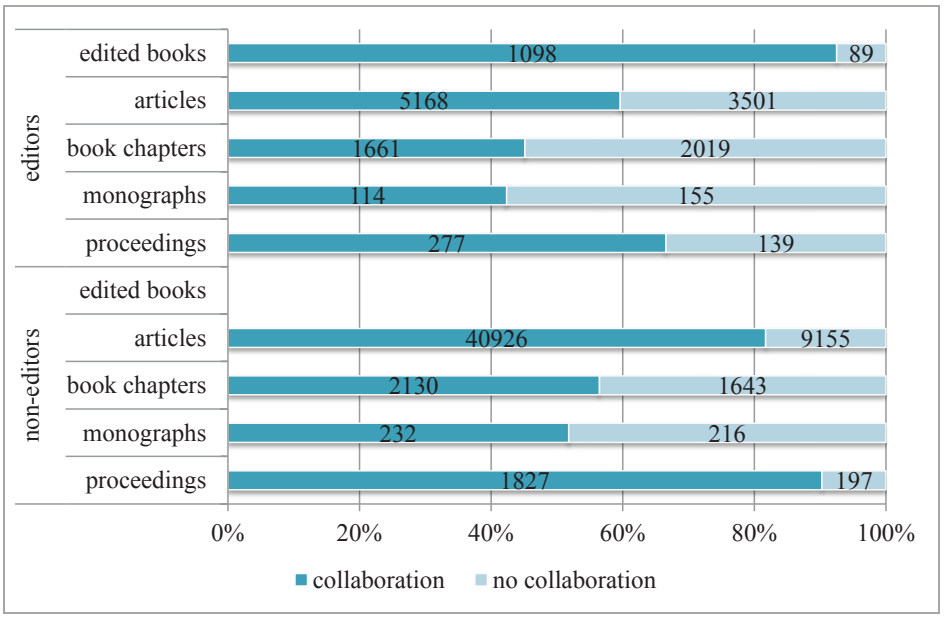

Figure 2: The proportion of collaborative and solo publications for all editors and non-editors by publication type.

Editors tend to publish significantly more articles, book chapters, monographs and proceedings than do non-editors. However, the differences are not statistically significant between the average number of proceedings of established editors and non-editors and between the average number of articles and proceedings of non-established editors and non-editors. Most non-established editors published only 1 edited book in the period under study, whereas more than half of the established editors published 2 or more edited books. This might be due to the need for a large network and good networking skills for gathering contributions from individual chapter authors for an edited book (Edwards, 2012; Thomas & Hrebenar, 1993). We therefore expected editors to be more collaborative than were non-editors for all publication types, but although 9 out of 10 editors collaborated while editing a book, non-editors collaborated significantly more for book chapters and monographs than did editors. Furthermore, no significant difference was found in the number of collaborative articles and proceedings between editors and non-editors. As edited books are more common in humanities disciplines (Engels et al., 2012) and the humanities have been known to collaborate less than the social sciences in articles and book chapters (Ossenblok, Verleysen, & Engels, 2014), the low level of collaboration of editors might be due to them tending to be humanities scholars.

Overall, the findings offer a first insight into some of the bibliometric characteristics of editorship. Future research will focus on disciplinary differences in collaboration practices between book editors and non-editors. A more detailed analysis of collaboration practices will involve not only the number of collaborative publications, but also the number of co-authors. As previous research (Ossenblok & Engels, 2015) has shown, edited books are often published in English, and so the study of the number of international co-authors and co-editors will broaden our knowledge about the international nature of the collaboration network of the editors. In addition, links between book editors and their chapter authors

would provide a more complete picture of the collaboration practices of book editors. This would contribute greatly to our understanding of collaborative practices in the SSH.

Acknowledgments

The authors thank their colleagues Nele Dexters, Tim Engels, Raf Guns and Frederik Verleysen for their useful comments.

Abstract
This paper presents an analysis of scientific research output of the republics of former Yugoslavia for the period 1970-2014. Thomson Reuters' Web of Science (WoS) database was used for data acquisition and 223 135 publications have been analyzed. The Yugoslav Wars were ethnic conflicts fought from 1991 to 1999 on the territory of former Yugoslavia, which accompanied the breakup of the country, and today, each republic of former Yugoslavia is an independent country, as well as the province of Kosovo. Results of the analysis are represented by four figures depicting cooperation networks between former Yugoslav republics and the province of Kosovo for the periods before the Yugoslav wars (from 1970 until 1990), during the wars (from 1991 until 1999), in the first decade after the wars (from 2000 until 2009), and in the last 5 years (from 2010 until 2014). The impact of the wars on scientific cooperation in the republics has been studied.

Conference Topic
Country-level studies

Introduction
The Socialist Federal Republic of Yugoslavia (SFRY) was established in 1946, after World War II. It was divided into six Republics (Serbia, Croatia, Slovenia, Bosnia & Herzegovina, Macedonia and Montenegro) and two autonomous provinces on the north and south of Serbia (Vojvodina and Kosovo). The Yugoslav Wars were ethnic conflicts fought from 1991 to 1999 on the territory of SFRY, which accompanied the breakup of the country. Today, each republic of former SFRY is an independent country. A Kosovo declaration of independence was adopted on 17 February 2008 by the Assembly of Kosovo, but the legality of this declaration have been disputed by the Serbian Government and other countries (e.g. the Russian Federation and China). This paper analyses the scientific cooperation in the republics of former SFRY and the province of Kosovo before, during and after the Yugoslav wars. The purpose of this analysis is to answer how the Yugoslav wars and social crises during and around those wars affected scientific productivity and scientific cooperation in these republics and whether this cooperation has recovered 15 years after the wars.

Related work
Bibliometric analysis is a useful method for characterising scientific research (Moravcsik, 1985; Fu & Ho, 2013) and this method can be used for analysing scientific cooperation in different countries and regions (Leta & Chaimovich, 2002; Wagner & Leydesdorff, 2005; Ho et al., 2010). Citations of a publication are not a direct measure of quality and significance, but they reflect the visibility and impact of the publication on the scientific community (Furlan & Fehlings, 2006; Baltussen & Kindler, 2004). The number of times an article was cited correlates significantly with the number of authors and the number of institutions

involved in collaboration (Figg et al., 2006) and highly cited articles are usually authored by a large number of scientists, often involving international collaboration (Aksnes, 2003). Thus, scientific cooperation is important for the further development of world science and for the further economic development of a region or country.

The impact of social aspects, economic and social crises, political crises and wars on scientific cooperation in some regions has already been studied. For example, de Bruin and colleagues (1991) stated that the cooperation between the Gulf States and former western and eastern bloc has been strongly affected by political crises, which culminated in the Operation Desert Storm in 1990. There are also studies that deal with the countries of the former SFRY like Lewison and Igic (1999), Igic (2002), Lukenda (2006), Đukić et al. (2011) and Kutlača et al. (2015). Furthermore, Jovanović et al. (2010). analysed the publications and cooperation between the republics of former SFRY and the province of Kosovo is analyzed for the years from 1970 until 2007. The authors found that the Yugoslav wars had a severe impact on the cooperation networks of former SFRY republics. Furthermore, they also found that the process of recovery started with the ending of the conflicts, but that scientific cooperation recovered faster in some of those republics. The current paper revisits the data and methods of this study by analysing publications of former SFRY republics and the province of Kosovo from 1970 until 2014, thus broadly extending the database and improving the methodology. Thus, the purpose of this analysis is to answer whether scientific cooperation in all former SFRY republics is fully repaired 15 years after the Yugoslav wars or whether the interpretation of the findings of the 2010 study has to be reformulated.

Methodology

Similar to the 2010 study, Thomson Reuters' Web of Science (WoS) database was used for data acquisition. This time, however, the Arts & Humanities Citation Index Expanded was not covered, because the authors' institutions did not have access. But in addition to the Science Citation Index Expanded (SCIE) and the Social Science Citation Index (SSCI) (which were also used in 2010), both conference proceedings citation indexes (Science and Social Sciences) were covered by the search queries. This was done in order to get a more complete coverage of the publication output of the former Yugoslav countries. Again similar to 2010, the search queries consisted of the names of cities from the former Yugoslav countries, since before 1990 all successor states belonged to SFRY. In 2010, a total of 133 city and town names were used in the search queries (including synonyms of city names). For the current study, we also used search queries that consisted of the country names (Yugoslavia and all successor states) in order to find city and town names (and synonyms), which were missing in our city search queries. In addition to that, the maximum number of 50 search arguments in WoS (still existing in 2010) is no longer limited which meant that we were able to use much longer search queries for the current study. Because of this, the new search query included 769 city and town names along with synonyms, misspellings etc. This has led to a much broader database and a better allocation of publications to their respective states, in comparison to the data used in 2010. In 2010, the data set consisted of 103 963 publications (for the years 1970 to 2007), the current study has 121 602 publications for this time period (20% more) plus 101 533 publications for the years 2008 to 2014, which brings the complete data set to a total of 223 135 publications. We rechecked whether these publications were all from the correct countries by using WoS exclude tool and removing all publications from the seven Yugoslav successor states. The remaining publications consisted of around 1% of the total data set and manual checks of these publications have shown that most of these were still relevant but wrongly indexed (for example publications from Kosovo which were attributed to Albania). This leads us to believe that our data set includes all publications from the former SFRY, which can be found in the WoS.

We analysed the data set using a proprietary bibliometry toolbox (programmed at Fraunhofer INT) and the following measures and method: (1) Absolute number of publications for each state (2) Absolute number of cooperation for each state and (3) Visualization of the Yugoslav cooperation network. In our future studies, we will add measures like Salton's measure and others.

Results

Results of the analysis are represented by four figures depicting cooperation networks between former Yugoslav republics and the province of Kosovo for the periods before the Yugoslav wars (from 1970 until 1990), during the wars (from 1991 until 1999), in the first decade after the wars (from 2000 until 2009), and in the last 5 years (from 2010 until 2014). Each republic's and the province of Kosovo's publications indexed by WoS have been represented in figures by a circle which size is proportional with the number of publications published by researchers from each respective republic. Lines between those circles represent cooperation of researchers in writing publications and line thickness is proportional with the number of collaborative publications of researchers from two republics whose circles are connected by the line. A cooperation was counted whenever more than one institution that published a paper was located on the territory of the former Yugoslavia and these institutions were not from the same republic. Cooperation between three or more republics are quite rare. These were enumerated as a set of multiple bilateral cooperation.

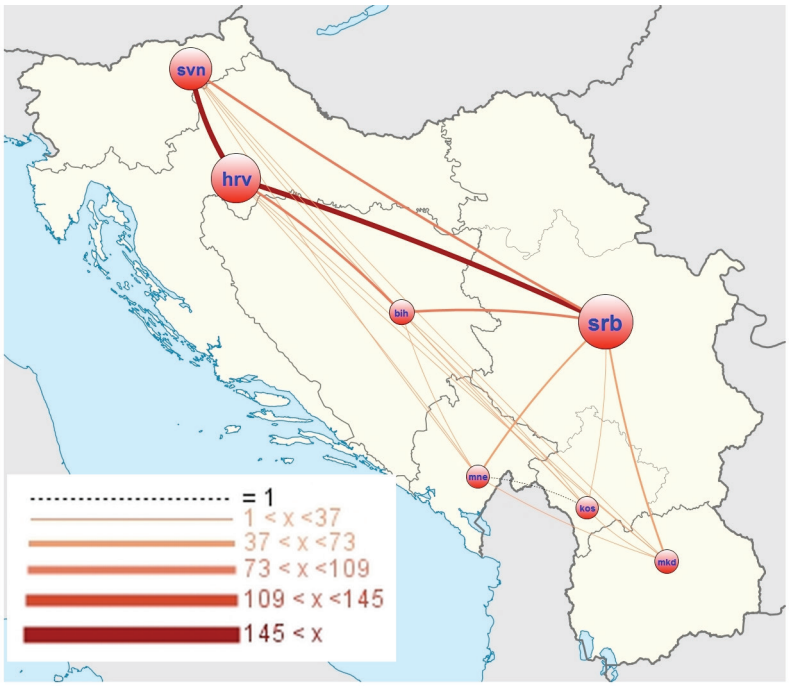

Figure 1. Visualisation of the cooperation network for 1970-1990 (before Yugoslav wars).

Figure 1 depicts the cooperation network for the period before the Yugoslav wars. Researchers from Serbia published the highest number of publications before the wars, followed by researchers from Croatia. Those two republics were the most productive republics and cooperated the most in former Yugoslavia. Slovenia, according to the productivity of its researchers and to the cooperation in this period, was in the middle between the groups of "big" republics by scientific productivity (Serbia and Croatia) and the group of "small" republics (Bosnia and Herzegovina, Macedonia, Montenegro and the province of Kosovo). Before the war, the most productive "small" republic was Bosnia and Herzegovina.

The Yugoslav wars started in 1991 and they led to a strong decrease of scientific cooperation in the republics in the 90's. Also, it affected the ratio of scientific productivity between republics during the wars. Figure 2 depicts the cooperation network for the period 1991-1999 which is the period of Yugoslav wars. Before the wars, Serbia was cooperating strongly with Croatia, Slovenia and Bosnia and Herzegovina. The cooperation triangle between Serbia, Croatia and Slovenia almost disappeared in the 90's, as well as the cooperation triangle between Serbia, Croatia and Bosnia and Herzegovina. However, scientific cooperation between Croatia and Slovenia was strengthened in this period. The reason for that is the fact that the conflict between Serbia, Croatia and Bosnia and Herzegovina during the wars was much stronger than the conflict between Croatia and Slovenia. Also, effects of the wars were much less on Slovenian economy than on the economies of other republics. War in Slovenia ended after ten days in 1991. Also, Macedonia remained at peace throughout the Yugoslav wars and declared its independence in September of 1991. Thus, the ratio of scientific productivity of Slovenian and Macedonian researchers in comparison to the other republics researchers had been changed in favour of Slovenia and Macedonia. In this period and in the followings periods Slovenia became a member of the group of "big" republics.

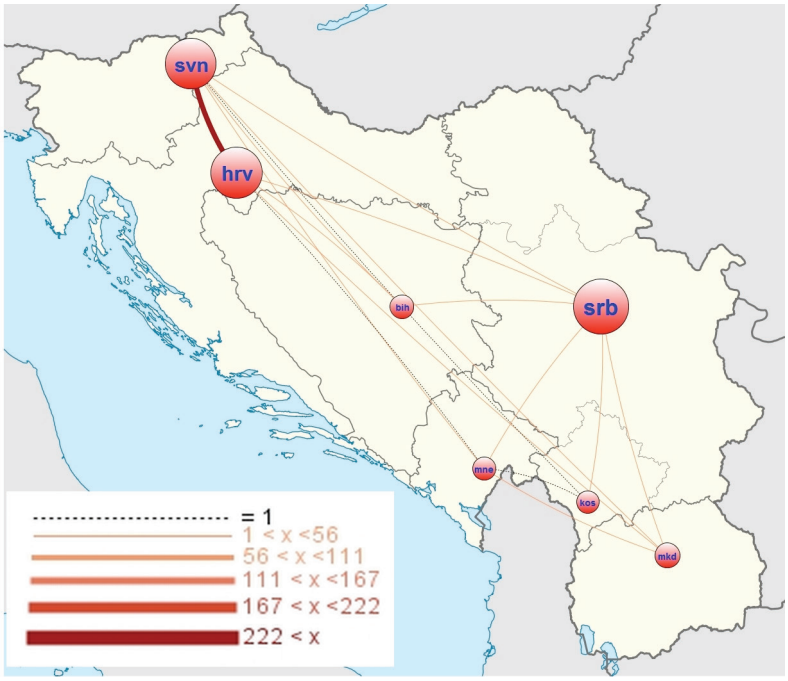

Figure 2. Visualisation of the cooperation network for 1991-1999 (during Yugoslav wars).

Figure 3 depicts the cooperation network for the period 2000-2009 which is the first decade after the Yugoslav wars. Scientific cooperation in this period between Serbia and Slovenia was strengthened again. The cooperation triangle between Serbia, Croatia and Slovenia was not as strong as before the wars (taking into account that the overall publication output increased), but it seems as if this cooperation triangle was resurfacing again.

Figure 4 depicts the cooperation network for the period 2009-2014. In this period Serbia has returned to having the most publications as before the Yugoslav wars. Reasons for this include introduction of a new rulebook for evaluation prescribed by the Ministry of Education, Science and Technological Development of the Republic of Serbia in 2008. That rulebook requires researchers must have articles published in journals in the Web of Science database for the promotion to scientific positions. In addition, the increase in the number of publications was influenced by the fact that several journals based in Serbia have, in recent years, started to be indexed by Web of Science: e. g. Vojnosanitetski Pregled, Archives of

Biological Sciences, Srpski Arhiv Za Celokupno Lekarstvo, Journal of the Serbian Chemical Society, etc. Those journals published a considerable number of articles written by Serbian researchers in the period 2010-2014 (Ivanović and Ho, 2014). The strengthening of the cooperation triangle between Serbia, Croatia and Slovenia started in the period 2000-2009 continues in the last five years. We conclude that this triangle is fully recovered.

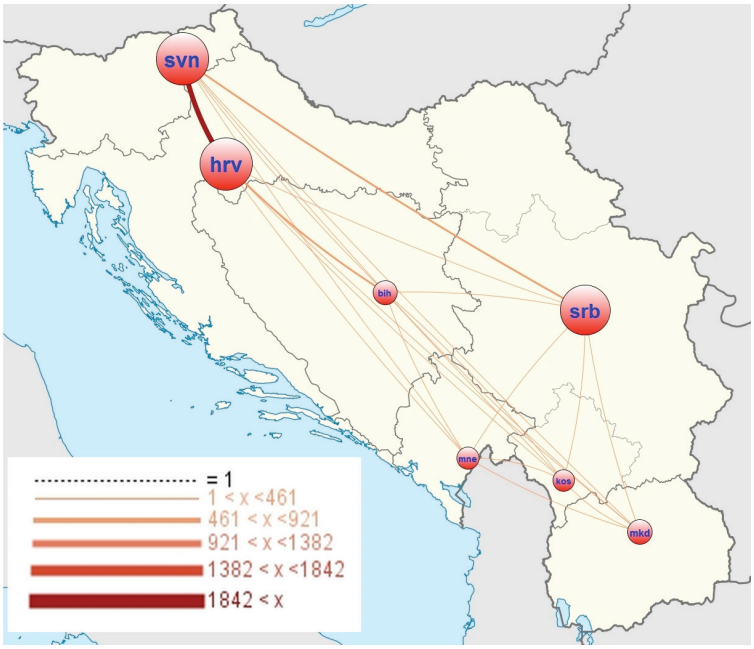

Figure 3. Visualisation of the cooperation network for 2000-2009 (1st decade after Yugoslav wars).

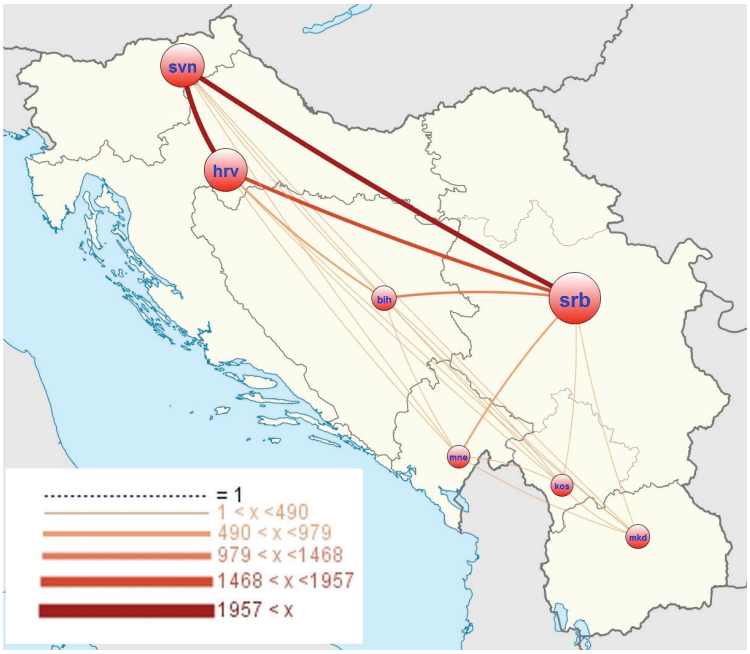

Figure 4. Visualisation of the cooperation network for 2010-2014.

Conclusion

The analysis of scientific-research outputs of the republics of former Yugoslavia for the period 1970-2014 has been presented in this paper. It reveals that civil Yugoslav wars affected the republics' productivities and scientific cooperation in different ways. The most

affected republics by wars and social crisis were Serbia and Bosnia and Herzegovina, while the least affected republics were Slovenia and Macedonia. However, it seems that in the last five years productivity and scientific cooperation look similar as before the Yugoslav wars. This result strengthens the results from the 2010 study. It would seem that old cooperation networks, which were disrupted during the Yugoslav wars, are in place again. However, our data cannot answer the question whether these are the same networks as before (i. e. the same researchers and/or institutions that are cooperating again) or whether new ones have taken the place of the old ones.

The presented results are the first part of our research. We are going to extend our research with following measures and methods: relative number of publications for each state and normalized cooperation score $R_i^{(cs)}$ (as described in Jovanović et al. (2010). Also, we are going to analyse the distribution of collaborative articles per the biggest Universities based in these states.

Abstract
A specific aspect of the scientific communication in non-English-speaking countries is the need for insertion in the global knowledge flows since a significant part of their publications occurs in national or regional journals. This had led many countries to create alternative ways to assess national journals, allowing a more trustworthy view of the national scientific production. This study aimed to characterize the journals used in the Brazilian scientific production in Web of Science and SciELO, in order to observe the dynamics along five triennia and across the Bradford Zones for both production and consumption in the different areas. Bradford zones showed to be an interesting relative indicator, when applied to evaluative purposes. Especially the joint analysis of production and consumption dimensions can bring a more complete view of the scientific communication system, and this study showed the flows of journals through zones in both dimensions.

Conference Topic
Country-level studies

Introduction
In the last years, several efforts were undertaken by the developing countries in order to improve their position in the global scientific scenario. However, as important as (or even more important than) improve their position is to formulate and implement initiatives for improving their research system, in which the scientific communication plays important role.

A specific aspect of the scientific communication in these countries, mainly in the non-English-speaking ones, is the need for insertion in the global knowledge flows (Ponomariov & Toivanen, 2014), because a significant part of their publications occurs in national or regional journals (Mugnaini et al., 2014). The researchers from these countries, many of them involved in scientific editing, face the dilemma between maximizing efforts to publish in *mainstream journals* and improve the national journals in order to internationalize them – and its negative consequences of such a process (Rego, 2014). Both aspects are typically treated as ways to internationalize the national science, but is this enough (Buela-Casal et al., 2006)? This duality comes from the national science policy, which in one hand valorizes the journals with high Impact Factor (IF) and, on the other hand, tries to attend the clamor for recognition of the national journals (Miranda & Mugnaini, 2013).

This had led many countries to create alternative ways to assess or classify the national journals, allowing a more trustworthy view of the national scientific production, identifying the role of the national journals. In order to do this, some countries built national citations indexes: SciELO Project (Packer et al., 1998), Chinese Science Citation Database (Jim & Wang, 1999), Korea Citation Index (Kim et al., 2013), Citation database for Japanese papers (Negishi et al., 2004) and Islamic World Science Citation Center (Mehrad & Arastoopoor, 2012). Other countries considered this kind of initiative as a solution only for the Humanities and Social Sciences, and are looking for different ways to include the national journals in their scientific evaluation process: Taiwan (Chen, 2004), Spain (Piñeiro & Ricks, 2015),

Poland (Winklawska, 1996), Serbia (Šipka, 2005), among other countries from Eastern Europe (Pajić, 2014) and a project originally european – European Reference Index for the Humanities and the Social Sciences-ERIH PLUS – which currently reaches worldwide.

By the way, despite being considered, national journals are minimally punctuated in comparison to journals indexed in WoS. One of the reasons of this non-recognition is the fact that many of these journals are not peer-reviewed, and, among the ones that are, some present and endogen editorial board (Packer, 2014). These facts explain the non-inclusion of these journals in the most recognized citation databases. Consequently, the commissions of researchers that tread the paths of the national research assessment exercise have to deal with these characteristics as extra factors. On the other hand, the creation of national data sources with defined selection process can be a solution.

The limited insertion of these countries' research in mainstream science finds no echo (Tijssen et al., 2006), since it lacks potential audience (MacRoberts & MacRoberts, 1996), indispensable to a consistent citation analysis. Thus, the evaluation is based strictly on productivity indicators, which impose even bigger challenge to establishing quality criteria. Therefore it became necessary the classification of the journals. A side effect of this is the need, for these researchers who work in a research area with local/regional focus (as typically occurs in Social Sciences and Humanities), to publish a significantly higher number of papers, inflating the entire scholarly communication system (Rego, 2014).

The journals evaluation performed by CAPES in Brazil fit these aspects and have considerably different criteria among the 48 areas (Miranda & Mugnaini, 2013). The most common criteria are (sorted in a decreasing way, according with the assigned importance): citation indicators (JCR Impact Factor, Scopus/SCImago or Google Scholar H-index, SCImago Journal Ranking, or a mix of more than one); indexing in databases with explicit selection criteria (such as Web of Science, Scopus, SciELO, thematic bases - e.g. MEDLINE, or regionals – such as, Redalyc, Latindex) or without explicit selection criteria (e.g. PASCAL); journals characteristics. All the journals where Brazilian researchers published their papers during the preceding triennium are classified. Some journals can receive different classifications from different areas (e.g. Cadernos de Saúde Publica).

Considering this scenario, stands out the need to complement the range of citation indicators for journals classification, providing a consistent view to the national context. In order to fulfill this need, in this paper a nationally recognized base - whose selection process considers explicit criteria – were created aggregating the national scientific production from SciELO and WoS (including the publications bibliographic references). The papers from this base were used to evaluate the national production and the references to evaluate the consumption. The former indicates the utility of each journal for its area; the latter indicates its impact. For both, the Bradford Zones (BZs) were calculated for each area and triennium.

This study aims to characterize the journals dynamics along five triennia and across the Bradford Zones for both production and consumption in the different areas. This study also searched for specific behaviors when comparing the journals from Brazil, from Latin America, and from the rest of the world. Other aspect analyzed was the temporal relationship in the climbs for the journals that presented climbs in both: production and consumption.

Methods

We retrieved the articles of Brazilian authors from Web of Science (WoS) and SciELO databases in a fifteen years period (1998 and 2012) - five triennia that match the national assessment exercise performed by CAPES. It was called production (PROD) data set, with 395,650 articles, published in 9,092 journals. WoS journals cover 56.4% of the articles, while 12.5% came from SciELO journals, and 28.8% from journals indexed in both databases. The remainder 23% came from journals indexed in SciELO in less than a half of a triennium

period, getting "not indexed" in such triennium - likewise, some SciELO journals turned SciELO/WoS in a triennial transition. We classified the journals using the Science Watch (2014) schema that relates WoS categories to 22 Essential Science Indicators categories, to which we added the Human Sciences. SciELO journals were classified at the same way.

Respectively, de consumption (CONS) data set was formed by 10,759,279 bibliographic references of the articles. In the case of SciELO, we just added references related to journals, but WoS data include references to proceedings, and sometimes, to thesis. These citations remained in such amount once it was discarded in the normalization process (described below) that resolved 71.3% of the references (7.67 million), as presented in Table 1.

For this first approach, we decided to restrict CONS information to citations directed to those titles that belong to PROD data set. The reason was the fact that we have almost 29% of total references not normalized automatically, and that PROD journals capture 90.3% of the normalized citation amount.

Table 1. Consumption data sets and its prevalence in the whole data set.

CONS data set (filters)	Citation window	Freq.	*% of* All citations	*% of* Normalized	*% of* Citations to PROD journals from any area	restricted to
All citations	all	10,759,279	*100.0%*			
	5 year	3,731,745	*34.7%*			
Normalized cited journal titles	all	7,666,238	*71.3%*	*100.0%*		
	5 year	2,777,013	*25.8%*	*36.2%*		
Citations to PROD journals, from any area	all	6,922,780	*64.3%*	*90.3%*	*100.0%*	
	5 year	2,655,547	*24.7%*	*34.6%*	*38.4%*	
Citations to PROD journals, restricted to its own area	all	3,748,044	*34.8%*	*48.9%*	*54.1%*	*100.0%*
	5 year	1,485,463	*13.8%*	*19.4%*	*21.5%*	*39.6%*

So we created four different CONS data sets (featured in bold in Tab. 1), resulting of crossing two dummy variables. The first one was the restriction or not of the citation window (all citations/5-year). The second concerns to the area from which the citation comes to one title. In one case we considered just the citation received from titles of the same ESI category (not too restrictive, since it aggregates lot of WoS categories). In the other case, we count the citations regardless the area. The former corresponds to 54.1% of the latter. To give an idea of our purpose on doing this, we calculated the share of citations each area receives on its own area. The first one in the list was Space Science (whose impact is the most endogenous, with 81.2%) and the last is Multidisciplinary (the least endogenous, as one can expect, with 2.3%).

The cited journal title normalization has been performed relating the ways a journal was cited by the papers' authors with a reference base which contains several variations of cited journal title for each journal obtained from different databases (ISSN, WoS, Scopus, SciELO and Lattes Platform). Thus, it was possible to identify the ISSN from the most of the cited journals. Whenever there were conflicts in this identification, i.e., the cited title could be referring to more than one journal, the year and volume of the publication was used. In order to do this, a database containing the valid years and volumes for each journal was created using information available from the citations were the normalization presented no conflict. If, even after the use of year and volume, the conflict persisted, the normalization was not performed for the respective citation.

Having the normalized data from PROD and CONS from the 9,092 journals, as well as their basic information (title, ISSN, classification area and citing and cited years) we identified BZs, with three partitions, for which of the 23 areas in each of the 5 triennia, totalizing 115 Bradford's distributions for PROD data set. In the case of CONS data sets we did the same,

but four times, resulting 460 distributions. Moreover, it was not assigned a BZ for the journals without production or consumption in a given triennium.

An initial analysis suggested some journals had to be discarded because there was not enough information to correctly identify the behavior of these journals along the triennia. It was the case of 2,376 journals that entered the PROD data set in the last two triennia (publishing less than ten papers per triennium). An opposite case consists of 39 journals that the community stopped publishing, having no publications in the last triennium. We also found 247 journals with no articles in four triennia, and no citation in four of five triennia. Without these exclusions, 6,492 journals remained in the analysis.

The dynamics of each journal across BZs in its area was assessed along the triennia. Journals without any change in the BZ along the five triennia were classified as Stable (S). The ones that climbed zones along the triennia without any fall were considered Up (U), and oppositely, journals that fell BZs across the triennia without any climb were considered Down (D). And a journal that had climbs and falls along the triennia was considered Oscillating (O).

Findings

The great amount of data demanded many cross-tabulations to define the way of treating the information of each variable. At this time, we decided not to differentiate if a journal climbed one (Z3 to Z2 or Z2 to Z1) or two (Z3 to Z1, in different triennium or in a unique double step). The same was proceeded in relation to journals that fell BZs.

As we needed to create a journal profile of change that combine both PROD and CONS, we aggregated it with the following ordered classification scheme: U, to any combination that occurred at least one Up, permitting one of them to be Stable (U-U, U-S or S-U, to both PROD and CONS, respectively); S-S, if the journal has being Stable in both dimensions; O, if it was found swinging in any of dimensions; and D, to any combination occurring a Down.

Table 2. Distribution of journals by profile of changes in Bradford zones of production and consumption, in the four CONS data sets – period 1998-2012.

Citation data sets	Journals (total)					
Publication country	U	S_S	O	D	%	Freq.
CONS, considering citations to PROD journals, from all areas						
all	***10.8%***	***76.1%***	***8.7%***	***4.4%***	***100.0%***	**6,492**
Other	*9.5%*	*77.3%*	*8.7%*	*4.4%*	*100.0%*	5,949
Latin Am. &Caribe	*2.6%*	*93.1%*	*3.4%*	*0.9%*	*100.0%*	233
Brazil	*41.0%*	*39.7%*	*11.0%*	*8.4%*	*100.0%*	310
5 year	***10.4%***	***73.4%***	***10.6%***	***5.6%***	***100.0%***	**6,410**
Other	*9.3%*	*74.5%*	*10.6%*	*5.7%*	*100.0%*	5,873
Latin Am. &Caribe	*3.1%*	*92.5%*	*3.9%*	*0.4%*	*100.0%*	228
Brazil	*38.2%*	*38.2%*	*14.9%*	*8.7%*	*100.0%*	309
CONS, considering citation to PROD journals, restricted to its own area						
all	***17.7%***	***65.0%***	***12.1%***	***5.3%***	***100.0%***	**6,430**
Other	*16.5%*	*65.8%*	*12.4%*	*5.2%*	*100.0%*	5,890
Latin Am. &Caribe	*3.9%*	*90.9%*	*3.9%*	*1.3%*	*100.0%*	232
Brazil	*50.3%*	*28.6%*	*12.3%*	*8.8%*	*100.0%*	308
5 year	***16.8%***	***60.9%***	***15.2%***	***7.0%***	***100.0%***	**6,310**
Other	*15.8%*	*61.6%*	*15.6%*	*7.0%*	*100.0%*	5,777
Latin Am. &Caribe	*4.8%*	*90.3%*	*3.5%*	*1.3%*	*100.0%*	227
Brazil	*45.8%*	*25.8%*	*17.6%*	*10.8%*	*100.0%*	306

So we first have looked to the general behavior of the journals, but focusing on the ones that improved across the triennia, at least in one of the dimensions. Tab. 2 shows that the great amount of journals (about 75%) are Stable in both dimensions, but we find 10% less journals

with this profile when we restrict the citations to the journals own area. It reveals that closing the context of citation to the specific area, we find more changes (and this tendency is even more evident in the 5-year citation window), especially for the journals that got climbed BZs.

Considering the publication country, we can realize that Brazilian journals present lesser stability, what is interesting to analyze changes, which is what we find abundantly: about 40% when considering citation from any area, and about 50% in the journals own area. Revealing the importance of studying the impact of these journals in their context.

Despite being less frequent, journals falling are more prevalent in the 5-year citation window.

All this tendencies have to be analyzed more carefully subsequently, since specific characteristics of the journals can help to understand such evidences.

Now focusing our analysis in U-U journals, it is important to mention that Clinical Medicine presents more journals (about 30), followed by Engineering (about 15), and in the opposite side is Physics (with 2). Another observation is that U-U Brazilian journals correspond to 14.5%, considering citations from all areas, and 18% in the journals own area. This is strongly different of journals out of Latin America & Caribe, whose correspondent percentage is about 3%. Among Brazilian journals, those indexed just in SciELO presents prevalence about 5% bigger than those indexed in both databases, when considering the citations in the journals own area. It reveals the growing importance of some journals in the national context, inside the area of specialty (data not shown).

Table 3. Distribution of journals U-U by triennium of first climb in Bradford zones of production and consumption, in the four CONS data sets – period 1998-2012.

Citation data sets		*% of journals: t* riennium of 1st climb in BZs (CONS)				Journals (total)	
U-U Journals		2	3	4	5	%	Freq.
CONS, considering citations to PROD journals, from all areas							
all		***11.4%***	***24.6%***	***29.8%***	***34.2%***	***100.0%***	**114**

	3	*19.5%*	*41.5%*	*31.7%*	*7.3%*	*100.0%*	41
	4	*3.7%*	*11.1%*	*40.7%*	*44.4%*	*100.0%*	54
	5	*6.3%*	*18.8%*	*25.0%*	*50.0%*	*100.0%*	32
CONS, considering citation to PROD journals, restricted to its own area							
all		***18.5%***	***24.3%***	***27.2%***	***30.1%***	***100.0%***	**173**
Triennium of 1st climb in BZs (PROD)	**2**	*41.4%*	*31.0%*	*20.7%*	*6.9%*	*100.0%*	29
	3	*8.6%*	*51.4%*	*28.6%*	*11.4%*	*100.0%*	35
	4	*22.2%*	*20.4%*	*31.5%*	*25.9%*	*100.0%*	54
	5	*9.1%*	*7.3%*	*25.5%*	*58.2%*	*100.0%*	55
5 year		***22.9%***	***24.0%***	***29.6%***	***23.5%***	***100.0%***	**179**
Triennium of 1st climb in BZs (PROD)	**2**	*44.0%*	*32.0%*	*24.0%*	*0.0%*	*100.0%*	25
	3	*20.0%*	*48.6%*	*25.7%*	*5.7%*	*100.0%*	35
	4	*27.3%*	*20.0%*	*40.0%*	*12.7%*	*100.0%*	55
	5	*12.5%*	*10.9%*	*25.0%*	*51.6%*	*100.0%*	64

Attempting to the temporal relation between Ups in PROD and CONS BZs, we performed a bivariate analysis considering the triennium each journal had its first climb in BZs. Tab. 3 presents the distribution of journals of different triennia of CONS (columns), related to each triennium of PROD (lines). The row cells with bigger prevalence of journals are identified in grey scale The row cells with bigger prevalence of journals are identified in grey scale. In the first CONS data set, considering the first line, that respect to 29 journals that climbed BZs first time in the 2nd triennium, we see that most of the journals climbed in CONS in the 3rd,

followed by the 4th. It shows that most of them improved CONS BZs after (as to say, both of them above the principal diagonal). When we drop to the next lines the two more prevalent cells change to the diagonal and one before. The same can be observed in the second CONS data set (5-year citation window) and a little bit more concentrated in the principal diagonal when restricting the citation to the journals own area. Maybe in subsequent analysis we can verify properly if the increasing of consumption is pulling the increasing of production.

Final remarks

As we can observe in this first approach, a national system combining publications from both contexts (national and international) can be a useful tool to research evaluation. Bradford zones showed to be an interesting relative indicator, when applied to evaluative purposes. Especially the joint analysis of production and consumption dimensions can bring a more complete view of the scientific communication flow, considering the changes of journals through zones in both dimensions. National impact indicators can complement Impact Factor, in the sense it can add the local importance, as observed about SciELO journals.

Abstract
We analyse the co-authorship and publication patterns of 863 mainstream WoS papers in the field of Chemistry co-authored between Mexican and French institutions from 1984 to 2013 with the purpose of identifying and characterizing the dynamics of sustained collaborative research partnerships in the field between the two countries. From a normalized set of the most productive authors with ≥ 5 co-authorships we selected three Mexican scientists for a detailed analysis of their co-authorship network visualized using Gephi software and its development over time. The first was the most productive Mexican author from the main national university whose collaboration with France spanned the period from 1987-2012, while the second and third researchers work in provincial universities and whose collaboration with France is more recent but lasting 10 and 15 years respectively, and also continues up to the present day. Preliminary results suggest that sustained partnerships are driven by a strong central bond between the Mexican researcher and their foreign partner. In the first two cases, the bond is with directly with a French scientist but in the third, is stronger with an Italian rather than with the French counterpart.

Conference Topic
Country level studies

Introduction
A recent paper examining the main research thrusts and future challenges facing research into scientific collaboration mentions the need to characterize the factors underpinning successful collaborations and to ascertain how collaboration can benefit scientific development in the less developed countries (González Alcaide & Gómez Ferri, 2014). International collaboration is known to be especially important for countries whose scientific infrastructure and capacity can benefit from forging alliances with researchers from institutions abroad. Colombian researchers for instance were found to increase team output by almost 40% by co-authoring with overseas partners (Ordóñez-Matamoros, Cozzens & García, 2010).

We know little about the duration of international research collaboration between individual researchers in terms of the number and timeline of co-authored papers. Two decades ago a study looked at the production and duration of collaboration between researchers from institutions in Mexico and France in all scientific areas (Narvaez-Berthelemot & Russell, 1996). Chemistry was the subject of the greatest number of bilateral publications as well as having the highest continuity index defined as the number of articles (>2) in a given period, in this case 1980-1989, that were co-authored by the same groups. More recently an analysis of co-publications between the two countries from 1984 to 2010, showed that Chemistry gradually lost ground with respect to other disciplines notably Physics, even though the number of papers increased with time (Ainsworth et al., 2014).

The present research in progress sets out to characterize the publication dynamics of sustained collaborative research partnerships between Mexico and France in Chemistry in the period 1984-2013. We take as our starting point, the most productive authors in papers with at least

one author from both Mexico and France. Considering that interpersonal links are the key drivers of collaboration (Gaillard et al., 2013) we are also interested in analysing the relationship between co-authors and tracing the development of their networks over time. Another aspect of the collaboration we consider is the level of importance of the relationship with Mexico in the case of the French scientists or France for the Mexicans, for the total body of work of the key players during the same period and who might be the senior partner in the bilateral relationship. We adopt two approaches when analysing our publication and co-authorships data based on the following assumptions: 1. Sustained collaboration is characterized by a central relationship established between one Mexican and one French scientist. 2. Sustained collaboration between the two countries is characterized by a series of relationships forged with different French scientists and institutions.

Data source and methods

Data source was the Web of Science searching France and Mexico in the country field, covering the period 1984-2013, in the discipline of Chemistry. WoS journal subject categories were adapted to the RFCD classification scheme for the assignment of the discipline (Butler, Henadeera y Biglia, 2006). Records were downloaded to a local MySQL database. Author names with ≥ 5 co-authorships were normalized and assigned (often several) Scopus author ids and affiliations, given that author identification in WoS proved less than adequate for our purpose. Case studies were selected from the group of the most prolific Mexican authors with bilateral France-Mexico collaboration. For this preliminary presentation of results we have selected three case studies based on our initial analysis of their collaboration dynamics. These include the most prolific Mexican researcher and two other productive researchers from established groups with substantial French collaboration from two provincial state universities, namely Cecilio Álvarez y Toledano from the Institute of Chemistry at the big national Mexican university, Universidad Nacional Autónoma de México (UNAM), Ricardo Navarro-Mendoza from the Universidad de Guanajuato (UG) and Claudio Marcelo Zicovich-Wilson from the Universidad Autónoma del Estado de Morelos (UAEM).

The interactive visualization open source software Gephi was used to select and represent these collaborations and to show sub-networks within clusters. Co-authors involved in each of the papers were examined to characterize the temporal collaboration, and separately the normalized author information from Scopus was used to represent the importance of the Mexico-France collaboration in the main authors' output. The corresponding author of each paper was also identified.

Overall panorama of Mexico-France co-authorship in Chemistry

The number of co-authored papers in Chemistry between Mexico and France showed a steady rise from a mere two in 1984 to 54 in 2013 (Figure 1). Social network graphs (not shown here) show an increasing dense and complex series of relationships when comparing the first 15 years (1984-1993) with the second period (1994-2013).

Publication dynamics of sustained partnerships

Figure 2, divided into three decades, shows the dense network of co-authorships of Cecilio Álvarez y Toledano with French institutions during our period of study. The strongest link is with Henri Rudler of the Université Pierre et Marie Curie, Institut Parisien de Chimie Moléculaire starting in 1987, and to a lesser extent with Andrée Parlier of the same laboratory except during the middle period 1994-2003. Rubén Alfredo Toscano works in the same institute as Cecilio Álvarez y Toledano as a highly specialized technician and is a regular co-author. Of the 29 papers of Álvarez y Toledano in co-authorship with a French institution, 23 were published in co-authorship with Rudler. There was a notable pause in their collaboration

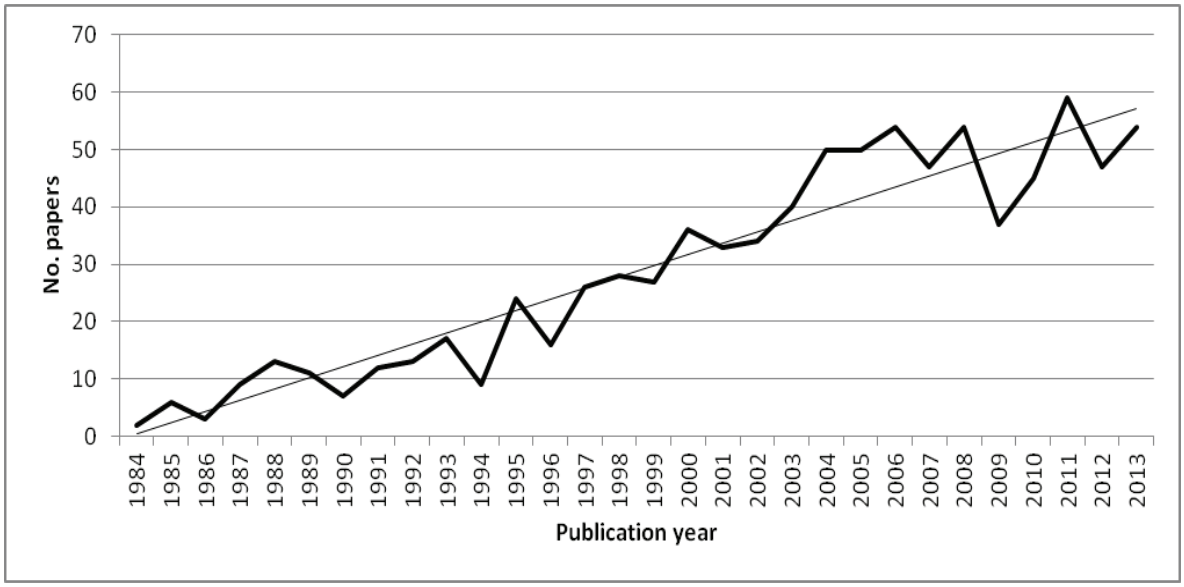

Figure 1. Papers in collaboration between Mexico and France in Chemistry 1984-2013.

from 1996 to 2004 when Álvarez y Toledano co-authored two papers with two other French authors, Henri Arzoumanian, Aix-Marseille Université, and Bruno Donnadieu now of the newly formed Université de Montpellier but at the time of the Universite Montpellier 2, respectively and involving a different set of co-authors. Nonetheless, Andrée Parlier and Henri Rudler continued their collaboration without Álvarez and Toledano during this period, together with Jacqueline Vaissermann, also from the same laboratory.

During the first two periods four clusters of co-authors are apparent, while in the most recent period 2004-2013, co-authorships are concentrated in two with Rudler and Parlier at the centre, respectively. A strong central bond with Henri Rudler is evident in the collaboration of Álvarez y Toledano over the whole period suggesting that this bilateral partnership is the motor driving this example of sustained co-authorship between Mexico and France.

Data taken from Scopus using the author id field for papers co-authored by Rudler and Álvarez-Toledano in Chemistry show Rudler to be senior (corresponding) author in 11 of these 29 papers as compared to 6 in the case of Álvarez-Toledano, which would seem to show that Rudler is the senior partner in this collaboration. The issues of authorship order are discipline-specific, but in many scientific areas it is accepted that the principal investigator is named as the corresponding author (Frandsen & Nicolaisen, 2010). These 29 papers represent 26% of all Rudler's papers as represented in Scopus, compared to 20% of those of Álvarez-Toledano suggesting that the bilateral partnership is of significance for the output in Chemistry for both researchers.

The network of collaboration with French institutions starting in 1998 around Ricardo Navarro Mendoza from the Universidad de Guanajuato appear in Figure 3 with strong links to Eric Guibal from the École des Mines d'Alès. Fourteen of the 15 papers published from 1998-2012 appear with both authors. Imelda Saucedo Medina, also from the Universidad de Guanajuato, is a co-author in 11 of these papers. In one article at the beginning of the period in 1998, there is a collaboration with other French authors, Denise Bauer and Gérard Cote, both from the École Nationale Supérieure de Chimie de Paris, and in two articles, 2000 and 2001 with Thierry Vincent from École des Mines d'Alès.

This suggests a consolidated partnership, though perhaps also an unequal one. Scopus data for papers co-authored by author Ricardo Navarro Mendoza and Eric Guibal in Chemistry show Navarro-Mendoza to be corresponding author in 8 of the 11 instances, compared to 3 for

Guibal. This would suggest that in this case the Mexican is the senior partner. These 11 papers represent 33% of all Navarro Mendoza's papers in Scopus, but only 7% of Guibal's.

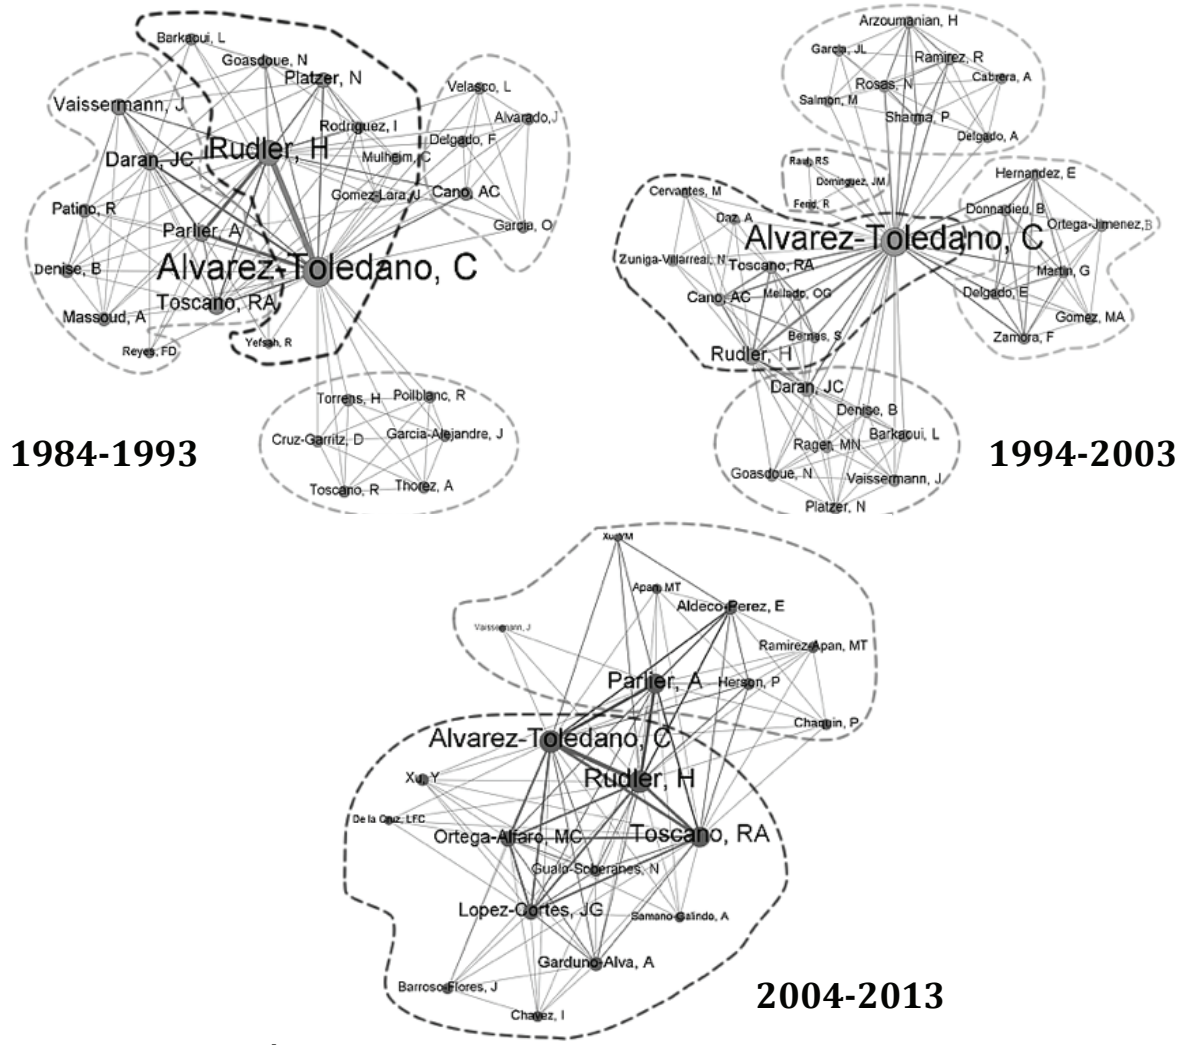

Figure 2. Álvarez y Toledano: Network of ≥ 3 co-authorships 1984-2013.

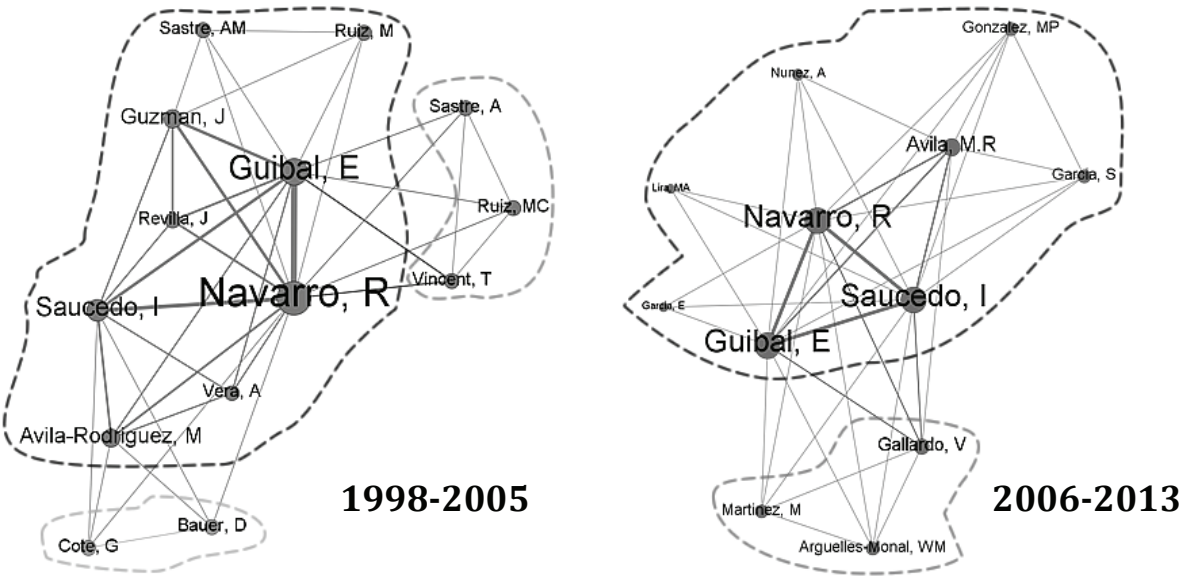

Figure 3. Navarro Mendoza: Network of ≥ 3 co-authorships 1998-2013.

The co-authorship of Claudio Marcelo Zicovich Wilson from the Universidad Autónoma del Estado de Morelos with researchers from France that began in 2004, is reflected in Figure 4, as is also the importance of a group of Italian authors for this collaboration. Roberto Dovesi from the Universita degli Studi di Torino appears as co-author in 13 of the 16 papers of Zicovich Wilson where there are also authors from French institutions in the period 2004-2013. Other researchers from the same Italian institution such as Roberto Orlando (6 papers), Piero Ugliengo (4 papers) Loredana Valenzano (3 papers 2006-2008) and Raffaella Demichelis (also 3) appear together with Dovesi, the latter co-author during 2010-2011. The predominant French author is Fabien de Pascale, at the time of Université Henri Poincaré - Nancy I, who is a co-author in 8 of the 16 papers during 2004-2010, Yves Noël, CNRS Institut des Sciences de la Terre de Paris with 5 papers 2007 then 2010-2012, together with Michel Rérat, Université de Pau et des Pays de L'Adour form a separate French collaboration, albeit together with Roberto Dovesi. The central role of Roberto Dovesi in the Mexico-France collaboration seems evident from the data taken from WoS. Data from Scopus for papers in Chemistry co-authored by Zicovich Wilson and Pascale reveal that the Mexican is corresponding author in only one of these, and Pascale not in any of them. (Pascale appears as first author in three of them.) The role of Roberto Dovesi in this collaboration seems to be confirmed in that he is corresponding author in 6 of these 10 papers. These papers correspond to 9% of all Zicovich Wilson's papers, 40% of Pascale's but only 4% of those of Dovesi. These data imply that Pascale is the junior partner here.

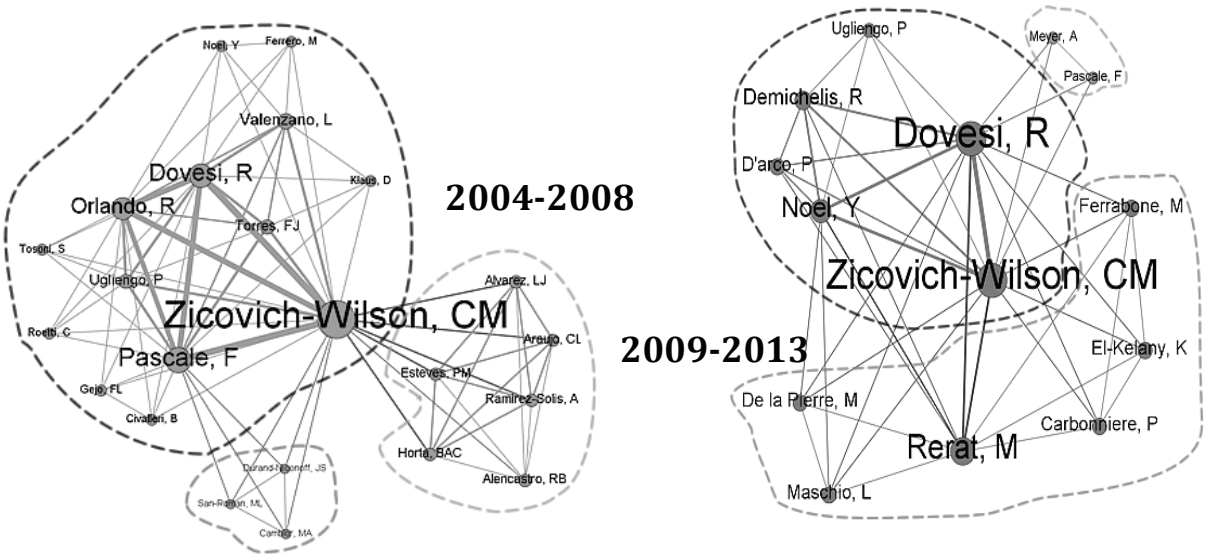

Figure 4. Zicovich Wilson: Network of ≥ 3 co-authorships 2004-2013

Preliminary Conclusions

Our detailed analyses of the co-authorship networks of three Mexican scientists, one from the large national university located in Mexico City where the national scientific research effort is centred and two from provincial universities, with ≥ 5 co-authorships with France in mainstream Chemistry journals during our period of study, lend support to our initial assumption that sustained collaboration is characterized by a central relationship established between two individual scientists but not necessarily directly between a Mexican and a French scientist. In the first two cases the bond is with a French scientist but in the third, is stronger with an Italian rather than with the French co-author. These central relationships are

strengthened and supported by frequent co-authorship from both Mexican and French groups in the first two cases and in the third, by the Italian group. A substantial number of one-time co-authors was evident in all three cases. We found differences with respect to the importance of the bilateral collaboration for the Mexican and French authors and with respect to which of the two could be considered the senior author. These preliminary conclusions will be tested by analysing further case studies of sustained partnerships between Mexican and French chemists.

Innovation and Economic Growth: Delineating the Impact of Large and Small Innovators in European Manufacturing

Jan-Bart Vervenne and Bart Van Looy

{jan-bart.vervenne, bart.vanlooy}@kuleuven.be
KU Leuven, Faculty of Business and Economics, Department of Managerial Economics, Strategy and Innovation, Naamsestraat 69, B-3000 Leuven (Belgium)

Abstract
In the course of the past decades, the link between innovation and economic growth has become a well-established one in the economic literature. In the current study an attempt has been provided to complement this line of research with an assessment of the wealth implications of the 'entrepreneurialisation' of innovation systems. Relying on a 9 year panel of post-millennial observations for 22 European countries and using stock based patent indicators, it was found that on top of the positive productivity impact of innovative activity growth, a premium effect can be observed when the stake of small firms in it increased at the same time. These findings can be interpreted as confirming Baumol's (2004) assignment of different roles to large and small firms in innovation systems: the former as provider of the technological breakthrough that the latter improves in a range of incremental steps. The entrepreneurialisation of manufacturing as a whole, measured by the stakes of small businesses in employment, yields a productivity discount: outside of innovative activities, economies of scale outweigh co-occurring diseconomies of scale. Distinct country groups in different stages of economic development form the main drivers of both entrepreneurialisation effects: a core of North-Western European countries that has attained the innovation-driven stage against a periphery of Southern and Eastern European countries around them that have not transcended the more preliminary efficiency-driven stage. Further rationales explaining the additional explanatory power of entrepreneurial innovation were found in the weakening of the link between innovation measured by patents and added value in large firms.

Conference Topic
Country-level studies; Patent analysis

Introduction
Substantial agreement exists among economists and policymakers that technological innovation is a key driver of sustainable economic growth. Technological innovation implies the implementation of inventions in the production of final goods or services and as such yields productivity gains for the innovating economy. Using knowledge capital to transform existing knowledge into such inventions, the amount of research and development (R&D) efforts is an important determinant of the pace of technological innovation.

Endogenous growth scholars have shown that technological innovation is an endogenous component of the process of long-run economic growth, both theoretically (Romer, 1986) as well as empirically (Nadiri, 1993). As opposed to their neoclassical counterparts (Solow, 1956), they postulate that technological innovation is an inherent component of the growth process: profit-maximising firms purposely allocate resources towards R&D in the presence of sufficient perspectives suggesting that they will be capable to appropriate the gains from it.

The analysis in this paper contributes to the mentioned line of research by complementing the measurement of overall technological innovation effects using patent statistics with an additional, patent-based indicator capturing the footprint of small, more entrepreneurial firms in the countries' stock of knowledge capital.[1] Further explanation for the rationale triggering

[1] Note that throughout this excerpt alternately we describe the firms of our interest as entrepreneurial or small. As Wennekers and Thurik (1999) argue, smallness and entrepreneurship can only be synonymous when management and ownership are not distinct. Subsidiaries of large business groups can qualify as small as well when shareholder information is not taken into account. This remark is of concern to us given the definition of small firms we will use in the empirical part (cf. below). However, given that small firms pertaining to larger

our interest to differentiate between innovation induced by small and large firms follows next. Subsequently methodology and results are reported, followed by some concluding notes. The focus on Europe in this study is justified among others by referring to the entrepreneurial innovation deficit Europe faces in comparison with the US (Veugelers, 2009).

Delineating the entrepreneurial contributions to innovation

The rationale to differentiate between incumbent and entrepreneurial innovation draws extensively from research on entrepreneurial innovation by Audretsch (2001), Baumol (2004) and Veugelers (2009). Whereas Schumpeter in 1942 predicted the gradual replacement of the entrepreneurial inventor - naturally associated with the small start-up - by routinized innovation organized by large industrials, Baumol (2004) emphasized the complementary relationship of both types of players within innovation systems. Their organizational design has induced them to specialize in different components of society's innovation process. Over the past decades revolutionary breakthrough inventions in the US have continued to come predominantly from small entrepreneurial enterprises whereas large industry have provided ever-increasing streams of incremental improvements to them multiplying capacity and speed and increasing reliability and user-friendliness. This is the result of the oligopolistic competition this relatively limited amount of very large firms, particularly in high-tech industries, engage in. It forces them to keep innovating in order to survive, but in a very risk-free and thus path-dependent way, avoiding the risks of the unknown that the revolutionary breakthrough entails. As such, inert incumbents leave plenty of room to explore for the enterprising entrepreneur. Unaffected by concerns relating to existing products and markets, the latter can pick up the ideas the former would deem too risky (Audretsch, 2001; Baumol, 2004). The other way around, incumbents are more suited to follow-up and improve those breakthrough innovations in more mature stages of the technology life-cycle (Baumol 2004).

Plugging the level of 'entrepreneurialisation' of innovation into a growth model

Methodology

The neo-classical growth model (Wong et al., 2005) we use to test a number of research questions distilled from the context described above is based on an augmented Cobb-Douglas production function:

$$Y = A^{O} K^{\propto} L^{\beta}$$

Where Y = output, A^{O}= total factor productivity, K = stock of physical capital and L = labor employed. Assuming constant returns to scale, $\alpha + \beta = 1$, both sides of the equation are then divided by labour. Taking natural logs the resulting model to estimate economic productivity per employee goes as follows:

$$\ln\left(\frac{Y}{L}\right) = lnA^{o} + \propto ln\left(\frac{K}{L}\right)$$

Following the approach by Wong et al. (2005), we assume that the stock of knowledge capital is the main determinant of total factor productivity, A^{O}. The stock of knowledge capital is captured using technological innovation statistics, among which patent based-indicators comprise one of the best proxies. More specifically, the level of innovation (*INNO)* is measured using stocks of patent applications depreciating at a rate of 20% per year as the

conglomerates in the countries of our sample never comprise a majority, on average our population of small firms can be described as 'more entrepreneurial'.

effects of investment in innovation transcend the short run.[2] The technological innovation variable was normalized by employment to capture its intensity and limit the effects of country size as much as possible. As suggested in the previous section, as factor of total productivity the general intensity of technological innovation is complemented by a patent-based indicator, measuring the degree of small firm engagement in innovative activity, and an equivalent employment-based indicator to control for overall small firm activity. The latter to make sure increased innovative activity of small firms is not simply capturing the potential productivity effects of an increase in entrepreneurial activity in general.

Determining the degree to which national innovation systems have ran on entrepreneurial initiative was based on the assignment of patents to small and large firms using the methodology presented in Eurostat (2014).[3] Due to shortcomings in the matching methodology and data gaps in the financial database - among others the result of country-specific disclosure exemptions rewarded to certain company types - only for approximately 62% of the corporate applicants in Europe firm size could be determined. We assume however that these country-level constraints equally hold for all years of the sample and as such are coped with by estimating coefficients using country fixed effects (cf. infra).

The effects of entrepreneurial and incumbent engagement in innovation could not just be measured by plugging raw stocks of their respective patent applications into the equation: R&D clustering dynamics within countries result in a high correlation – more than 0.97 even when removing country effects – with the annual innovative activity deployed by the national innovation system as a whole, that is already captured in the core variable measuring technological innovation. Given our main interest towards the benefits of entrepreneurial innovation and to avoid multicollinearity, the degree of 'entrepreneurialisation' of corporate technological innovation (*ENTR_INNO*) was measured by computing the share of small firms in the stock of patents assigned to firms with identified size.

The within variance of this share value captures to what extent small firms have shown relative over- or underactivity in R&D in comparison with their large counterparts. Given the large level of correlation among the small firm, large firm and overall patent stocks it is safe to assume that entrepreneurial and incumbent innovation do not have an opposite effect on economic productivity which would hamper a straightforward interpretation of *ENTR_INNO*. At most one of them can have a relatively larger impact on productivity. In line with the rationale elaborated above we expect that to be the small innovators. The result of that should

[2] All patent statistics were extracted from EPO's Worldwide Patent Statistical Database 'PATSTAT' (Autumn version 2014). In general we relied on EPO patent applications, including granted and non-granted patents, with the idea that counting both yields a relatively more input-oriented measure capturing the level of R&D spending than if one would stick to grants only (Ernst, 2003). Depreciation of the patent stock at a rate of 20% per year is based on the perpetual inventory method described in Ulku (2004). The patent stock variable incorporates annual EPO patent counts from 1970 onwards. The restriction of our attention to EPO patents can be easily justified given the geographical reach of our dataset and their costliness, which is a direct result of their supra-national character. Being that expensive, especially for more financially constrained SMEs, counts of them at the macro-level bear the potential to be good signals of R&D input & output levels per country over time.

[3] The lack of dynamic shareholder data in BvD's Amadeus (a database gathering annual account information) withheld us from determining firm size at the business group level. In contrast with the matching exercise presented in Eurostat (2014), firm size was determined dynamically by linking patents to financial information from the financial years that corresponded with the patent application filing year. In addition financial account data from Amadeus 2012 was enriched with equivalent information from earlier versions (2004 and 2007) to dispose of financial information in the earliest years of the matched sample (1999-2011) and to account for the BvD rule to discard companies not filing accounts for 5 years in a row. Firm size – or rather entity size – classification for patenting companies from 1999 onwards was based on the European Commission SME definition (2005): enterprises that employ fewer than 250 employees and which have an annual turnover not exceeding 50 million euro, and/or an annual balance sheet total not exceeding 43 million euro.

be *ENTR_INNO* exerting a positive effect on productivity, which would imply the existence of a productivity premium to an increased entrepreneurial stake in corporate innovation.

Given that the large majority of patents in Europe can be assigned to the manufacturing industry (Fraunhofer, 2003), downloads of observations for the non-patent based variables of country *c* in year *t* were restricted to that sector. Indicators for value added at factor cost (*VAFC*), the number of persons employees (*NPE*), gross investment in tangible goods (*GITG*) and the share of small firms in corporate employment (*ENTR_EMP*) were extracted from the Eurostat website.[4] [5] Furthermore, a quadratic year trend is included to capture time effects.[6] Conform previous research all R&D related indicators are lagged since it is assumed that the effects of R&D on economic performance take a couple of years to surface. In line with Ulku (2004) and given the limited time-series at our disposal we opted for a 2-year time lag. Following an equivalent rationale, the physical investment and share of entrepreneurial employment variables were also lagged by 1 year.

The resulting equation to be estimated using panel data techniques is:

$$lnVAFC/NPE_{ct} = \propto + \beta_1 lnGITG/NPE_{c,t-1} + \beta_3 INNO/NPE_{c,t-2} + \beta_4 ENTR\_INNO_{c,t-2} + \beta_5 ENTR\_EMP_{c,t-1} + year + year^2 + u_c + \varepsilon_{ct}$$

Results

Coefficients are estimated using fixed effects OLS.[7] Table 1 reports the estimation results, including robust standard errors, for the overall set of European countries (panel 1: ALL) and split sets of countries that lead (panel 2: LEADERS) or lag behind (panel 3: LAGGARDS) in terms of innovation according to the European Commission's (EC) Innovation Union Scoreboard (2015). The left hand of each panel contains estimates for the basic model as expressed in the equation above. The right hand side in addition reports an additional interaction effect between the technological innovation intensity and its degree of 'entrepreneurialisation'.

Conclusion and directions for future research

Apart from confirming previous findings regarding the positive impact of technological innovation on economic output, overall results (ALL) reveal that there is an additional productivity premium to a larger share of entrepreneurial engagement in the development of new, patented technology. The entrepreneurialisation of employment on the other hand, a broader measure of corporate activity, appears to be negatively associated with productivity.

---

[4] The resulting set of 22 countries consists of: Austria, Belgium, Germany, Denmark, Finland, France, United Kingdom, the Netherlands, Norway, Slovenia, Sweden (LEADERS), Czech Republic, Cyprus, Estonia, Greece, Hungary, Italy, Latvia, Poland, Portugal, Slovakia and Spain (LAGGARDS). Other European countries were discarded for multiple reasons: a lack of employment, investment or gross added value statistics available to the public or a too low rate of patenting companies matched to companies in the financial database, as such, hampering a representative image of the distribution of patents between incumbents and small businesses. Unusual annual productivity growth induced by preferential tax regimes for foreign firms, inciting those to shift profits to local subsidiaries, resulted in elimination of Ireland and Luxemburg from the sample as well.

[5] All currency-based series – expressed in Euro – were deflated using per country GDP price deflators (World Bank WDI website). Due to the lack of availability of stock variables capturing the total amount of outstanding fixed capital, in line with Ulku (2004) we used the flow variant.

[6] Preferably time dummies are included but using a functional form, in this case a quadratic trend allowing for one up and one down trend, can be an alternative in order to preserve degrees of freedom. Results turned out to be largely consistent for trend- and dummy-based models.

[7] Correlations among demeaned variables suggest that multicollinearity is not an issue for within-transformed variables.

The dynamics behind these observed effects could be explained among others by referring to a mix of economies and diseconomies of scale (Brock & Evans, 1989). The observation of an entrepreneurial innovation premium could be attributed to the higher likelihood that patents introduced by small businesses will be high impact ones, making the average small firm patent more technically and thus more economically important. This finding complies with Baumol's (2004) assignment of different roles to small and large firms in innovation systems with the former being relatively better at the introduction of radical new technologies and the latter in perfecting those by incremental improvements. The observed discount observed on the entrepreneurialisation of employment suggests that in the non-innovation-related aspects of business operations the economies of scale outweigh the diseconomies of scale. This observation counters earlier findings underlining the increasing importance of non-technologically oriented scale diseconomies that result from growing markets valuing specialized products, increasing advantages to flexibility in a globalized world, the rising availability of educated labour to recruit from and decreasing standard fixed costs of running a business (Brock & Evans, 1989).

Separate results for countries tagged by the EC as innovation leaders and laggards further reveal some of the potential deeper dynamics behind this. Not surprisingly, the innovation leaders turn out to be the driving force behind the productivity premiums to technological innovation in general and entrepreneurial innovation. The former and latter can be seen as highly intertwined: established knowledge-based economies possess the critical mass that is necessary to produce knowledge that matters. Knowledge stock growth in turn increases the potential for spill-overs of various ideas to entrepreneurs. On top of that, local rivalry between high-tech entrepreneurial ventures capturing the same localized knowledge flows increases their respective efficiency (Furman et al., 2002). The laggard countries appear to be the

driving force behind the productivity discounts associated with small firm employment share growth. The distinct geographic origins of the premium effect on entrepreneurial innovation and discount effect on entrepreneurial employment confirm the heterogeneous nature of the European economic landscape. Relying on Porter et al.'s (2002) framework of economic development to explain differences between split dataset results one could claim that it consists of less developed countries in a 'preliminary' efficiency-driven stage and more advanced countries in the 'final' innovation-driven stage (Porter et al., 2002; Acs et al., 2008).

In a complementary attempt to explain the additional explanatory power of entrepreneurial innovation in general we refer to the increasing disjunction between patents as measure of innovation and productivity in large firms: the availability of in-house IP departments increase their propensity to patent low-value inventions and tax optimization strategies applied by multinationals blur the value of license fees as proxy for added value.

Future research is necessary to further disentangle the mechanics behind the observed effects. Measurement of knowledge spill-overs could help to provide insights about their nature, origins and the direction in which they are heading. Adding proxies capturing the distinct drivers of scale diseconomies is another potential direction for future research. Further inquiry is also needed to list the policy implications of our findings.

Introduction

Chemistry is the most preferred research area among Indian scientists for quite some time in terms of total number of publication, global share, visibility and citation impact are concerned. Growth rate of India in chemistry research area is more than that of global growth rate as evidenced from the data covered in Web of Science database (WoS). The trend of research output in chemistry clearly indicates that India is steadily putting stiff challenge to traditionally established countries like Japan and Germany and even surpassed them in 2014 to acquire 3rd position in global ranking. From this study we predict that India will grow further in chemistry research area and even can put challenge to USA and China in long run.

The output and trend of science & technology (S&T) research in India are of considerable interest to scientometricians from all over the world for quite some time. Gupta and Dhawan (2009), Glänzel and Gupta (2008) and Gunasekaran, Batcha and Sivaraman (2006) have studied different aspects of S&T research in India.

Methodology

Data sources and processing

All bibliometric data have been extracted from WoS Core Collection of Thomson Reuters till April 30, 2015. The period for publication activity has been taken for six years (2009-2014) as findings till 2008 are available in literature.

Results and Discussions

In chemistry research area a total 1,045,343 number of papers has been published during the period 2009-2014. USA and China are leaders in this field in terms of number of publications with global share of 22.502% and 20.792% respectively. India is at 5th position with global share of 5.767%. Chemistry research output of ten most productive countries excluding USA and China in terms of global share has been shown in Figure 1. India's growth is very steady during this period and acquired 3rd position in 2014 followed by USA and China, with global share of 6.456%. India has published maximum number of research papers in Chemistry compared to other research areas and its global share in chemistry research has been increased steadily during 2009 to 2014.

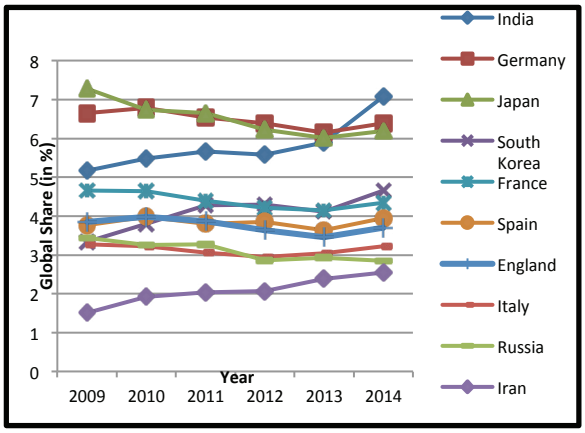

Figure 1. Global share of countries in chemistry.

It is evident from Figure 1 that global share of Japan has been decreased during 2009-2014 and its positions in global ranking have been fallen from 3rd position in 2009 to 5th position in 2014. Global share of Germany in Chemistry research has been decreased slightly during this period but Germany has managed to keep its position at 4th during the entire period. South Korea and Iran have increased their research output in chemistry steadily in terms of global share during this period. Research output of other countries (France, England, Spain, Italy and Russia) shown in this Figure are comparable to each other in chemistry and they are placed in between 7th to 11th positions during this period.

Table 1 shows India's ranking in major research areas covered in WoS during 2009-2014. In terms of number of publications and global share, India's performance is the best in Chemistry.

In Table 2 we have shown the h-index and average citation per article in chemistry during 2009-2012. We see that h-index and average citation per article are comparable with that of Japan and Germany.

Table 1. India's Position in major research areas in terms of global share.

Research Areas	2009	2010	2011	2012	2013	2014
Physics	10	9	8	8	7	**7**
Chemistry	5	5	5	5	5	**3**

Neuroscience Neurology	18	17	17	16	**16**	17

Table 2. Comparison of citation and h-index of chemistry publications during 2009-2012.

Countries	2009		2010		2011		2012	
	h- index	Avg Citation	h- index	Avg Citation	h- index	Avg Citation	h- index	Avg Citation
India	83	11.54	78	10.39	66	8.41	57	6.49
Japan	106	15.83	97	13.81	89	11.63	66	7.94
Germany	118	19.86	125	19.29	95	14.04	74	9.94

Conclusions

This study clearly indicates the trends in chemistry research during 2009-2014 for most productive countries in terms of number of publications and global share. It is evident from the results that India has done remarkable progress in chemistry research area during this period. One of the reasons for this progress is that quite a few key persons in science policy makers in India are having chemistry background. Indian scientists working in the field of chemistry are more focused and recognized worldwide as many of them have been awarded TWAS prize and fellowship, FRS, and other distinguished international fellowships and medals. Strong collaboration between India and other countries in chemistry research is worth mentioning as 10,941 numbers of papers out of total 60,285 are published in collaboration. As a traditional subject, most of the Indian universities teach chemistry and around 40% of total publications is contributed by the universities. Research laboratories also get a steady flow of trained students with chemistry background from universities. Looking at the distribution of the publications to the institutes we see that CSIR laboratories publish most (11,037) followed by IITs (7,382) in chemistry. Some of the most productive laboratories in chemistry research in India are BARC (2,394), IICT (2,210), IISc (2,065), IACS (1580) and NCL (1,508). Prominent universities in chemistry research are JU (1,262), DU (1,182) and BHU (1,136). We see that there is almost no role of industries as per the funding of research is concerned in the field of chemistry in India. CSIR, DST and UGC are the major sponsors in chemistry research in India. As per the topic or subject category is concerned where Indian scientists publish more, we see Physical chemistry is the most focused (29%) followed by Organic (20%), Inorganic (11%), Analytical (10%), Applied (7%), Nanoscience (6%) and Atomic-Molecular (5%) respectively. The bright side of chemistry research in India is also reflected in the number of patents granted in this subject area. From Derwent Innovations Index of WoS, we see that out of total 462 numbers of patents granted to Indian innovators during 2009-2014, 330 numbers i.e. 71% are in the field of chemistry. Interestingly, DRDO, India holds most (79%) of the patents. The picture is not much different in Indian patent database (http://ipindiaservices.gov.in/publicsearch/), where we see 4,801 numbers of patents (i.e. 37%) have been granted in chemistry research area out of total 12,982 patents granted in all fields during 2009-14. India has a large consumer base. As a result chemical industries in different sectors like fertilizer, pesticide, plastic, paint, petro-chemical, medicine, cosmetics and health care products are thriving in India. So career as research scientist in chemistry is attractive for better placement in the R&D labs of those industries. India's contribution in chemistry research has been recognized by ACS and designated IACS, Kolkata on 15/12/1998 as International Historic Chemical Landmark for C V Raman and the Raman Effect.

Introduction

The study of national efforts in R&D by institutional sector is a matter of great concern because sectors differ in their main activities, accounting systems, orientation towards research and type of R&D (OECD, 2003). However, bibliometric analyses at the level of institutional sectors are not very common because the assignation of centres to sectors is not free of difficulties and the resulting sectors may entail a certain degree of heterogeneity. The role of institutional sectors in the scientific activity of countries, either for the total country (Godin & Gingras, 2000; Moya et al., 2013) or in a given field (Lander, 2013), has been analysed in the literature, although studies dealing with specific sectors such as universities or companies are much more frequent.

In most countries, main institutional sectors in publications include universities, hospitals and public research centres, while papers from non-profit entities (NPE) are usually scarce. Although this applies in Spain, an impressive increase in papers from NPE has been observed in the last fifteen years. This paper aims to analyse the research performance of non-profit entities in Spain with regard to activity, impact and collaboration; to locate them in the national context; and to identify main types of active organisations.

Methods

Spanish publications (original articles and reviews), hereafter papers, covered by Web of Science (WoS, 2000-2011), search strategy CU=Spain and PY=2000-2011, are analysed. Six institutional sectors are identified in all addresses through a semi-automatic process (Morillo et al., 2013) followed by a manual revision to assess validity: companies, health sector, non-profit entities, public administration, public research centres and university. A full counting method is used.

The impact of publications is analysed through the percentage of papers in first quartile journals within each field (%Q1), normalised position (NP) (Bordons & Barrigón, 1992), relative impact factor (RIF), % non-cited papers and citations relative to country average (RC) (three-year citation window). The orientation of sectors towards collaborative research is explored through the number of authors per paper, number of institutions per paper and collaborative pattern (percentage of papers with a single institution, percentage of papers with national collaboration, percentage of papers with international collaboration). An in-depth analysis of NPE is carried out. The NPE's activity index (AI) in ten broad thematic areas is obtained to gain insight into the specialisation profile of these entities as compared to Spain.

Results

Main institutional sectors in Spanish papers in WoS (2000–2011) include university (66%), public research organisations (22%) and the health sector (18%). Non–profit entities amount to 10% of the papers, and show the highest increase during the period (3% of the country output in 2000 vs. 18% in 2011). This sector shows high specialization in Biomedicine (AI=1.59) and Clinical Medicine (AI=1.67). Collaboration in NPE is above the country average in terms of team size (11 vs. 8), number of institutions per paper (5 vs. 3) and share of collaborative papers (91% vs. 68%). NPE show also the highest shares of both nationally and internationally co-authored papers (75% vs. 41% and 45% vs. 40%, respectively). NPE display the highest percentage of papers in high-quality journals and the highest impact through relative citations (Table 1).

From the inspection and categorization of the NPE, the following organisational types emerge: foundations (50.3%), research networks (24.6%), consortia (16.0%), research management entities (12.2%), associations (6.5%), and scientific parks (1.0%). The highest increase during the period corresponds to research management entities and research

networks. Research management entities stand out because of their high figures in both the percentage papers in high impact factor journals and relative citations (Table 2).

Research management entities show the lowest proportion of papers with a single institution (2%), a high share of papers with national (89%) and international collaboration (68%), and the highest average team size. The highest share of papers in Q1 journals is observed for co-authored activity between national and foreign partners for all sectors except associations and research networks.

The specialization of NPE varies according to the organisational type: Biomedicine and Clinical Medicine for networks, consortia and foundations; Physics for research management entities; Biomedicine and Chemistry for scientific parks; and Engineering for associations.

Conclusions

The in-depth analysis of the NPE in Spain shows the rising trend of different organisational types which differ according to the field and respond to specific strategic procedures to manage research (creation of foundations in the context of medicine, networks for clinical research, scientific parks to link basic and applied research in the university context, etc.). Interestingly, some of these organisational types (research networks, consortia, parks) include cross-sector and cross-discipline collaboration which is supposed to lead to major discoveries in science and even to radical innovation. Collaboration in the context of the structured and stable framework provided by these organisational forms is more effectively enhanced than through occasional collaborative projects. Our data indicate the success of these emerging organisations in supporting/conducting high impact research.

Reform of Russian Science as a Reason for Scientometrics Research Growth

Andrey Guskov

guskov@spsl.nsc.ru
The State Public Scientific Technological Library of Siberian Branch of the Russian Academy of Science, Voshod Str. 15, Novosibirsk (Russia)
Novosibirsk State University, Pirogova Str. 2, Novosibirsk (Russia)

Introduction

After the USSR had fallen down in 1990, there was a steady stagnation of Russian science for fifteen years. Iron curtain that separated soviet researchers from the international science disappeared, but research funds sharply decreased due to the economic problems. As a result, the number of publications registered in Web of Science, stayed between 30 000 and 34 000 per year. Thus, Russian science moved from the group of leading countries to the second dozen.

Restoration of Russian Science started in 2006 after government had introduced a new model of the research process. Essential part of the model was wide application of the formal scientific results assessment. This approach triggered a rapid growth of scientometrics publications written by mathematicians, physicists, philosophers and others. The main goal of this paper is to make a review of new Russian scientometrics landscape, which could help to determine its strengths and weaknesses and launch new collaborations.

Method

In this paper basic set of scientometric articles produced by Russian scientists is analysed. It consists of two periods: 1988-1999 and 2000-2014. The data for the first part (99 publications) was extracted from Russian Institute for Scientific and Technical Information database, abstract journal "Informatics" (Penkova, O. & Tyutyunnik V., 2011) Publications from 2000 until 2014 were requested from Russian Science Citation Index (national bibliometric database) by using context search with terms "bibliometric", "scientometric", and "webometric" (in Russian) in titles and annotations.

For every article in this set we identified topic category according to its title, annotation and, in some cases, full text. Afterwards, we analysed the distribution and dynamics of the categories and of the whole set.

Dynamics of Russian scientometric researches

Noteworthy, scientometrics in Russia has very meaningful historical background. It was Russian philosopher and mathematician V. Nalimov, who in 1969 introduced the term "Scientometrics" in his famous book. In 1973 Marshakova and Small simultaneously introduced co-citation analysis, which is used for research front findings now. Dutt, Garg & Bali in 2003 analysed fifty volumes of journal Scientometrics during 1978 to 2001 and examined the distribution of the output of different countries. According to their paper, former USSR contributed 59 of 1317 articles that are emphasized on history of science, theoretical studies and scientometrics distribution. Despite these go-ahead results, scientometric researches became a trend in Russia only after 2006 (Fig.1).

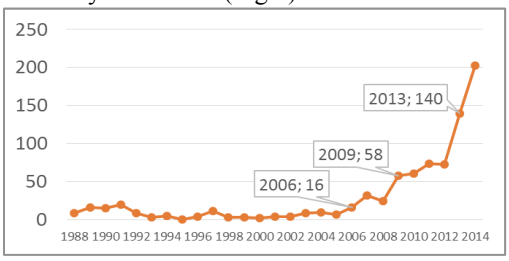

Figure 1. Dynamics of scientometric publications in Russian journals.

There are three sharp increases at Fig 1: in 2006, 2009, and 2013. The first growth in 2006 relates to the reformation of salary system, which implied significant dependency of the payment bonuses upon publication scores for every single scientist. Facing this new challenge, a number of researchers considered its fairness; some of them noticed the helpfulness of the bibliometric methods and started to apply it for their subject area. The second wave started in 2009th after the end of the salary system reformation. From that moment, every researcher became financially interested in improving his scientometric indicators. Research society had to analyze these changes, thus we can observe sharp increase in 2009th at Fig 1.

Despite the rapid growth before, in 2013th the number of scientometric publications had doubled. The reason is clear: in May 2012, President of Russia V.V. Putin proclaimed that the fraction of publications of Russian researches indexed by Web of Science in 2015th has to be greater than 2.44%. This was quite a big challenge for national science, because it literally meant that the annual number of articles has to be increased from 32-33 thousands in 2010-2011 to 46-50 in the next 3 years. The

reasons, the ways and the possibilities of that breakthrough were the main topics for discussion over the year. After that, in June 2013 another dramatic event occurred: restructuring of the Russian Academy of Science (RAS), headquarters of fundamental sciences. This tough stage was accompanied by criticism of the Academy for low scientometric indicators. Unfortunately, scientometrics has been used as an instrument for a radical transformation of management of Russian science.

Directions of researches

We defined 16 categories and analyzed the articles distribution (Fig.2). 33% of researches were devoted to a specific subject area investigation. It is followed by: development and applying of indicators (13%), general discussions about scientometrics and its place in research management (11%), impact-factors and journal improvement issues (7%), positions of Russian science in a global scope (6%). According to our estimates, from 50% to 75% of publications were made using bibliometric methods, principally in categories: "Subject areas", "Journals", "National science", "Dissertations", "Regional research", "Leading scientists research", "Science in HEI", "Conferences", "Organizations", "Collaborations", "Patents".

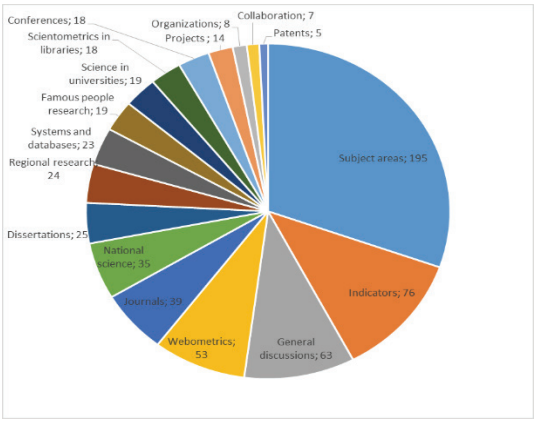

Figure 2. Distribution of scientometric researches by categories (number of publs.)

We determined the most developing categories and analyzed the dynamics. The main contribution to publication rise, shown at Fig.1, was made by "Subject area" category from 2007 to 2012. The second contributing category "Indicators" contains a number of articles about publications and citations amount, impact factor and Hirsh index. The third category supports general scientific discussion about scientometrics, started in 2009. Three more categories significantly increased in 2013: "Journals", "Science in universities", "Systems and databases".

Conclusion

Figure 1 can be thought of as an indirect measure of the influence of the State on Russian Science. Indeed, there was a lack of scientometricians and poor scientometric publication activity in Russia before 2006th, the very beginning of reformation. The following alterations made many researches slow down or suspend what they had been doing before and start making their own scientometric investigations. The more severe were the changes, the more scientists were influenced. Furthermore, it seems there were no other reasons for the mentioned breakthrough. At first glance, scientometrics is supposed to benefit from it. That would be so, excepting two facts. First, concerning scientometrics as an instrument of reformation, many scientists consider it primarily as a stick for punishment and do not trust it. This creates quite a negative environment for further development, but this story has already happened. "When a system of assessing and funding researchers was introduced in South Africa, there were cases when scientists attacked scientometrics…" (Pouris, 1994). Second, the most of the scientometric researches, which were published in Russia the last years, relate to one of the groups: 1) Position of the scientometrics and its indicators in the processes of the management of Russian science. 2) Bibliometric researches of science disciplines and Russian science as a whole. 3) Bibliometric and webometric researches of various sources of publications: journals, organizations (incl. universities), famous scientists, conferences, projects, dissertations sets and so on. Since those three groups include up to 90% of publications, there is not much space left for more complicated and go-ahead researches, such as collaboration studies, research fronts detecting, R&D cycle analysis, altmetrics, society impacts, etc. At the moment, scientometrics in Russia remains the "product for internal use" mostly. Still, we expect the internalization of this research field and the increase of the visibility of Russian publications worldwide.

Introduction

The Marine Biotechnology (MB) research area is gaining increasing relevance in Brazil. Its analysis is a challenge owing to the inherently multidisciplinary nature, and the study of research groups (RGs) may support this work. The task of analysing RGs is facilitated in Brazil, which has a national source gathering the country's RGs, maintained by the National Council for Scientific and Technological Development (*Conselho Nacional de Desenvolvimento Científico e Tecnológico* - CNPq): the Directory of Research Groups of the Lattes Platform (*Diretório dos Grupos de Pesquisa da Plataforma Lattes,* http://lattes.cnpq.br/web/dgp), with information from RGs related to: i. institutional headquarters; ii. Research Group name; iii. First leader name, iv. Second leader name (if any), and v. Predominant area. This source allows automatic data extraction already made available by research groups, allowing for full and systematic exploitation. This work aims to present first findings from exploitation on research groups in MB existing in Brazil registered in the Directory of RGs of the Lattes Platform, checking the collaboration networks formed by the leaders of these groups, mainly highlighting the natural influence that leaders have on other peers, meaning a leadership, focusing on research groups through the topological properties of networks with the use of Social Network Analysis (Abbasia, Wigand & Hossain, 2014), in order to behold their evolution and the role of the RGs' leaders in MB in Brazil and testing if it is possible to establish a relationship between the degree of leadership of the leaders considering topological information from networks.

Methods

This initial approach is focused on three points: 1. networks characterization in number of RGs involved, the active institutions and their location, and the dominant areas in multidisciplinary research; 2. description of the dynamic aspect of the network formed by these RGs through its evolution over the last 15 years, distributed in three five-year periods; and 3. determination of the "degree of leadership" of these networks' leaders, as measured by AuthorRank indicator, which is a numerical value that indicates the impact of a member in collaboration graph. This measurement is similar to PageRank for directed graphs (with weights) (Liu et al., 2005). Thus, the aim was to consider this indicator as an attribute of the leadership for the leaders of these RGs in the analyzed period.

Data collection and analysis

First, the MB research groups were identified by search using 37 MB terms raised in the related literature. Following, it was obtained data related to RGs such as institutions involved, 1st Leader name, and Main Area, allowing identify the Lattes ID (researcher identification number registered in the Lattes Platform) of the groups' leader. Second, we used scriptLattes tool (Mena-Chalco & Cesar Junior, 2009) in order to extract information associated with all the investigated leaders during the period of 15 years (1999-2013). We obtained data from the scientific production of each leader related to total articles, books, book chapters, and conference papers. For data analysis, we consider the professional addresses recorded for each leader to obtain the geographic location of each group through Google Maps tool. We obtained lists of full papers (solely) of the groups' leaders published in journals, and with scriptLattes tool we identify all publications in co-authorship. In addition, there were obtained the endogenous networks (internal collaboration) of the leaders. The AuthorRank was calculated for each actor. This indicator is commonly used for measuring the impact of members of an academic collaboration network (Liu et al., 2005). Our analysis was outlined considering four time periods: A global period (1999-2013) and three five-year periods: 1999-2003, 2004-2008, and 2009-2013. This division into different periods allows to study distinct topological characteristics of the network and its evolution.

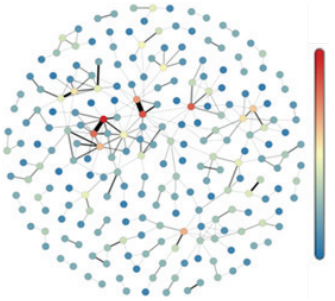

Figure 4. AuthorRank of the Leaders of the Brazilian research groups in Marine Biotechnology: co-authorship network

Discussion and conclusion

There are 402 RGs working in one or more topics related to the MB field from 34 different subject areas, main ones showed in Figure 1. RGs are from 110 institutions geographically concentrated along the Brazilian coast (South and southeast prevailing in number of institutions and research groups – Figure 2). We identified the leadership of the ten most active researchers in the co-authorship networks, with AuthorRank varying between 2.33 and 4.1 (Table 1). It was observed that there is a systematic increase in academic interactions during the considered period (Figure 3) and that academic leadership is not uniform among the leaders (Figure 4). The task of characterizing the emerging area of research in MB has grown in importance in Brazil, and this work relates to this issue.

Abstract
Patent classification analyses are usually conducted using issued patents. Issued patents however suffer lengthy examination and the derived analytic results reflect R&D activities occurring considerable time in the past. The only option for an analyst to reduce such observational time delay is to use the so-called pre-grant publications (PGPubs) that are open to public 18 months after patent applications are filed. The PGPubs and their corresponding issued patents are both assigned classification symbols. If the two sets of symbols are very different, using patent classification analysis on PGPubs to observe R&D activities is dubious. This study therefore compares the United States Patent Classification (USPC) symbols assigned to about 235,000 pairs of U.S. utility patents issued in 2012 and their PGPubs in three ways, each corresponding to an approach of a conventional patent classification analysis: (1) considering only the class codes of the main classification symbols; (2) considering only the main classification symbols; and (3) considering both main and auxiliary classification symbols. The study finds that only the class codes of the PGPub main classification symbols are reliable enough for patent classification analysis as there are about 78% of the PGPubs have identical class codes as their corresponding issued patents.

Conference Topic
Patent analysis

Introduction
A patent application is classified during its prosecution process based on its inventive content by an examiner and one or more classification symbols are assigned in accordance with a standard scheme such as International Patent Classification (IPC), Cooperative Patent Classification (CPC), U.S. Patent Classification (USPC), etc. Patent classification analysis (PCA) is a popular practice by patent analysts using the patent classification symbols, and it is so popular that, to the authors' knowledge, all commercial patent analytic systems/services, such as Thomson Innovation® and WIPS Global®, have various types of PCA built-in.

A common type of PCA is to investigate the R&D focuses of an entity (i.e., a company, an institute, a country, a technical field, etc.). An analyst gathers the patents affiliated with the entity, collects the classification symbols assigned to these patents, counts the number of times each classification symbol is assigned to these patents, and usually produces a diagram such as a histogram, a heat map, etc., to visually manifest the assignment frequencies of the classification symbols. By observing the diagram, the analyst then claims that the entity has its R&D focused in a few technical areas denoted by the most frequently assigned classification symbols.

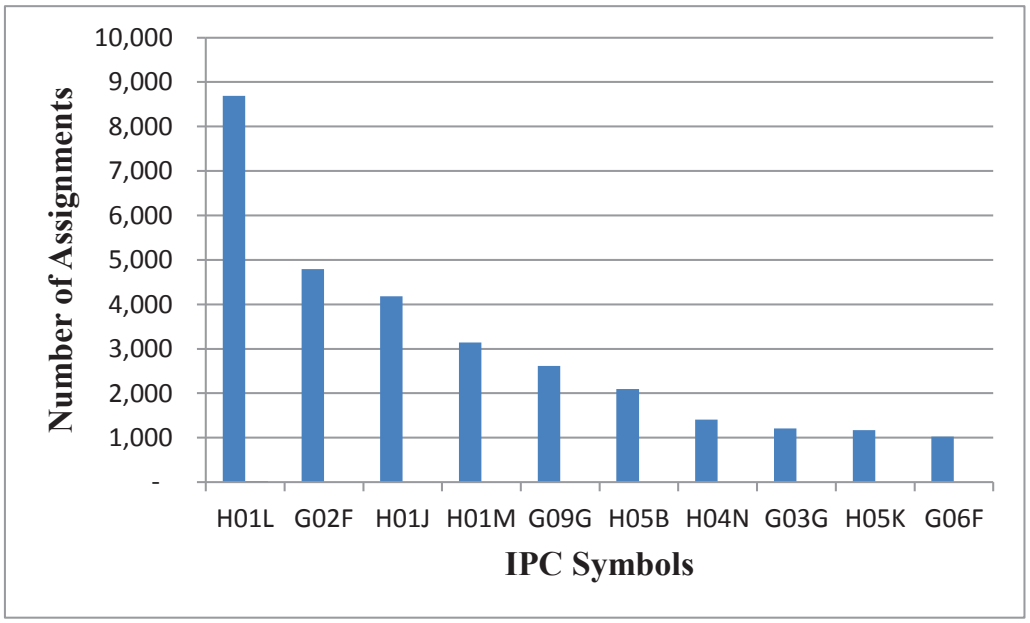

Figure 1. A sample histogram from a fictitious PCA.

A sample histogram from a fictitious PCA using IPC symbols for a company is shown in Figure 1. As illustrated, the company is considered to have its R&D effort mainly focused in the field Semiconductor Devices denoted by the most frequently assigned IPC symbol H01L.

Other than the real-life application described above, patent classification symbols are considered as a viable source of technological information by researchers, and various types of PCA have been proposed in the literature. To mention just a few, the number of different classification symbols assigned to an entity's patents is used as a proxy to the entity's technological diversity (cf. Lerner, 1994), the co-classification of patents (i.e., patents assigned one or more identical classification symbols) is used to investigate the linkage among technologies (cf. OECD, 1994), or the relationships among organizations (cf. Leydesdorff, 2008). There are also studies investigating the technological relatedness of two entities using the classification symbols assigned to their patents (cf. Jaffe, 1986; 1989). In addition, the classification symbols of a patent's forward and backward citations are used to evaluate the patent's "generality" and "originality" (cf. Henderson, Jaffe, & Trajtenberg, 1997). However it should be noted that there are opinions considering the existing patent classification schemes are "never intended to provide conceptual delineations of technology areas, but instead identify inventions by function at very low levels of abstraction in order to serve as aids to prior art searching" (Allison et al., 2004).

As described above, PCA can be used to observe the focus of an entity's R&D activities up to the time of analysis or, if the entity's latest patents are gathered, of the entity's recent R&D activities. However, what is revealed by the latter is actually not the R&D activities happened around the time of analysis but a considerable amount of time in the past. To see this, the curve with diamond marks in Figure 2 depicts the distribution of U.S. utility patents issued in the year 2012 according to their application years. About three quarters of the 2012-issued utility patents are actually filed between 2007 and 2010. In other words, if a histogram similar to Figure 1 is derived from these 2012-issued patents, the revealed R&D focuses actually occur and disperse in a period of time quite in the past.

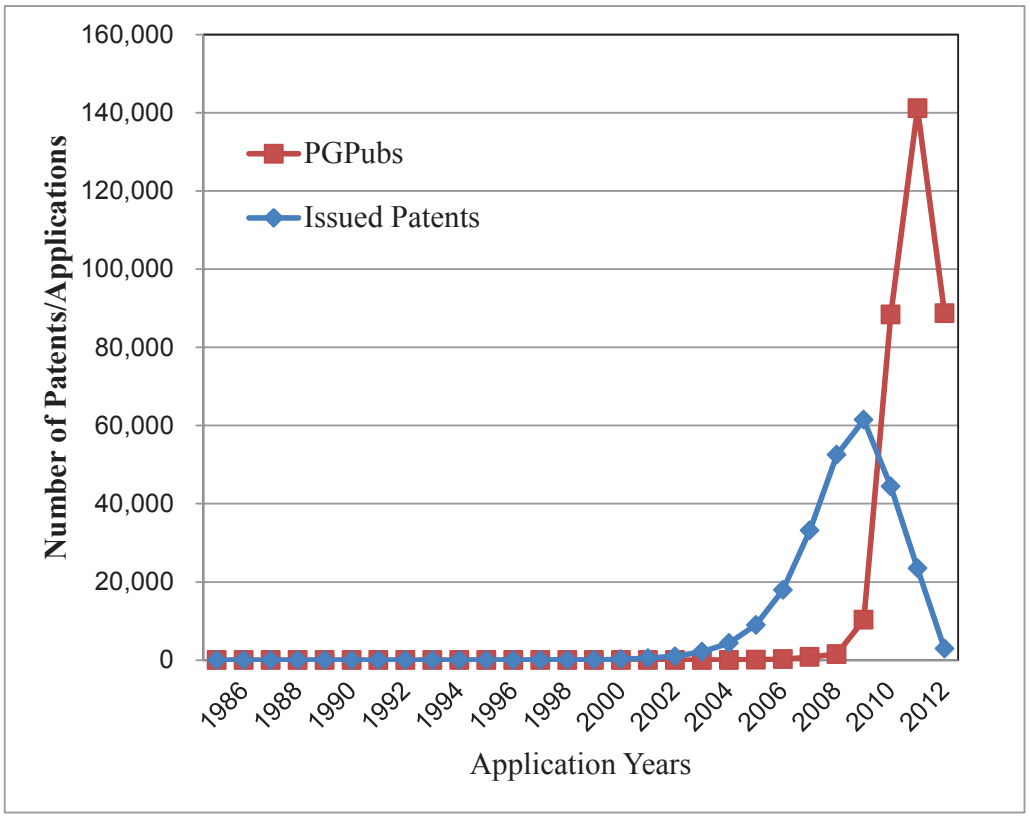

Figure 2. Distributions of 2012 issued patents and PGPubs based on application years.

The only possible way to reduce this time delay is to use the so-called *pre-grant publications* (PGPubs), instead of the issued patents. A patent application usually undergoes an early publication process before the patent is issued by the authority or before the patent application is given up by the applicant. Again taking Figure 2 as example, the curve with square marks depicts the distribution of U.S. PGPubs published in the year 2012 according to their application years. As illustrated most PGPubs are filed between 2010 and 2012, which are concentrated in a more limited period of time and in a more recent past.

The early publication process is a common practice for authorities across various nations and regions. For example, U.S. Patent Act (35 U.S.C. § 122(b)) specifies that, "each application for a patent shall be published … promptly after the expiration of a period of 18 months from the earliest filing date for which a benefit is sought under this title." There are indeed exceptions that an application is not early published if the application is (i) no longer pending; (ii) subject to a secrecy order; (iii) a provisional application; (iv) an application for a design patent; or (v) requested by the applicant. These exceptions are not common and, for utility patent applications, which are the most common type of patent applications, it is very possible that an issued utility patent is early published. According to our statistics, there are 253,580 utility patents issued in the year 2012 and 17,993 of them (7.1%) do not have corresponding PGPubs.

When a patent application is filed, the patent application is initially classified and classification symbols are assigned so as to route the patent application to an appropriate examiner team (USPTO, 2004). Then, after the patent application has undergone substantive examination, its examiner may alter the initial classification and assign different classification symbols (USPTO, 2005). As such a PGPub and its subsequently issued patent have their respective classification symbols and their classification symbols may not be identical.

PCAs usually utilize the issued patents, instead of PGPubs, most likely due to that the PGPubs have not undergone substantive examination, and their classification symbols may

not fully reflect their inventive contents. Yet PGPubs are better subjects for investigating the latest R&D focuses as they do not suffer lengthy pendency and strict screening by the examination process as reflected in Figure 2.

This study therefore tries to investigate the adequacy of using PGPub classification symbols for PCA. If the answer is yes, analysts can effectively reduce the time delay of their analytic observations to about 18 months, which is a significant improvement. On the other hand, even if the answer is no, analysts would know that PGPub classification symbols are not reliable, and they should avoid using them or at least be cautious about PCAs based on PGPub classification symbols.

Methodology

To investigate the adequacy of PGPub classification symbols for PCA, we collected U.S. utility patents issued in 2012 and their corresponding PGPubs for comparison. Utility patent is chosen because, for the three types of U.S. patents, utility patent is the most common and numerous one, design patents do not undergo the early publication process, and there are only a small number of plant patents. According to our statistics, there are only 868 plant patent applications filed each year between 1992 and 2011 on the average.

Each U.S. utility patent/PGPub is classified with three classification schemes: IPC, CPC, and USPC, and we choose the USPC symbols for comparison. This is because USPC is the default scheme for United States Patent and Trademark Office (USPTO) (USPTO, 2012), the IPC symbols are most likely machine-converted from the USPC symbols, and the CPC are not popular yet. Most importantly, USPC scheme does not have versions as it is updated every two months and the USPC symbols of all documents contained in USPTO databases are thoroughly and automatically re-classified accordingly (Wolter, 2012). In other words, when the USPC symbols of an issued patent are compared against those of its PGPub, whether the USPC symbols are of the same version is not an issue. One may question that USPC, as a domestic scheme, may not be representative. However, we believe that what this study observes from using U.S. patents and USPC could provide us at least some hint when dealing with patents of different countries and using different classification schemes.

Like all other classification schemes, USPC provides a hierarchical taxonomy of technical areas. Each USPC symbol contains a class code and a subclass code separated by "/." For example, a USPC symbol 623/2.1 has class code 623 and subclass code 2.1. The class code (e.g., 623) represents a highest level of non-overlapping technical area whereas the subclass code (e.g., 2.1) represents a lower level of technical area belonging to the one denoted by the class code. For subclass codes under the same class code, they may have hierarchical relationship among themselves. For example, 623/2.11 and 623/2.12 represent parallel technical areas but the two technical areas both belong to the technical area denoted by the symbol 623/2.1 (USPTO, 2012).

A U.S. utility patent/PGPub is assigned one or more USPC symbols. Among them, one and only one is expressed in boldface in the patent/PGPub documents. For issued patents, the official name for the bold-faced symbols is *original classification* symbols and, for the normal-faced symbols, *cross-reference classification* symbols by USPTO. As to PGPubs, the official name for the bold-faced ones is *primary classification* symbols and, for the normal-faced ones, *secondary classification* symbols. For simplicity's sake, we refer to the bold-faced symbols as the *main classification* symbols whereas the rest of the normal-faced symbols as the *auxiliary classification* symbols, whether or not they are from issued patents or PGPubs. The main classification covers the novel and non-obvious information contained in a patent/PGPub whereas the auxiliary classification covers other information considered to be valuable for searching (USPTO, 2012).

To determine whether PGPub classification symbols is adequate for PCA, we use the classification symbols assigned to the corresponding issued patents as reference as they are assigned by examiners after substantive examinations and therefore assumed to have better reflected the inventive contents of the patents.

Table 1 provides a number of examples where the sets of classification symbols assigned to three U.S. utility patents issued on 2015/02/10 and their PGPubs are listed side by side for comparison. As illustrated in Table 1, the two sets of classification symbols may not be identical, and the set assigned to the issued patent indeed seems to be more detailed than that assigned to the corresponding PGPub.

Table 1. The classification symbols assigned to three sample pairs of PGPubs/patents.

PGPub no./Patent no.	*PGPub symbols*	*Patent symbols*
20140289912/8,955,161	**850/18**	**850/1**; 250/339.11; 250/339.14; 73/105; 850/5; 850/50; 850/6
20120124680/8,955,160	**726/34**	**726/34**
20110252484/8,955,159	**726/32**	**726/32**; 380/201; 705/57; 726/27; 726/31; 726/33

There are quite some researches involving the measurement of similarity between nodes in a hierarchical taxonomy of concepts, which can be applied to classification symbols as well. For example, in one so-called edge-based approach, the similarity between two nodes is calculated based on the numbers of edges from the root of the hierarchical structure to the two nodes and to their nearest common ancestor node (Slimani, Yagahlane, & Mellouli, 2008). Similar edge-based approaches can be found in McNamee (2013). There are also so called node-based approaches, which capture a node's feature in the hierarchical structure as a vector and calculate a similarity measure based on the concept vectors of two nodes (cf. Liu, Bao, & Xu, 2012).

These studies do have their academic merit but cannot directly tell us whether PGPub classification symbols is reliable or not for PCA. We therefore adopt a different and practical treatment to the comparison of the classification symbols. First, we notice that existing commercial analytic systems/services conduct PCA using one of three simple approaches:

- PCA using Approach 1 counts only the class codes of the patent or PGPub main classification symbols so as to obtain a broad picture of the distribution of R&D activities;
- PCA using Approach 2 counts only the main classification symbols and ignores all auxiliary classification symbols of patents or PGPubs, considering that the main classification symbols are the most representative ones; and
- PCA using Approach 3 counts all patent or PGPub classification symbols with no distinction between main and auxiliary classification symbols, believing all classification symbols are equally important.

To demonstrate the three approaches, using the Patent Symbols column listed in Table 1 as example:

- Approach 1 counts the class codes 850 as being assigned once, 726 being assigned twice;
- Approach 2 counts each of the main classification symbols 850/1, 726/34, and 726/32 as being assigned once; and
- Approach 3 counts each of the 14 classification symbols as being assigned once.

Please note that, to the authors' knowledge, commercial analytic systems/services ignore the hierarchical relationship between classification symbols. For the above example, 850/6 is actually a technology area belonging to that of 850/5 but commercial analytic systems conducting PCA using Approach 3 treat 850/5 and 850/6 as denoting distinct technology areas probably for simplicity's sake.

Then, to see whether PCA using one of the above approaches on PGPubs classification symbols would deliver trustworthy result, we conduct three analyses as follows, each corresponding to one of the approaches above:

- Analysis 1 compares the main classification class codes of PGPubs to those of the corresponding issued patents.
- Analysis 2 compares the main classification symbols of PGPubs to those of the corresponding issued patents and calculates the consistency rate.
- Analysis 3 compares the sets of classification symbols of PGPubs to those of the corresponding issued patents.

Then all three analyses calculate the percentage of PGPubs having *identical* main classification class codes, main classification symbols, and sets of classification symbols to their corresponding issued patents. Since commercial analytic systems/services ignore the hierarchical relationship between classification symbols, our three analyses follow the same practice.

A 100% percentage indicates that PCA on PGPubs using one of the approaches would yield a result identical to that using their issued patents, meaning that using PGPubs can achieve reduced time delay with total accuracy. But a 0% percentage implies that PCA on PGPubs using one of the approaches delivers totally incorrect result. We therefore specifically refer to the percentage as *consistency rate* so as to avoid confusion with the general term *percentage*.

If statistically there is a very high consistency rate or similarity from the PGPubs, a histogram such as Figure 1 obtained from PGPubs using Approach 1, 2, or 3 would be very close to one from the corresponding subsequently issued patents. An analyst then can confidently utilize the PGPubs for PCA by Approach 1, 2, or 3 and achieve a reduced time delay.

To demonstrate the three analyses, again using the three sample pairs of PGPubs/patents listed in Table 1 as example:

- Analysis 1 shows that PCA using Approach 1 on PGPubs has a 100% consistency rate (i.e., all three pairs' PGPubs have identical main classification class codes to those of their issued patents);
- Analysis 2 shows that PCA using Approach 2 on PGPubs has a 66% consistency rate (i.e., except the first pair, the other two pairs' PGPubs have identical main classification symbols to those of their issued patents); and
- Analysis 3 shows that PCA suing Approach 3 on PGPubs has a 33% consistency rate (i.e., only the second pair's PGPub has an identical set of classification symbols to that of its issued patent).

For PCA using Approach 3, the simple consistency rate described above is too narrow to give us a complete picture. For example, even though the two sets of classification symbols from the third pair of patent/PGPub listed in Table 1 are different, the PGPub classification symbol {726/32} is actually a proper subset of the issued patent's classification symbols {726/32, 380/201, 705/57, 726/27, 726/31, 726/33} and therefore still captures a portion of the inventive content. The calculation of the consistency rate however ignores this condition.

Therefore in conducting Analysis 3, we divide the PGPub-patent pairs into 5 categories based on the relationships between their sets of classification symbols so as to gain more insight.

- Category 1: their sets of classification symbols are identical (i.e., $\{\text{PGPub}\} = \{\text{Patent}\}$).
- Category 2: their sets of classification symbols are entirely different (i.e., $\{\text{PGPub}\} \neq \{\text{Patent}\}$ and $\{\text{PGPub}\} \cap \{\text{Patent}\} = \emptyset$).
- Category 3: the PGPub's set of classification symbols is a proper subset of that of the corresponding patent (i.e.,$\{\text{PGPub}\} \neq \{\text{Patent}\}$ and $\{\text{PGPub}\} \subset \{\text{Patent}\}$).
- Category 4: the patent's set of classification symbols is a proper subset of that of the corresponding PGPub (i.e.,$\{\text{PGPub}\} \neq \{\text{Patent}\}$ and $\{\text{Patent}\} \subset \{\text{PGPub}\}$).

- Category 5: their sets of classification symbols are not entirely different, do not belong to each other, and have a non-empty intersection (i.e.,$\{\text{PGPub}\} \neq \{\text{Patent}\}$,$\{\text{PGPub}\} \not\subset \{\text{Patent}\}$, $\{\text{Patent}\} \not\subset \{\text{PGPub}\}$, and $\{\text{Patent}\} \cap \{\text{PGPub}\} \neq \emptyset$).

Then, for the patent/PGPub pairs belonging to each category, we calculate an average Jaccard Coefficient (Jaccard, 1901) as expressed in (1) where {PGPub} and {Patent} are the two sets of classification symbols assigned to the PGPub and the corresponding issued patent, respectively. Jaccard Coefficient, or Jaccard Index, or Jaccard Similarity Coefficient, was originally designed for comparing similarity between sample sets, and has already been applied in patent bibliometrics such as co-citation analysis (Small, 1973). Here we use it to capture the degree of discrepancy between {PGPub} and {Patent}.

$$J = \frac{|\{\text{PGPub}\} \cap \{\text{Patent}\}|}{|\{\text{PGPub}\} \cup \{\text{Patent}\}|} \quad (1)$$

Findings

We collected 253,580 utility patents issued in the year 2012 from USPTO database. After removing those having no corresponding PGPub, those having no classification symbol (e.g., these patents are withdrawn and withdrawn patents do not have patent classification symbols recorded in the USPTO database), and for unknown reason those having no main classification symbols, there are total 234,966 patents eligible for analysis. As mentioned in the previous section, USPC is updated every two months and all patents are re-classified accordingly. We collected the USPC symbols assigned to the 234,966 patents and their corresponding PGPubs under the USPC scheme up to 2013/10/31.

An initial statistics shows that the 234,966 patents have average 3.9 USPC symbols and their corresponding PGPubs have average 2.2 USPC symbols, and that 64.16% of the 234,966 patents have a greater number of USPC symbols than that of the corresponding PGPubs, indicating that issued patents seem do have more careful assignment of classification symbols than their PGPub counterparts. In some extreme cases, PGPub No. 2010/0316607 has the greatest number of USPC symbols (48) among all PGPubs whereas patent No. 8,179,540 has the greatest number of USPC symbols (65) among all patents. The latter is also the case having the greatest difference (63) between the issued patent and the corresponding PGPub.

Analysis 1

For each pair of the 234,966 PGPubs and corresponding issued patents, we compared the class code of the PGPub's main classification symbols against that of the corresponding issued patent, and we found that the consistency rate is 77.89%. That is, 183,024 out of the 234,966 pairs of PGPubs and patents have identical main classification class codes, and the remaining 51,942 pairs (22.11%) have difference main classification class codes. In other words, there is a 22.11% probability that a PGPub's main classification class code does not accurately reflect the inventive content of the corresponding patent.

Analysis 2

For each pair of the 234,966 PGPubs and corresponding patents, we compared the main classification symbol of the PGPub against that of the corresponding issued patent, and we found that the consistency rate drops to only 36.42%. That is, 85,584 out of the 234,966 pairs of PGPubs and patents have identical main classification symbols, and the rest 149,382 pairs (63.58%) have different main classification symbols. In other words, there is a very

significant 63.58% probability that a PGPub's main classification symbol does not accurately reflect the inventive content of the corresponding patent.

Analysis 3

For the 234,966 pairs of PGPubs and corresponding patents, we categorized them into 5 categories based on the relationships between their sets of classification symbols, and calculated the average Jaccard Coefficient for each category. The result is summarized in Table 2.

Table 2. Comparison result from Analysis 3.

Category	*Pairs*	*Percentage*	*Avg. Jaccard Coefficient*	*Std. Deviation*
1	14,958	6.37%	1	0
2	89,981	38.30%	0	0
3	63,057	26.84%	0.34	0.16
4	10,693	4.55%	0.45	0.15
5	56,277	23.95%	0.22	0.11

As illustrated, PGPubs in Category 1 are those having identical sets of classification symbols to their issued patents and their share (6.37%) among the 234,966 PGPubs is exactly the consistency rate of Analysis 3.

PGPubs in Category 2 are those having totally different sets of classification symbols from their issued patents and, for a PCA on these Category-2 PGPubs using Approach 3, the analytic result would be totally incorrect, but PGPubs of this category has the greatest share (about 38%) among all PGPubs.

PGPubs in Category 3 are those having sets of classification symbols being proper subsets to those of their issued patents, and cover about 27% of all PGPubs. For these Category-3 PGPubs, their classification symbols capture only 34% of the inventive content as reflected by their average Jaccard Coefficient. We can imagine that, for a PCA on Category-3 PGPubs using Approach 3, a histogram such as Fig. 1 would miss a significant amount of information.

Category 4 is a special case where PGPubs have sets of classification symbols that are proper supersets to those of the corresponding issued patents, and therefore covers the smallest share (less than 5%). For these Category-4 PGPubs, their classification symbols capture all inventive content but unfortunately provide on the average 55% (1-0.45) surplus and erroneous information. Again we can imagine that a histogram from PCA on Category-4 PGPubs using Approach 3 would contain too much noise.

Category 5 is a combination of Categories 3 and 4, meaning these 24% of the PGPubs have sets of classification symbols that not only miss significant amount of information but also provide significant amount of erroneous information, as reflected by the very limited average Jaccard Coefficient (0.22).

Conclusion

This study arises out of an attempt to use PGPub classification symbols for PCA so as to investigate an entity's latest R&D focuses with limited time delay. It is however speculated that the PGPub classification symbols are not carefully assigned and their adequacy for PCA has to be determined first.

We therefore gathered 234,966 pairs of issued patents and corresponding PGPubs, and compared their classification symbols in accordance with the three approaches that a commercial patent analytic system/service usually employ.

Assuming that the classification symbols of the corresponding issued patents better reflect the inventive contents of the patents and as such using them as reference, we find that, if the commercial patent analytic systems/services count the main classification symbols, or the entire sets of classification symbols of the PGPubs for PCA, only 36.42% of the PGPubs have identical main classification symbols, and only 6.37% of the PGPubs have identical sets of classification symbols to those of the corresponding issued patents. PCA using PGPubs as described can hardly be considered as reliable.

The best candidate for using PGPubs in PCA is the PGPubs' main classification class codes. We find that as high as 77.89% of the PGPubs have identical main classification class codes to those of the corresponding issued patents. The main classification class codes, however, represent the broadest technical areas and using them to investigate R&D focuses would provide only limited insight.

This study can be further carried out as follows. In order to make the main classification class codes even more useful for PCA, the consistency rate for each individual class can be determined. For some classes that have statistically very high consistency rate, PGPubs assigned with these class codes can be used for PCA with high confidence whereas, for classes of low consistency rate, an analyst should avoiding using them for PCA.

Additionally, one may be curious about why some class codes reveal higher consistency rates than the others. We speculate that, for some well-developed technical fields, the consistency rates of their class codes would be high as the classification of the related technology should be familiar to the examiners whereas for emerging technical fields, the consistency rates of their class codes would be low as the examiners may have different opinions on what the related technology should be classified. The investigation of this speculation is currently under way.

If both reduced time delay and better analytic insight are required, an analyst would require a better tool that can take the hierarchical relationship among classification symbols into consideration. If this kind of tool is available, we speculate that some specific technical areas may reveal a high consistency rate or similarity measure even for PCA using Approaches 2 and 3. The identification of these specific technical areas and how reliable the PGPub classification symbols are in these specific technical areas can be further investigated.

Abstract
Relying on the perfect integration of Internet technology, new business format and financial services, the Internet finance is developing at an unexpected speed, bringing impacts to Chinese-funded banks in the traditional business and emerging areas such as customization. Based on the preliminary study of the close contact between Chinese-funded banks and Internet financial enterprises as well as the necessity of patent protection, the paper proposes a comprehensive analytical framework and makes statistical comparison between 5 well-known Chinese-funded banks and Alibaba Group's patents from the perspective of annual trend, collaboration, application organizations, citation and other characteristics with data up to 2014 collected from Derwent Innovations Index(DII). It builds a Derwent Manual Code co-occurrence network with time coordinate by combining with visual tools and quantized the respective patent focuses of banks and Internet financial enterprises from the perspective of frequency and burst. After analysing the patents' contents, the paper discusses the mode of patent assignment. Finally, according to the status of patents, the paper concludes the strategic layout of domestic banks and Internet financial enterprise's intellectual property protection to predict the trend of further competition and alliance.

Conference Topic
Patent Analysis

Introduction
The data of British magazine "Banker" showed that in 2014, 13 Chinese banks ranked among the world's top 100 banks. Among them, Industrial and Commercial Bank of China ranked No.1 with the fund scale of 2,076.14 billion U.S. dollars, followed by China Construction Bank, Bank of China and other Chinese-funded banks, highlighting the fast growth and significant expansion of Chinese-funded banks. Nevertheless, the rates of return on assets of these banks were less than 3%, indicating that although the overall profit scale of China's banking ranked No.1 in the world, its profitability was not the case. With the slowdown of economic growth, substantial promotion of interest rate liberalization and further standardization of banking regulation, it is difficult for banks to maintain rising profit by relying on traditional channels. Like a huge dam, commercial banks store the saving deposits and collaborative deposits, but now there is a gap in the dam and the initiator is Internet finance. In the extensive penetration of Internet technology, traditional financial industry is undergoing dramatic changes: financial services have become the area competed by major institutions. Investors' "financial outlook" is corrected and the process of interest marketization has been promoted virtually (SOHO, 2014). The release of small and micro enterprises and individual consumer market's demand for loan is accelerated and the financing market presents a thriving prospect. With huge dividends of reform as well as the progress of big data and cloud computing technology, the Internet financial innovation is increasingly deepening. The rapid rise of Internet financial enterprises obliges Chinese – funded banks to face the continuous overlapping business, increasing demand for product service, competition and challenges brought by the application of innovative technologies.
In the new era, the competition between Chinese-funded banks and Internet financial giants does not only stay in the extent of business coverage, and more importantly, it is a rigid form

of innovation, which has been highly concerned by famous financial institutions, especially international banks, and produced historical and substantial effect on financial markets, services, products and management (Chen, 2006). Meanwhile, as an important link of financial products and intellectual properties, patents reflect the high degree of innovation of bank and Internet financial enterprises in service and product development. Meanwhile, in the period of patient protection, the banks exclusively enjoy the market of the innovative product, increase extra profits and safeguard fundamental interests. Events including the determination of the United States on the patentability criteria of bank business methods in 1998 or the patent bulk purchase of Alibaba Group before the listing in the United States in 2014 indicated that the field of financial patent protection has always been a focus of people. With the constant innovation of e-commerce and in-depth integration of Internet and mobile communication network, transaction platforms and payment means represented by e-banking, online banking and mobile banking will be bound to become the main form of future financial services. This control of the patents closely related to high-tech may become constitutor of financial market rules.

Theoretical basis and analytical framework

The slight decline of net interest margin posed no threat to large banks like ICBC, and the real blow came from the endogenous market force, the counterattack of Internet financial enterprises. For example, Ali Group's financial system has fundamentally broken the ice of the domestic credit loan by the "one-stop" service of customer absorption, credit assessment, loan review and issuance via e-business platform, providing more possibilities to the SME's problem of "difficult financing and expensive financing". In addition, Ali Group does not only involve in traditional fields of commercial banks including deposits and loans, financing, payment and settlement, but resulting in profound impact on commercial banking services and business philosophy. The formal establishment of Zhejiang E-business Bank ("Ali Bank") in 2014 intensified the potential threat to traditional banks. The strengthening of intellectual property protection strategy fired the first shoot of the competition between domestic banking industry and Internet financing; meanwhile, to defend the intellectual property disputes with foreign companies, especially under the circumstances of Ali's listing in the United States, Chinese companies will be exposed to a wider range of patent competition, so the enhancement of information sharing, innovative alliance building (Feng, 2013), and especially the optimization of patent protection become particularly important.

Overseas research on the relationship between Internet finance and banks was significantly earlier than China. Chou, et al, believed the in-depth integration of Internet and bank caused a revolutionary upheaval to the banking sector (Chou & Chou, 2000); Tsai, et al held the customers of Internet financial enterprises and traditional commercial banks varied in age, which was related to the degree of acceptance of innovative technologies and uncertain risk factors (Tsai, Huang & Lin, 2005). Meyer pointed out compared with commercial banks, P2P platform has lower operating costs and higher utilization of funds (Meyer, 2007); Ocean believed Internet financial enterprises provided more convenient credit business than bank process (Tess, 2013).

Chen believed the pressure of commercial banks caused by Internet finance should not be overlooked, forcing commercial banks to accelerate the pace of reform and strengthen customer customization (Chen, 2014); according to the status quo of competition between Internet financial enterprises and traditional commercial banks, Wang proposed four competitive strategies such as growth-orient strategy and aggressive strategy (Wang & Wang, 2014) by using the SWOT analysis; Gong thought the Internet financial model would not shake the traditional business model and earning way of commercial banks in a short term, and commercial banks should seek new development opportunities by using the Internet

(Gong, 2013). The above literature study involved the impact of Internet finance on traditional commercial banks as well as the business model based discussion on how commercial banks deal with Internet finance. However, its analysis of the relationship between commercial banks and Internet finance from the perspective of patent and technological innovation is still a blank area. This paper makes econometric analysis of the patents of Chinese banking industry and Internet financial giants, providing important reference basis for the development and improvement of the related patent protection system and patent strategy, the comprehensive analytical framework is proposed as shown in Figure 1.

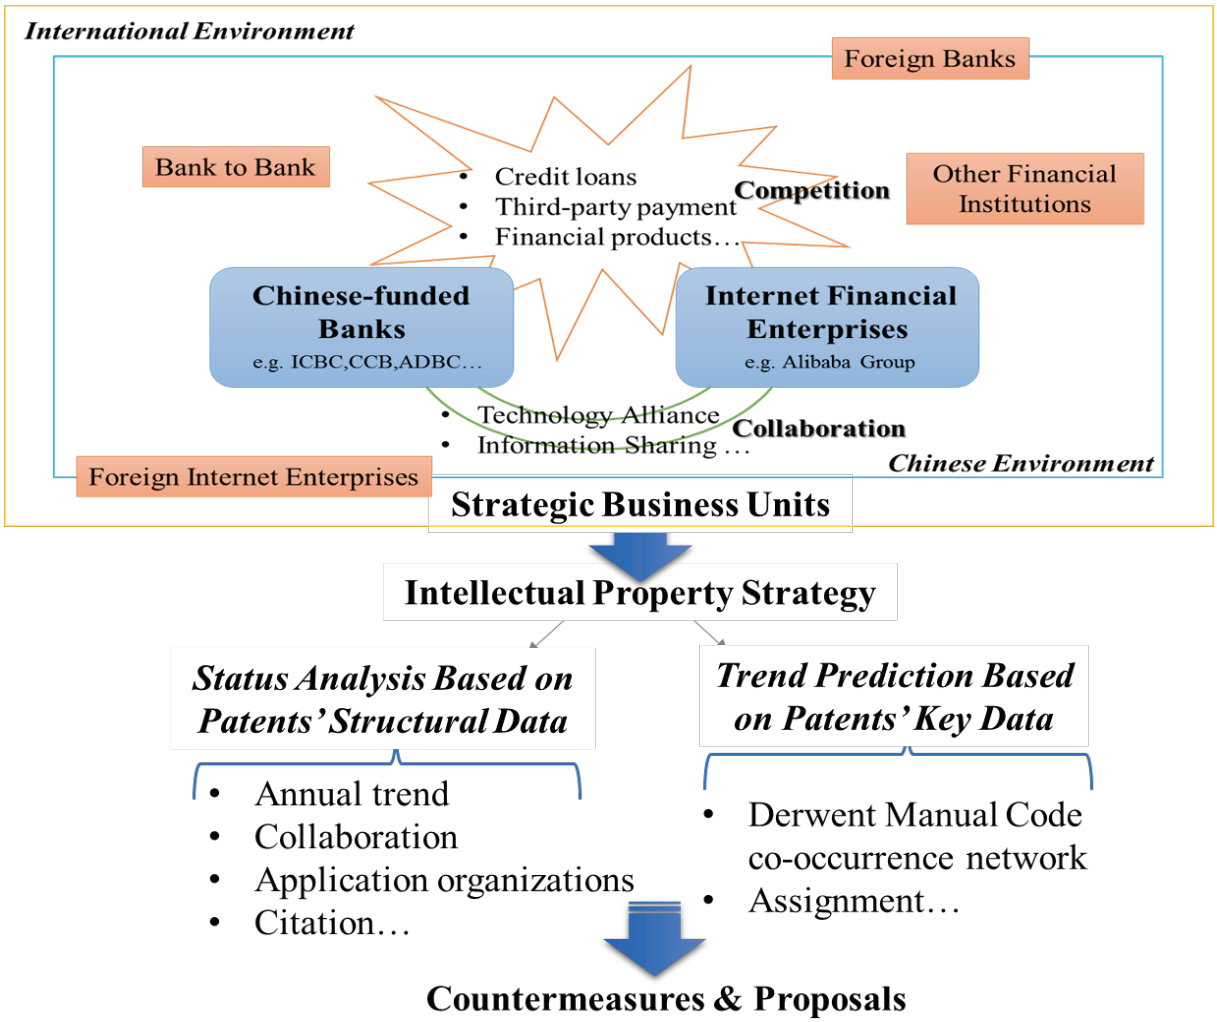

Figure 1. Patent analytical framework of Chinese-funded banks & Internet financial enterprises.

Data collection and analysis approach

The paper acquires the patents of the five representative Chinese-funded banks (ICBC, CCB, ADBC, BOC and BOCOM) and Alibaba Group Holding Limited on Jan.7, 2015 in DII by the way of Assignee Name and Assignee Code complex retrieval mode (Assignee Name and Assignee Code is connected by "OR" internally and by "AND" between two), the time span is from 1963 to 2014. After manual screening and exclusion, 917 Chinese bank patents and 1088 Ali patents are finally obtained.

The paper generalizes the patent development status and trend prediction of Chinese-funded banks and Internet financial enterprises by approaches of patent quantity statistical analysis

and patent content measurement in combination of visual tools, and proposes strategies and measures for the two sectors to improve patent protection, enhance technological innovation capacity, share information and build technology-business alliance if necessary, providing reference for the new development layout.

Results

Results of status analysis based on patents' structural data

Although the five Chinese-funded banks were built significantly earlier than Alibaba Group, they didn't occupy a striking advantage in the patent protection starting year, and lagged behind Ali in the total number of patents. In 2002, ICBC's patent of bank-card with dual account's processing device and method (PN: CN1397916-A) started the bank patent applications. Three years later, Alibaba carried out comprehensive patent protection and gradually exceeded the banks at an amazing growth. The annual patent application amount is shown in Figure 2.

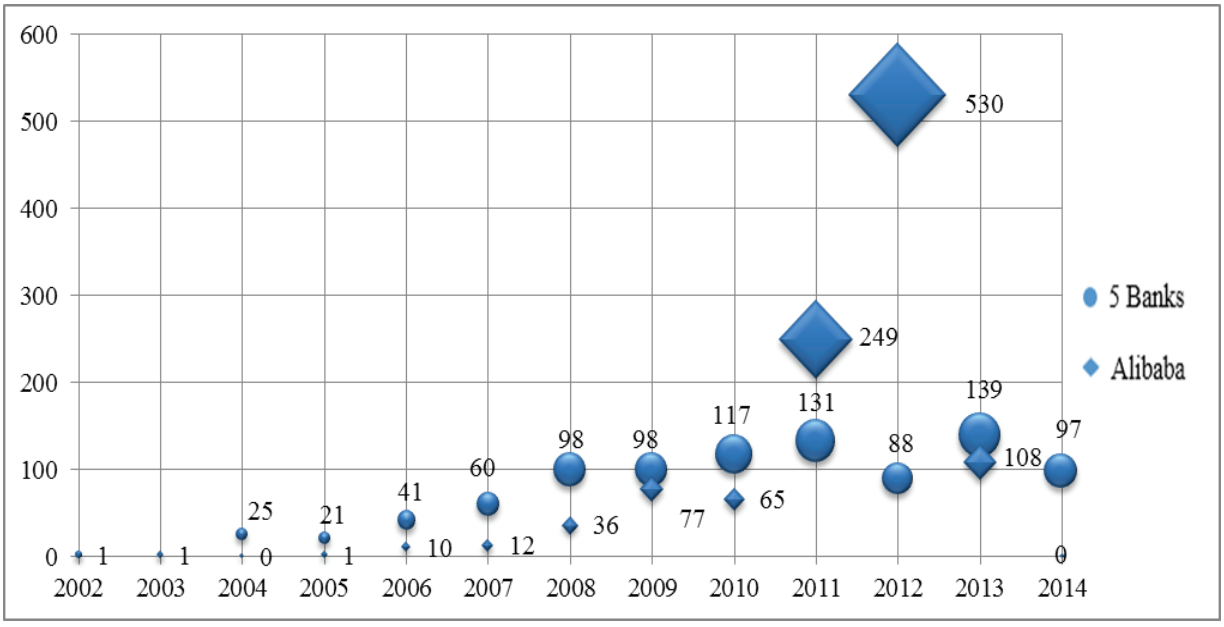

Figure 2. Annual trend of five Chinese-funded banks and Alibaba Group's patent quantity.

Figure 2 shows that the patent application amount of the selected banks has entered into fast growth since 2004. Though with slight fluctuation, but the overall situation is stable and the annual application number is relatively balanced. ICBC (549 patents) and CCB (253 patents) occupied a dominant position and led domestic banks to quickly engage in the patent development gradually integrating high-tech into the enterprise strategic level. In contrast, Ali Group's patent application was almost in exponential growth trend. The number of patent in 2012 was as high as 530, and the growth declined since 2013. The rapid deployment of domestic banks and financial enterprises was inseparable from the guidance of a series of policy documents including "National Intellectual Property Strategy" and also inseparable from the continuous expansion of Chinese enterprises and high-tech application.

By making statistics according to the patentee, we found all the 2005 patents were independently applied by banks and Ali Group. Few patents were produced via internal cooperation, and the branches concentrated in Zhejiang and Jiangsu. This phenomenon indicated that Chinese-funded banks and Internet financial enterprises didn't have close external relation in the patent activities, with a low degree of cooperation. To some extent, it

indicated that in the scope of finance, domestic enterprises have the relatively independent R&D team and were not positive enough in the flow and share of knowledge and information. If the external cooperation characterizes the degree of openness of proprietary technology, the geographical distribution of patent pending organizations is the indicator of measuring the corporate strategic deployment breadth. By the patent geological layout, we can learn and predict the key development areas of banks and Internet financial enterprises as well as the market distribution status of financial products and services (Luan, 2012). This paper makes analysis based on the connotation of the patent pending areas and organizations represented by the first two bits of code, we find only three patents of the Chinese-funded banks are applied in the non-Chinese mainland pending organizations, which are held by ICBC and distribute in WIPO, Taiwan and Russia. Although ICBC ranked No.1 in the world by a higher core capital and positively promoted international business strategy by means of organization application, mergers and acquisitions (till 2014, ICBC set up more than 330 overseas establishments in 41 countries and regions), its patent strategy failed to achieve the corresponding expansion (People, 2014). In contrast, Aliaba's patent has a wider geographical distribution; up to 71.7% (780pcs) of the patents were applied in organizations out of China. The average number of non-Chinese mainland patent application is 2.4 times (non-Chinese mainland application number/ non-Chinese mainland patent application number 1879/780), and the application of a number of patents has covered the range of over 6 organizations, and the pending mechanisms mainly distribute in Hong Kong, the United States and Europe (Table 1). Since the expansion of overseas business (since the establishment in 1998, Ali Group has set international headquarters in Hong Kong, offices in the United States, European and Japan), maintaining a highly consistent direction.

Table 1. Distribution of Ali's patent applications (outside of mainland China).

Region	*QTY*	*PCT(%)*	*Region*	*QTY*	*PCT(%)*
HK	631	33.58%	JP	186	9.90%
US	337	17.94%	KR	2	0.11%
WO	321	17.08%	SG	1	0.05%
EP	201	10.70%	AU	1	0.05%
TW	196	10.43%	DE	1	0.05%

Furthermore, the paper analyses status of two sections with patent citation data. These citations open up the possibility of tracing multiple linkages between inventions, inventors, scientists, firms, locations, etc. (Hall, Jaffe & Trajtenberg, 2001). 171 and 101 patents of Chinese banks and Ali Group were cited by other patents, respectively; patents with high citing frequency (top 5) were selected for analysis by combining with the cited patent information, and Table 2 is derived. Data showed that all the highly cited patents of Chinese banks were from ICBC, highlighting its outstanding R&D level among the peers.

Table 2. Highly cited patents of Ali and ICBC (Top 5).

ICBC		*Ali Group*	
PN/Freq. (cited patents)	AE/Freq. (citing patents)	PN/Freq. (cited patents)	AE/Freq. (citing patents)
CN1556449-A/19	BEIJ-Non-standard/10	CN101562543-A/7	GOOG-C/5
CN101183456-A/7	INCO-Non-standard/3	CN101662460-A	SALE-Non-standard/4
CN1588846-A/7	TNCT-C/3	CN101662460-A/6	IPCU-Non-standard/3
CN101119202-A/6	JIED-Non-standard/2	CN1835438-A/6	HUAW-C/2
CN101393671-A/5	SONG-Individual/2	CN101685516-A/5	TNCT-C/1

The patents of ICBC and Ali Group were mainly cited by enterprises, and a small number distributed in the patents held in the name of individuals and universities. Enterprises cited the patents of ICBC including categories of marketing, communications, telecommunications, network equipment, data security, authentication and other related categories, of which the citing frequency of BEIJING FEITIAN CHENGXIN SCI & TECHN CO (a world leading professional software protection and authentication of high-tech intelligence company), indicating the important of the authentication–related technology included in ICBC patents and also reflecting the close relation between the company products and ICBC business. Enterprises' citations of Ali Group involved customer consulting, Internet, software, communications (communications equipment), electronics, telecommunications, investing and financing, and the patent citers distributed in the United States and Japan. It is noteworthy that enterprises with similar business as Alibaba like Google, Tencent, are also among the citing group, showing Ali's patent technology is playing a guiding role in the Internet industry. In addition, Beijing Institute of Technology and Taiyuan University of Technology cited the patent of Ali and ICBC once, respectively.

Results of trend prediction based on patents' key data

Compared to other classification system, Derwent manual code (MC) outlines more detailed indexing information in retrieval of patent's theme and core content based on the uses and applications of an invention, rather than just a straight forward description of what the invention is (Stembridge, 1999).

Table 3. High frequency Derwent Manual Codes (Top 10).

Alibaba freq			*Five Chinese-funded banks*		
Freq	MC	Content	Freq	MC	Content
310	T01-J05B4P	Database applications	175	T01-J05A1	Financial
230	T01-N01D3	From remote site or server	140	T01-N01A1	Eft/banking
184	T01-S03	Claimed software products	139	T01-N01D3	From remote site or server
172	T01-N02A3C	Servers	134	T01-J05B4P	Database applications
154	T01-N03A2	Search engines and searching	81	T05-L03C1	General control system
126	T01-J05B3	Search and retrieval	75	T01-N02A3C	Servers
123	T01-N01D2	Document transfer	69	T01-D01	Data encryption and decryption
77	W01-A07G1	Transmission control procedure	67	T01-N01A	Financial/business
74	T01-N01A	Financial/business	59	T01-N01D2	Document transfer
65	T01-N02A2C	Client/server system	57	T01-N02B2B	System and fault monitoring

Further, we transforms the bibliographic data of all the 2005 patents into WoS logging data and introduced into the CiteSpace, and set the analysis interval as 1 year, then drawing the maps (Figure 3 and Figure 4). By depicting the association and combination between the MCs, it can analyse the correlation between patents and even technologies, and can also facsimile the internal technology composition and structure (Shen, Gao & Teng, 2012). Timeline visualization provides a directly temporal overview of technologies, columns are time periods of co-occurrence of technologies and rows are clusters (Gong, Jiang, Yang& Wei, 2011). The dynamically changing course of banks and Internet finance patent technologies can be revealed by combining with the attribute changes in timeline axis. Moreover, the development trend can be predicted through their restive business characteristics. The top 10 high-frequency manual codes of Chinese-funded banks and Ali Group (Table 3) were intercepted respectively to explore the hot fields.

It can be seen from the analysis that the technical research of both subjects was carried out by centring the category of "T01", showing the Chinese banks and Internet financial enterprises are very concerned about the application of digital computer in financial services. A series of patent activities were conducted by combining with the research of "database applications" and "application originating from remote sites or remote servers". It is noteworthy that in the distribution of the top 10 high-frequency bank patents, Internet financial patents showed a high degree of overlap in some technical contents. In addition to "database applications" and "remote service", "document transfer" and "Financial/business" were also included in the key content of their patent developments. In contrast, the patents of banks are more inclined to the study of financial, banking, system monitoring and related technology; Ali Group makes innovation and protection based on the contents of search engine and software.

As the largest cluster in the bank MC network, "bank background" demonstrated the general picture of banking business featuring electronic funds transfer point of sale equipment, currency handling systems, smart media and the Internet and information transfer, which occupied the central position in the entire time chain.

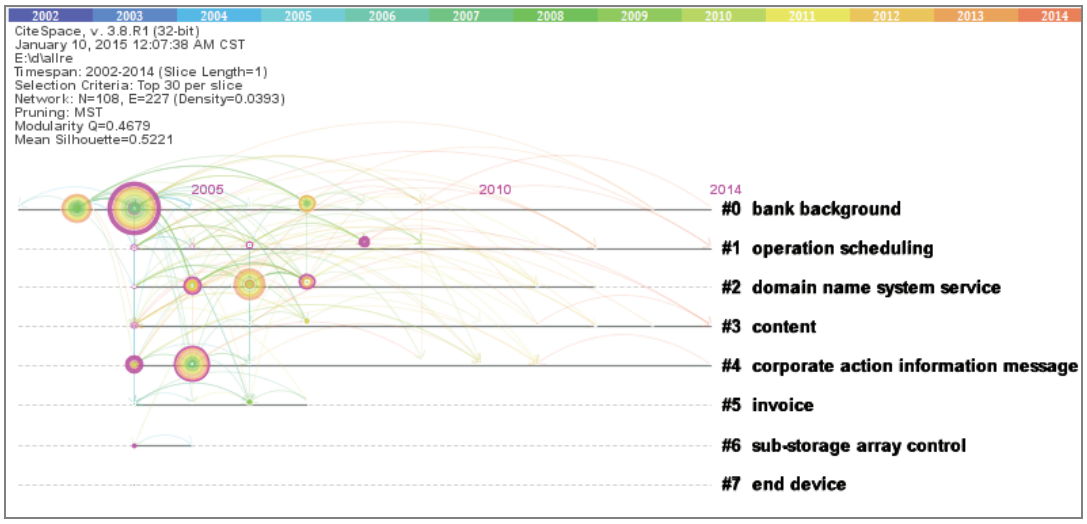

Figure 3. Five banks' Derwent Manual Code co-occurrence network (Timeline view).

Figure 4. Alibaba Group's Derwent Manual Code co-occurrence network (Timeline view).

In Ali's network, the cluster "outgoing message" constituted by the close connection of digital information transmission, Internet and messaging, data processing systems and process control comprehensively summarized the business flow carried out by Ali Group based on Internet data. Second, the cluster "central account registration system" composed by audio / video record and Internet-based information processing and transfer, and nine clusters including data and communications. The overall technology relevance and research contents are similar to these shown in the MC of Chinese bank patents, but more emphasis was made on the application of Internet in business.

On this basis, codes with high frequency change rate with the time sequence (burst term, Table 4&5) further determined the technology frontier and development trend of Chinese banks and Ali (Huang, Wang &Wang, 2014).

Table 4. Bursts of Banks' Derwent Manual Codes

Burst	*MC*	*year*	*Content*
5.77	T05-L03	2002	Cash dispensing and depositing machines

3.04	T04-K03B	2012	Rfid/transponder

Table 5. Bursts of Ali' Derwent Manual Codes

Burst	*MC*	*year*	*Content*
5.12	T01-N01A1	2005	Eft/banking
3.14	T01-N02A3C	2006	Servers
5.02	T01-E01A	2007	Sorting
4.48	T01-S03	2007	Claimed software products
2.86	T01-J16C3	2007	Natural and pictorial language processing
4.58	T01-M02	2008	Multiprocessor systems
6.29	T01-E01	2009	Sorting, selecting, merging or comparing data
4.63	T01-J20C	2011	Software test, verification, debug, optimization
2.73	W01-A06E	2013	Network control and software

The patented technology burst of Chinese banks are more evenly dispersed in 2002~2012, following the development course of bank reserves appliances → electronic funds / bank → online business and data processing → database applications → specific project management and data transfer → search engine, control → wireless communications, showing the trend of gradual evolution from traditional banking to Internet financial sector. Since 2005, Ali's patent started from e-funds/e-bank technologies, and then underwent a series of technology evolution of data processing from server, data sorting, and software to graphic language processing, which is currently in the data processing optimization and study of Internet control technology. Although the related technologies of e-transaction technology appeared earlier in the patent of Chinese banks, but Ali Group is more sustainable in the ongoing online transactions, which continues to carry out the research based on big data and gradually establish technology chain in the field of Internet finance.

Technological evolution is the exploration on the development route and trend of bank and Internet financial enterprises based on patent, and the conclusion of patent assignment information can provide references to the patent development mode of the two. In 2014, Alibaba Group made IPO financing amounted to 25 billion U.S. dollars, which was the largest IPO. The United States is a country with frequent patent disputes, to avoid the patent infringement issues encountered by Facebook or Twitter in IPO, Ali Group has made significant patent deployment in the U.S. since 2013, where a lot of patents have been reserved. Till the retrieval date of this paper, 399 U.S. patent family cases were found and more than 50 have been authorized (Chinaip, 2014). In addition to independent application, Alibaba purchased 21 patents from IBM in 2013, and one of which was for Amazon, the largest U.S. e-commerce platform, and also prepared for coping with the patent competition and litigation. We made inquiry of the operating data of Ali Group and five Chinese banks in Chinese patent database and found that Ali Group started to purchase the patents of other organizations since 2012 onwards, but only limited to the category of invention patents. Patent seller expanded from domestic organizations to international institutions, such as Shanghai Yiren Information Technology Co., Ltd. and IBM; in addition to enterprises, Ali also purchased patents from Chinese Academy of Science Institute of Computing Technology; the change of some patent was caused by the changes of the corporate nature, such as Alibaba to Alibaba Group Holding Limited. The aforementioned technical fields of patent change included electric digital data processing, transmission of digital information, arrangements of circuit components or wiring on supporting structure and coin-freed or like apparatus. However, the patent purchased by Chinese banks included patent, utility models and appearance design, and the patents with internal change were almost 1/2 of the total patent transfer amount. These patents mainly came from the bank branches and individuals, and only CCB had one patent purchase from enterprise (Shandong Confucian Culture Communication Co., Ltd.), and the technical fields of patent change mainly involved the bank cards, security cards, teller settings and other contents, no transactions concerning goods and services of bank financial commodities and services were made.

Discussion and conclusions

General comments

In a long term in the past, Chinese banks made huge profits by relying on monopoly advantages and policy bonus, and occupied the position on the top of financial ecology. However, the single channel and curing product business model can no longer work. In China, the rapid development trend of Internet finance represented by Alibaba does not only occupy a significant share in domestic financial sector, but also causes widespread concern in the overseas business expansion. Traditional profit making channels of banks have been

hindered in a variety of aspects, including the competition of domestic and overseas banking industries and the pressure caused by the enhancement of overlap ratio with Internet finance business. With the development of commodities and services based on big data, Internet financial enterprises are inseparable from the application of technology. In the new situation, it faces the transfer from purely financial products to technical competition; whether banks or Internet financial enterprises, technology innovation and application have been upgraded to a new strategic plan.

By the comparison of patents of 5 Chinese banks and Alibaba Group Holdings Limited, we found that the patent activities of Chinese banks started late, with limited number, especially in key business areas like e-commerce. Most of the bank patents were independently applied in China, and their overseas IPR protection does not match their development of business, which may become a potential hazard for patent disputes arising from overseas promotion of financial products and services. Although the banks have higher patent citing frequency, the citing parties are mostly in China and the all the highly cited patents are held by ICBC. In contrast, Ali Group has achieved rapid progress of patent activities, with advantages in the total number, patent geographical distribution and the composition of citing groups. However, like banks, Ali Group also has low degree of external cooperation, indicating their closure and limitations in patent research and development. We can learn from MC co-occurrence network that banks and Internet financial enterprises have relatively concentrated technology, which were the patent R&D centred by computer and showed a high degree of overlapping in database use, financial/commercial and remote control, etc. The patent contents of Chinese patents tend to the research of digital communication, hardware equipment and banking business operation, whereas Alibaba pays more attention to search engine and software-related innovation and protection. From 2002 to 2014, bank patent technology showed the shift from bank reserves appliance to e-funds/banking, online services and data processing. Currently, it is in the stage of network and wireless communications, whereas the research of Alibaba has undergone a series of technology evolutions from e-funds/e-banking, data processing from server, data processing, software to graphic language processing. Patent assignment data showed that independently developed ones are still the main source of banks and Internet financial enterprises' patents, while the patent purchase of Internet financial enterprises are quietly rising, and may form a new patent development mode of "independent R&D and purchase".

Countermeasures & Proposals

Based on the abovementioned patent status and future development direction of banks and Internet financial enterprises, China's banking industry shall attach important to the development, protection, management and utilization of bank patents at all levels. Moreover, it is essential to set up product and service technology early warning, make technical prediction and selection in fields with priority. At the same time, cooperation with high-tech industries represented by information technology shall be emphasized to improve the patent technical quality. At the same time, on the basis of full study of international regulations and overseas local laws and regulations, Chinese banks shall learn from Alibaba's international patent strategies to increase the overseas patent application quantity, expand market share and gain competitive advantages. After the listing in the United States, as the leader of Internet financial industry, Alibaba shall not only strengthen the risk control effort, promote the innovation of financial products and services and customer participation as well, but shall accelerate the deployment of intellectual property, take the mode of simultaneous patent purchase and independent R&D, to avoid patent disputes with overseas companies and win market opportunities by appropriate use of patents. In addition to strengthening their competitive advantages, banks and Internet financial enterprises shall strengthen cooperation

to make best use of the advantages and bypass the disadvantages, so as to form a new finance-technology alliance. Banks can use the network resources, information data and cloud computing of Internet financial enterprises to play their professional administration, thus introducing customers to the professional advantages via network channel. Likewise, by relying on the financial background of banks, Internet financial enterprises shall set up long-term, stable relationship with mutual trust to expand the scope of commercial exchanges, strengthen financial risk management and control, thereby providing a cooperation and win-win opportunity to both parties.

Further research

In the process of researching the status quo and future trend of Chinese-funded banks and Internet financial enterprises, this paper only took into account of their competition and cooperation. In fact, we can learn from the framework of this paper that factors affecting the development of them are multifaceted and complex. Hence, in the following study, the author will put overseas companies into the comparison to explain the development situation of banks and Internet financial enterprises in detail.

Acknowledgments

We would like to thank the anonymous reviewers for their important comments. Thanks to Dr. Liu and Dr. Tang for his assistance in data cleaning.

Abstract
This paper employed the US Patent Application Database to find out who files provisional applications in the United States. Preference rates, use rates, and provisional application to non-provisional application rates were used to evaluate the filing behaviour of provisional applications with respect to non-provisional applications. Factors weighing toward filing provisional applications include filing date sensitivity, patent term sensitivity, and necessity of promoting. Factors weighing against filing provisional applications include cost sensitivity and English abilities. These factors were discussed in order to explain the filing behaviour of provisional applications with respect to non-provisional applications. Applicants form English speaking countries are more likely to file provisional applications than applicants from other countries. We reasoned that the English ability of applicants might be the cause for such a result. Applicants from the fields of Computers and Communications and Drugs and Medical are more likely to file provisional applications than applicants from other fields. We reasoned that patent term sensitivity and filing date sensitivity might be the cause for such a result.

Conference Topic
Patent Analysis

Background and purpose
A provisional application for patent (hereafter referred to as 'provisional application') is a US national application filed in the United States Patent and Trademark Office (USPTO) that has been offered to applicants since June 8, 1995 and was designed to provide a lower-cost first patent filing in the United States. A provisional application is not required to have a formal patent claim or an oath or declaration. Provisional applications also should not include any information disclosure (prior art) statement since provisional applications are not examined. A provisional application provides the means to establish an early effective filing date in a later filed non-provisional patent application (hereafter referred to as 'non-provisional application'). It also allows the term "Patent Pending" to be applied in connection with the description of the invention. A provisional application has a pendency lasting 12 months from the date the provisional application is filed. The 12-month pendency period cannot be extended. Therefore, an applicant who files a provisional application must file a corresponding non-provisional application for patent during the 12-month pendency period of the provisional application in order to benefit from the earlier filing of the provisional application. By filing a provisional application first, and then filing a corresponding non-provisional application that references the provisional application within the 12-month provisional application pendency period, a patent term endpoint may be extended by as much as 12 months. (USPTO, 2014).

Although the provisional application filing approach has been offered to applicants for almost two decades, the USPTO does not make its database of provisional applications publicly available other than the individual files in Patent Application Information Retrieval (PAIR). Therefore, it is still difficult to answer the following two crucial questions: (1) Who files provisional applications in the United States? (2) Why do applicants file provisional applications in the United States?

Dennis Crouch (2008) studied approximately 15,000 utility patents issued in April and May 2008 and found out that only 21% of issued patents claiming priority from a provisional application, only 5% of the patents that associated with a provisional application were assigned to international applicants while 30% of the patents that associated with a provisional application were assigned to a U.S. applicant, Israel and Canada filed the highest proportion of provisional parent claims, only 2% of the Japanese & Korean patents included provisional parent claims, new drug inventions have the highest rate of association with a provisional application, and patents on electrical and electronic applications had the lowest rate of provisional filing. Dennis Crouch provided a rough first look of provisional application filings in the United States, but the dataset used by Dennis Crouch was rather small and time-limited (approximately 15,000 utility patents issued in April and May 2008). Therefore, it seems that the dataset used by Dennis Crouch was not sufficiently large to guarantee the results; and moreover, Dennis Crouch provides the results but lacked to explain the results.

The purpose of this paper is to address the two questions identified with sufficient dataset and detailed analyses to guarantee the results and to fully understand the filing behaviour of applicants. First, we employ the US Patent Application Database for 2005-2013 to find out who files provisional applications by checking the provisional application filings in different countries of origins, technological categories, assignee types, and assignees. Second, we explain why applicants file provisional applications in the US According to the USPTO, most obvious advantages of filing a provisional application are: (1) obtaining an effective filing date with a lower cost and an easily prepared application; (2) extending the statutory patent term up to one year; and (3) the ability to use the term "patent pending" (USPTO, 2014). Therefore, we assume that the following factors are weighing toward filing provisional applications: (1) filing date sensitivity; (2) patent term sensitivity; and (3) the necessity of promoting. Although the provisional application is designed to provide a lower-cost first patent filing in the US, an applicant still needs to spend extra money to file a corresponding non-provisional application in order to obtain a patent. In addition, although the provisional application was supposed to be an easily prepared application as it may be filed in a foreign language, an applicant still requires the English ability to prosecute the provisional application. Therefore, we assume that the following factors are weighing against filing provisional applications: (1) cost sensitivity; and (2) the English ability of applicants.

Trends in filing provisional applications

Since the database of provisional applications is not published, the filing numbers of the provisional applications can only be obtained from annual fiscal reports by the USPTO. Moreover, since the USPTO has never made publicly available the provisional applications that are not relied on for claiming priority by non-provisional applications, we employed the USPTO Patent Application Database to find out the number of provisional applications that have been claimed for priority by at least one non-provisional application.

Figure 1 shows the trends in filing provisional applications. The black bars represent the number of utility applications (non-provisional applications) filed each year from 2005 to 2013; the hatched bars represent the number of provisional applications filed each year from 2005 to 2013; and the grey bars represent the number of provisional applications filed each year from 2005 to 2013 that are relied on as priority documents in non-provisional applications. Please note that the USPTO only reported the number of provisional applications by fiscal year. So in Figure 1, the hatched bars were calculated by the fiscal year (October 1 to September 30), not by the calendar year (1 January to 31 December).

As shown in Figure 1, from 2005 to 2013, over 4.29 million non-provisional applications and over 1.27 million provisional applications have been filed. Among the 1.27 million

provisional applications, over 0.71 million provisional applications have been converted to non-provisional applications. It can be inferred that both non-provisional application filings and provisional application filings continued to rise, with over 570,000 and 170,000 filed in 2013. There was a drop in each of the non-provisional application filings and the provisional application filings in 2009. A possible explanation for such a drop could be attributed to the financial crisis of 2008.

Figure 1 also shows the provisional applications that have been relied on for claiming priority by non-provisional applications. It is observed that the number of provisional applications that have been relied on for claiming priority by non-provisional applications is growing. Although the provisional applications continued to be more popular, applicants have abandoned more of the provisional applications without relying upon them for claiming priority. The difference between each pair of the hatched bar and the grey bar is the number of provisional applications abandoned without being used as priority documents each year.

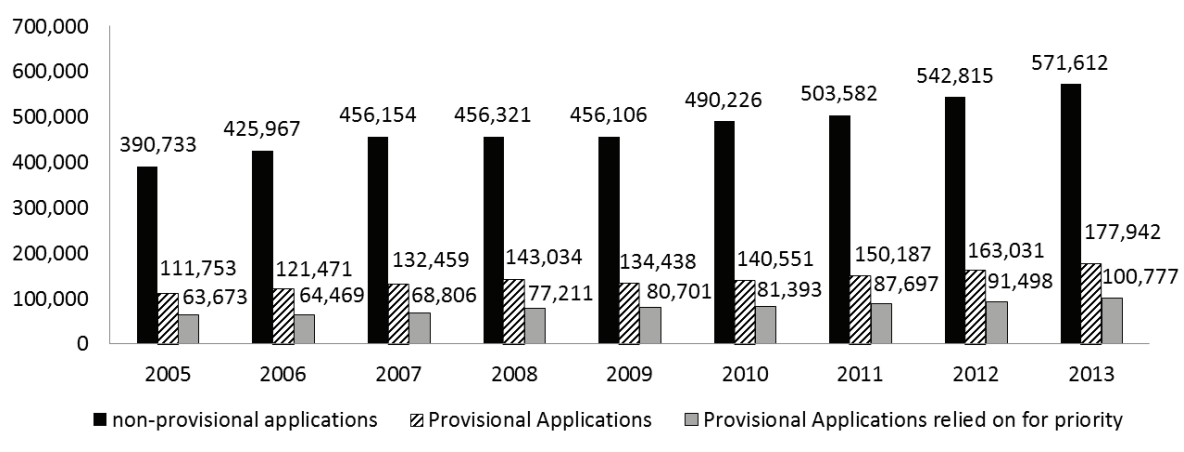

Figure 1. Non-provisional applications, provisional applications, and provisional applications relied on for priority filed each year for 2005-2013.

Rates of provisional applications/non-provisional applications

Rates of provisional applications/non-provisional applications (hereafter referred to as preference rates) show the preference of applicants in filing provisional applications with respect to non-provisional applications. The preference rate represents the percentage of a provisional application being filed in proportion with a non-provisional application in deciding filing patent applications in the United States. In Figure 2, the dotted line shows the preference rate of all provisional applications filed each year from 2005 to2013. It is clear that the preference rate remained steady during the period, except for 2009-2010, and the preference rate continued to slightly rise to 31.13 % in 2013.

Rates of provisional applications relied on for priority /provisional applications

As mentioned above, a provisional application has a pendency lasting 12 months from the date the provisional application is filed. An applicant who files a provisional application must file a corresponding non-provisional application for patent during the 12-month pendency period of the provisional application in order to benefit from the earlier filing of the provisional application (USPTO, 2014); otherwise, the provisional application will be automatically abandoned. Therefore, it is interesting to find out the use rate of the provisional applications that have been used for claiming priority by non-provisional applications (hereafter referred to as use rate). The use rate represents the usage of provisional applications. The result is shown in Figure 2, where the first solid line represents the use rate of all provisional applications filed each year from 2005 to 2013. As shown in Figure 2, the use rate

of provisional applications was located between about 52% and about 60% in 2005-2013, that is, about 40% to about 48% of the provisional applications were abandoned without being converted to non-provisional applications each year during 2005 and 2013.

Rates of provisional applications relied on for priority/non-provisional applications

Rates of provisional applications relied on for priority/non-provisional applications (hereafter referred to PA to NPA rate) show both the filing preference and the usage of provisional applications. The PA to NPA rate can be calculated by the preference rate times the use rate. Since the USPTO has never mad publicly available the provisional applications that are not relied on for claiming priority by non-provisional applications, the PA to NPA rate became the only practical rate for evaluating the provisional application filings with respect to non-provisional application filings in different countries of origins, technological categories, and assignees. As shown in Figure 2, the second solid line represents the PA to NPA rate of all the provisional applications filed each year between 2005 and 2013. It can be seen that the PA to NPA rate remained steady during the period, except for 2009-2010, and it continued to slightly rise to 17.63% in 2013. In other words, approximately one in six non-provisional applications was expected to claim priority upon a provisional application.

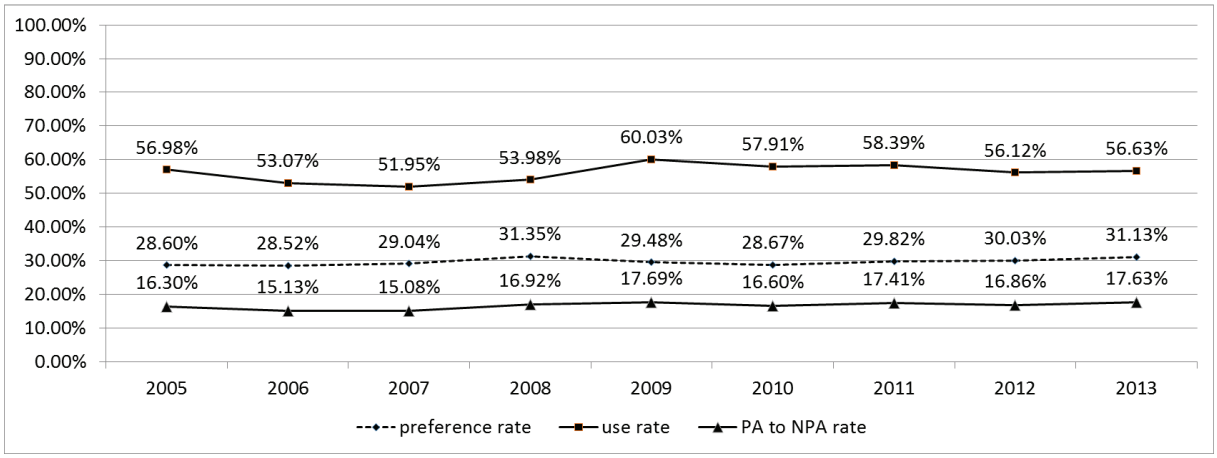

Figure 2. Preference rate, use rate and PA to NPA rate each year from 2005-2013.

Provisional applications by different countries of origins

The date of the filing of the provisional patent application can also be used as the foreign priority date for applications filed in countries other than the United States. Therefore, the need is identified for a foreign applicant to file a patent application as a provisional application in the United States first, and then to claim the priority of the provisional application to file a regular patent application in the United States as well as in the countries other than the United States.

Table 1 shows the ranking of the top 10 countries of origins where applicants filed provisional applications and non-provisional applications in the US in 2005-2013. During this period, the top 10 countries were: United States of America (US), Canada (CA), Germany (DE), Japan (JP), Israel (IL), Netherlands (NL), Korea (KR), Taiwan (TW), France (FR), and Switzerland (CH). It can be seen in Table 1 that the ranking of provisional applications and that of non-provisional applications varied for some countries. For example, JP was ranked second in non-provisional applications but fourth in provisional applications; KR was ranked fourth in non-provisional applications but seventh in provisional applications; TW was ranked fifth in non-provisional applications but eighth in provisional applications; FR was ranked sixth in non-provisional applications but ninth in provisional applications; and CN (China) was

ranked seventh in non-provisional applications but was not ranked in the top ten in provisional applications. It can be concluded that applicants in JP, KR, TW, FR and CN prefer filing their first applications in the United States as regular non-provisional applications rather than provisional applications. On the contrary, applicants in the US, CA and IL very much prefer filing their first applications in the US as provisional applications.

Table 1. Ranking of the top 10 countries of origins where applicants filed provisional applications and non-provisional applications in the US in 2005-2013.

ranking	*1*	*2*	*3*	*4*	*5*	*6*	*7*	*8*	*9*	*10*
provisional applications	US	CA	DE	JP	IL	NL	KR	TW	FR	CH
non-provisional applications	US	JP	DE	KR	TW	FR	CN	NL	CA	GB

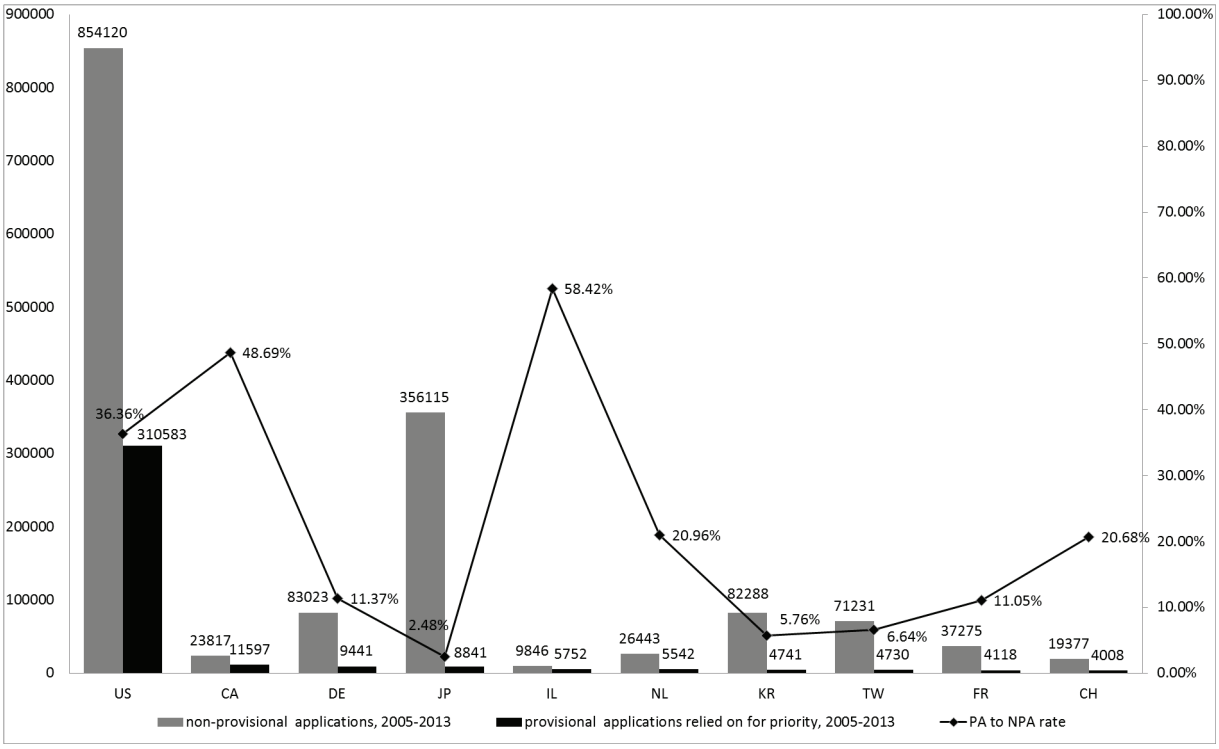

Figure 3. Top 10 countries of origins where applicants filed provisional applications with respect to corresponding non-provisional applications and the PA to NPA rate in the US in 2005-2013.

Furthermore, we checked the PA to NPA rate in order to find out the preference of filing provisional applications for applicants in different countries of origins. Figure 3 shows the top ten countries of origins, where applicants filed provisional applications with respect to corresponding non-provisional applications and the PA to NPA rate in the US in 2005-2013.

In Figure 3, the black bars represent the number of provisional applications filed by applicants from each country in the US in 2005-2013; the grey bars represent the number of non-provisional applications filed by applicants from each corresponding country in the US in 2005-2013; and the solid line represents the PA to NPA rate of each corresponding country in 2005-2013. Figure 3 shows that the PA to NPA rates of the US (36.36%), CA (48.69%) and IL (58.42%) were very much above the average percentage (about 17%). Contrarily, the PA to NPA rates of JP (2.48%), KR (5.76) and TW (6.64%) were far less than the average percentage. We reasoned that the English ability of applicants might be the cause for such a result. Comparing to applicants from JP, KR and TW, applicants from the US, CA and IL are either native English speakers or having good English abilities, so it is relatively easy for applicants in these countries to prepare a provisional application that is suitable for being

relied on for claiming priority by a non-provisional application. Moreover, some foreign laws limit the filing of patent applications abroad before a national patent application filing or authorization occurs. So the PA to NPA rate is expected to be low for applicants from those countries. For example, CN has this kind of law, and its PA to NPA rate was only 2.75%.

Provisional applications by different technological categories

In this paper, we used the six main technological categories (i.e. Chemical, Computers & Communications, Drugs & Medical, Electrical & Electronic, Mechanical, and Others) developed by The National Bureau of Economic Research (NBER) (Hall et al., 2001) to analyse provisional applications by technological categories.

Figure 4 shows the provisional applications relied on for priority filed each year from 2005 to 2013 divided by the NBER main technological categories. As shown in Figure 4, Computers and Communications and Drugs and Medical were the most popular main technological categories, in which applicants filed provisional applications and further converted them to non-provisional applications by claiming priority.

Sukhatme and Cramer (2014) suggested that an applicant who cares about the patent term will seize an opportunity to increase the term if it is offered to him/her. Applicants in industries in which the patent term is especially important would be more likely to file provisional applications than applicants in industries in which the term is less important. In the Drugs & Medical industry, the patent term is critical, i.e. applicants consider the patent term sensitivity, so the applicants tend to extend the statutory patent term up to one year by filing provisional applications first instead of non-provisional applications. In the Computers & Communications category, technologies change rapidly, i.e. applicants consider filing date sensitivity, so obtaining an early effective filing date is important to inventions in this category.

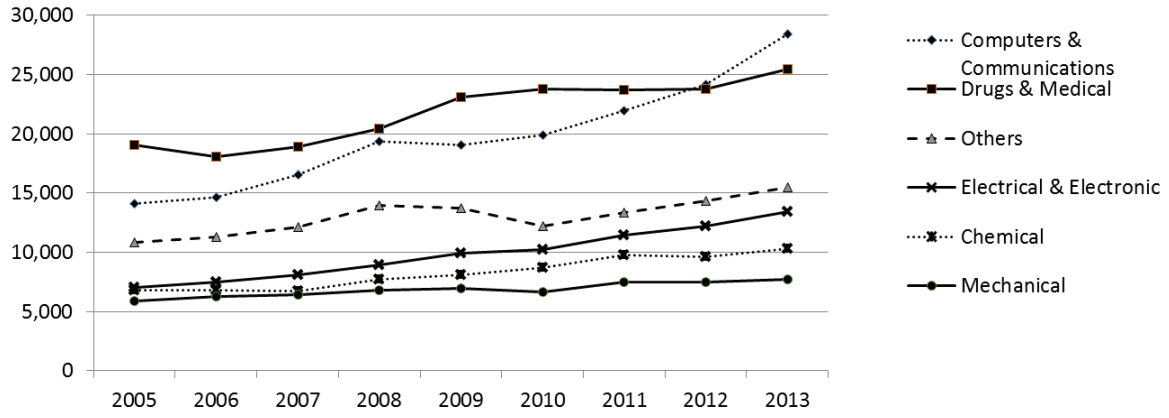

Figure 4. Provisional applications relied on for priority filed each year from 2005-2013, by NBER main technological categories.

Provisional applications by different assignees

Table 2 displays the top ten assignees filing provisional applications that were relied on for priority in the US in 2005-2013. Table 2 also shows the corresponding non-provisional applications by the top ten assignees, and their PA to NPA rates. It is clear that except for Samsung (5.68%) and Microsoft (9.27%), the PA to NPA rate of each of the other assignees was very much above the average percentage (about 17%). Take California University as an example, its PA to NPA rate was up to 81.28%. That is, in about every ten non-provisional

applications, over eight non-provisional applications claimed priority based upon early filing provisional applications.

Table 2. Top ten assignees filing provisional applications that were relied on for priority in the US in 2005-2013, the corresponding non-provisional applications, and the PA to NPA rates.

Assignee	*provisional applications relied on for priority*	*non-provisional applications*	*PA to NPA rate*
Qualcomm	6291	10018	62.80%
California University	3426	4215	81.28%
Broadcom	2876	4963	57.95%
Samsung Electro-Mechanics	2771	48814	5.68%
Koninklijke Philips Electronics N.V.	2519	12386	20.34%
Microsoft	2483	26799	9.27%
DuPont	2429	3286	73.92%
Texas Instruments	2353	5943	39.59%
LG Electronics	2318	9211	25.17%
Apple	1772	5124	34.58%

Table 3 shows main patent areas of each of the top ten assignees. For example, Qualcomm focused on the Computers & Communications field. So among all the 6291 provisional applications that relied on for priority, 5612 applications (about 89%) filed in the category of Computers & Communications. Broadcom, Samsung Electro-Mechanics, Microsoft, Texas Instruments, LG Electronics, and Apple also focused on the field of Computers & Communications.

Table 3. Provisional applications filed by the top ten assignees in the US in 2005-2013 by technological categories.

Assignee	*Chemical*	*Computers & Communications*	*Drugs & Medical*	*Electrical & Electronic*	*Mechanical*	*Others*
Qualcomm	0	5612	0	483	74	106
California University	514	269	1702	716	102	123
Broadcom	0	2264	0	441	0	145
Samsung Electro-Mechanics	0	2187	0	318	0	206
Koninklijke Philips Electronics N.V.	0	852	761	649	53	175
Microsoft	0	1880	0	107	0	474
DuPont	1007	0	509	394	95	374
Texas Instruments	0	1439	0	792	60	0
LG Electronics	0	2041	0	122	0	140
Apple	0	1169	0	429	38	107

It appears that applicants in the Computers and Communications field tend to file more provisional applications than those in other fields. We checked provisional applications that

were relied on for claiming priority filed by the top ten assignees in the Computers & Communications field each year between 2005 and 2013 and all provisional applications that were relied on for claiming priority filed by each of the top ten assignees each year between 2005 and 2013. The result was shown in Figure 5. For all the ten assignees, provisional applications filed in the Computers and Communications field were very close to all provisional applications. It indicates that, applicants in the Computers & Communications field only focused on one field.

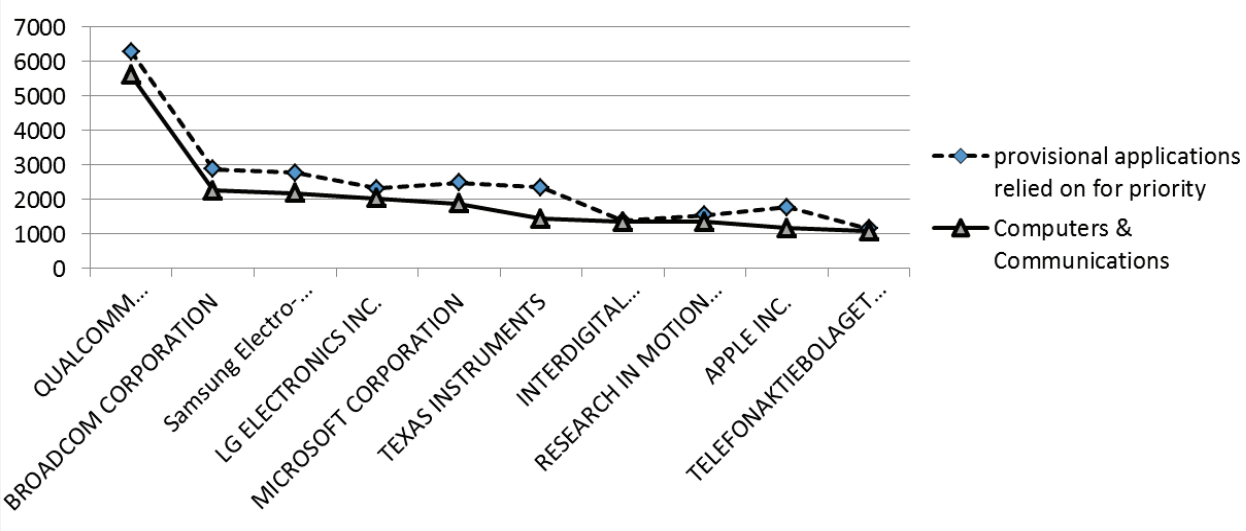

Figure 5. Provisional applications that were relied on for claiming priority filed by the top ten assignees in the Computers & Communications field each year between 2005 and 2013 and all provisional applications that were relied on for claiming priority filed by each of the top ten assignees each year between 2005 and 2013.

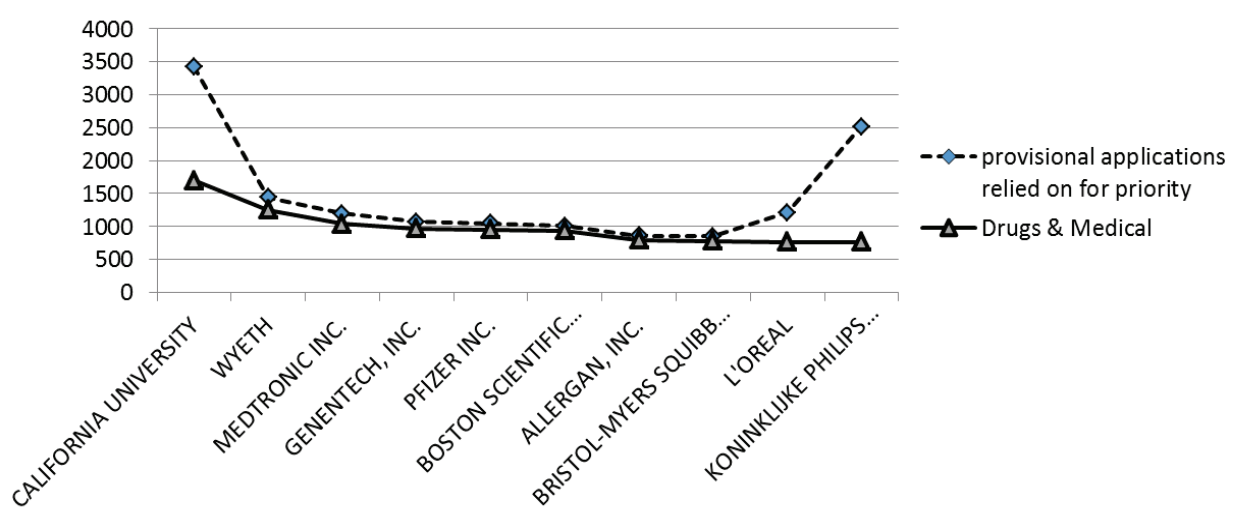

Figure 6. Provisional applications that were relied on for claiming priority filed by the top ten assignees in the Drugs & Medical field each year between 2005 and 2013 and all provisional applications that were relied on for claiming priority filed by each of the top ten assignees each year between 2005 and 2013.

Furthermore, we checked the provisional applications that were relied on for claiming priority filed by the top ten assignees in the Drugs and Medical field each year between 2005 and 2013 and all provisional applications that were relied on for claiming priority filed by each of the top ten assignees each year between 2005 and 2013. The result was shown in Figure 6.

Except for California University and Koninklijke Philips Electronics N.V., assignees filing provisional applications in Drugs & Medical also performed similarly to those in Computers & Communications, i.e. they had less diversity and only focused on one field.

Conclusion

It was found that provisional application filings continued to rise with an increase of non-provisional application filings between 2005 and 2013. The preference rate remained steady with a slight increase. The use rate of provisional applications was about 52% to 60% each year between 2005 and 2013. The PA to NPA rate can be used to evaluate the provisional application filings with respect to non-provisional application filings in different countries of origins, technological categories, and assignees. Filing date sensitivity, patent term sensitivity, and the necessity of promoting were regarded as factors weighing toward filing provisional applications. Cost sensitivity and English abilities were regarded as factors weighing against filing provisional applications.

For provisional applications by different countries of origins, applicants from Eastern Asian countries, including Japan, Korea, Taiwan and China, were less likely to file provisional applications in the US Contrarily, applicants form English speaking countries, including the US, Canada and Israel, were more likely to file provisional applications in the US. Therefore, applicants' English ability might be a major factor that influenced whether or not they would like to file provisional applications in the US.

For provisional applications by different technological categories, applicants in the fields of Computers and Communications and Drugs and Medical were more interested in filing provisional applications in the US.

For provisional applications by different assignees, most of the top ten assignees came from the Computers and Communications field.

Abstract
This study aimed to investigate technological evolution from the perspective of the USPC reclassification. The results showed that there existed significant differences among five types of patents based on the USPC reclassification: Patents reclassified to Class 001, Patents with Inter-field Mobilised Codes, Patents with Intra-field Mobilised Codes, Patents with Abolished Codes, and Patents with Original Codes. Patents reclassified to Class 001, mostly related to the topic of "Data processing", performed better than other patents in novelty, linkage to science, technological complexity and innovative scope. Patents with Inter-field Mobilised Codes, related to the topics of "Data processing: measuring, calibrating, or testing" and "Optical communications", involved broader technology topics but had a low speed of innovation. Patents with Intra-field Mobilised Codes, mostly in the Computers & Communications and Drugs & Medical fields, tended to have little novelty and a small innovative scope. Patents with Abolished Codes and patents with Original Codes performed similarly – their values of patent indicators were low. It is suggested that future research extend the patent sample to subclasses or reclassified secondary USPCs in order to understand the technological evolution within a field in greater detail.

Conference Topic
Patent Analysis

Introduction
For patented inventions, their technological novelty is indicated through their U.S. Patent Classification (USPC) assigned by the U.S. Patent Office. However, patent technology codes are an underutilized data resource for research on technological capabilities, technological novelty, technological complexity and technological change (Strumsky, Lobo & van der Leeuw, 2012). In order to fill the research gap, this study takes a first step towards using the USPC reclassification to trace technological evolution in the past two decades. This section introduces basic information regarding the USPC reclassification and sets out the research aim for investigation.

Reclassification of the U.S. Patent Classification (USPC)
The USPC is a system for organizing all U.S. patent documents and many other technical documents into relatively small collections based on common subject matter (USPTO, 2012b, I-1). A combination of a *class* (i.e. a major component) and a *subclass* (i.e. a minor component) is used to indicate every subject matter division in the USPC system. Based on the technology used, each patent is assigned specific USPC technology code(s) to reflect their technological topics. In order to distinguish from other patent classification schemes, this study only focuses on the USPC classification.

According to the USPTO (2012b, I-15), "[r]eclassification is the process of changing classifications assigned to documents classified in the USPC." There are different types of

modification of the USPC codes originally assigned to patents, including: creating, abolishing or modifying USPC class schedules. The USPC reclassification is seen necessary to reflect the evolving technological changes. For instance, Strumsky, Lobo and van der Leeuw (2012) used patent technology codes to study technological change.

Five types of patents based on the USPC reclassification

In order to keep pace with knowledge, modification/updates of classes and subclasses have been made to the Dewey Decimal Classification (DDC) system regularly. For instance, one of the new features in the DDC (Edition 23) was an update of "004–006 Computer science (and parallel provisions in 025.04 Information storage and retrieval systems and 621.39 Computer engineering) to reflect current technical trends" (Online Computer Library Center, 2013, p.3). Therefore, this study aims to investigate technological evolution from the perspective of the USPC reclassification.

As a result of the USPC reclassification, technology codes assigned to patents were created, modified and abolished. To this end, this study divided the utility patents into the following five types, according to the types of the modification of their original USPC:

- **Class 001:** If the record for a patent is incomplete and contains no *Primary Classification*[1], or if the USPTO is unable to assign specific technology codes to the patent, then the patent is reclassified to class 001, titled "CLASSIFICATION UNDETERMINED" (USPTO, 2012b).
- **Intra-field Mobilised Code:** A patent's newly assigned codes are derived from the same technological field as its original codes. Six technological fields are discussed in this paper, which are defined by Jaffe, Trajtenberg and Romer (2005).
- **Inter-field Mobilised Code:** A patent's newly assigned codes are derived from a different technological field from the original codes.
- **Abolished Code:** A patent's original technology codes are abolished and reclassified to new codes based on the Current USPC.
- **Original Code:** A patent's original technology codes remain the same as the newly assigned codes based on the Current USPC.

Based on the aforementioned five types of the utility patents, this study conducts a 20-year trend analysis and compares their variances using six patent indicators.

Methodology

Patent bibliometrics

In this study, patent data were collected solely from the United States Patent and Trademark Office (USPTO) database, which is generally accepted and is accessible to the researchers. While there exist different categories of patents (e.g. plant patents, design patents, reissues, and continuations), this study, based on the recommendations offered by Narin (2000), collected the number of regular U.S. utility patents to keep the focus of the database on the key category of patents, which contributes to corporate technological strengths. In order to observe the recent development of patents with the USPC reclassification, this study covered the past two decades. This study used the following six patent indicators to analyse the differences between different types of USPC reclassified patents.

- **Technology Cycle Time (TCT)** indicates the speed of innovation of a patent. Companies with a shorter cycle time than their competitors in a given technology area

[1] According to the USPTO (2012b), U.S. PGPub documents classified in the USPC are assigned one, and only one, principal mandatory classification, known as the *Primary Classification* (PR).

may be advancing more quickly from prior technology to current technology (Narin, 2000).

- **Non-Patent Reference (NPR)** indicates a patent's linkage to science. Narin (2000) proposed that the average rate of citations to scientific papers can be used to indicate the patent's science linkage. Other scholars (Gupta, 2006; Lo, 2010) also regarded the average rate of citations to NPRs as the patents' linkage to science. Therefore, this study used the number of NPRs to indicate the strength of linkage between the patent and science.
- **Patent Reference** indicates the novelty of a patent. A higher number of patent references generally indicate a reduction of invention novelty.
- **USPC Count** indicates the breadth of the technology topics of a patent. If a patent has broader technology topics, it tends to belong to a more highly applicable technological field.
- **Patent Term Extension** indicates the technological complexity of a patent. If the term of a patent is extended, it usually means that the patent involves a higher level of technological complexity and therefore requires more time for examination (Pantros IP, 2013).
- **Patent Claim** indicates the innovative scope of a patent. Patents containing a higher number of claims have been shown to have a wider innovative scope (Pantros IP, 2013).

Data collection

The empirical data analysed in this study were collected from the USPTO Granted Patent Database. The sample was restricted to the utility patents granted from 1994 to 2013. According to the classification system of Jaffe, Trajtenberg and Romer (2005), the U.S. patents were classified into six technological fields: Chemical, Computers and Communications (C&C), Drugs and Medical (D&M), Electrical and Electronics (E&E), Mechanical, and Others. The six fields were used to form the basis for an analysis of the patents with USPC reclassified inter-field or intra-field. USPC patents (with/without reclassification) were identified through the use of XML to compare Original USPC (i.e. USPC codes before reclassification) and Current USPC (i.e. USPC codes after reclassification). USPC reclassified patents in the recent 20 years were collected. In order to conduct a comparison analysis, the sample was randomly selected from the patents with Original USPC Codes that had the same patent count with Current USPC Codes each year.

Descriptive statistics

Descriptive statistics provide brief summaries about the sample and the observations made. Such summaries may be either quantitative (i.e. summary statistics) or visual (i.e. clear graphs). These summaries may either form the basis of the initial description of the data as part of a further statistical analysis, or they may be sufficient in and of themselves for a particular investigation. This study used the Line Chart to analyse the trends of patent counts for all types of the USPC reclassified patents granted each year. For the characteristic differences of each type of the USPC reclassified patents, this study used One-Way ANOVA to conduct significant difference tests on the patents' TCT, NPR, Patent Reference, USPC Count, Patent Term Extended, and Patent Claim.

In statistics, one-way analysis of variance (abbreviated one-way ANOVA) is a technique used to compare means of three or more samples (using the F distribution). The ANOVA tests the null hypothesis that samples in two or more groups are drawn from populations with the same mean values. To do this, two estimates are made of the population variance. If the group means are drawn from populations with the same mean values, the variance between the group means should be lower than the variance of the samples, following the central limit

theorem. A higher ratio therefore implies that the samples were drawn from populations with different mean values (Wikipedia, 2014).

Results

Trends of the USPC reclassified patents

There were 3,342,076 U.S. utility patents granted between 1994 and 2013. Among them, 102,204 patents belonged to the main class in Primary USPC reclassification, which accounted for 3.1% of the total utility patents. Calculations of those patents by their types showed that patents with Abolished Codes accounted for the majority (42.53%), which was followed by patents with USPC Intra-field Mobilised Codes. Patents with Class 001 or Inter-field Mobilised Codes accounted for appropriately 15% respectively. See Table 1.

Table 1. Counts of patents with/without USPC reclassification.

Patent with/without USPC Reclassification	Count
Main class in Primary USPC Reclassification	**102,204(100%)**
A. Class 001	15,862(15.52%)
B. Abolished Code	43,465(42.53%)
C. Inter-field Mobilised Code	15,740(15.40%)
D. Intra-field Mobilised Code	27,137(26.55%)
E. Random selection of patents with Original Code	**102,204**

Observed from the yearly distribution of the patent counts of various types of USPC reclassification, it was found that the number of USPC reclassified patents tended to be higher in the early stage, which indicated that the USPC was revised in accordance with the evolution of technologies. From the perspective of the Current USPC, some Original USPC appeared inappropriate in today's context and therefore the count of the USPC reclassified patents has increased. Furthermore, when the advance of newer technologies adopted the Original USPC that was similar to the version of October 2014, the number of USPC reclassified patents decreased in tandem.

The number of patents with Abolished Codes dramatically increased prior to 2000 but dramatically dropped after 2001, meaning that the elimination of main class did not occur after 2001. The number of patents with USPC Intra-field Mobilised Codes was above 1,000 before 2009 and started to decrease after 2010, which was considered relevant to "Technological development for stability". The numbers of patents with USPC Inter-field Mobilised Codes and with Class 001 tended to decrease in 2010, which was also considered relevant to "Technological development for stability".

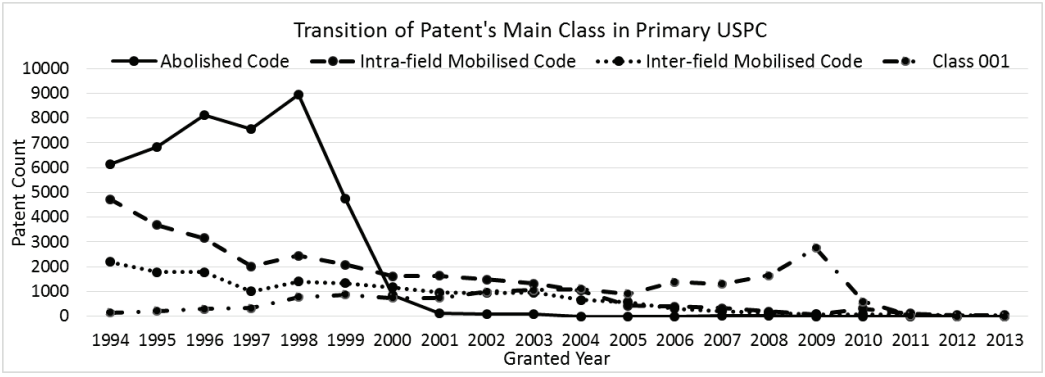

Figure 1. Transition of patents' main class in primary USPC.

Average citation rates were used to represent the quality of patents. This study calculated patents' average citation rates from 1994 to 2013, as shown in Figure 2. Due to the fact that the citation window of patents has become shorter each year, patents' average citation rates also decreased gradually. Figure 2 shows that the average citation rates of patents with Class 001 were the highest, which was followed by patents with USPC Inter-field/Intra-field Mobilised Codes. (They performed similarly in terms of their average cited rates recently.) The average citation rates of patents with Abolished Codes were higher than patents with Original Codes before 2002, but their average citation rates became the lowest among all types of patents.

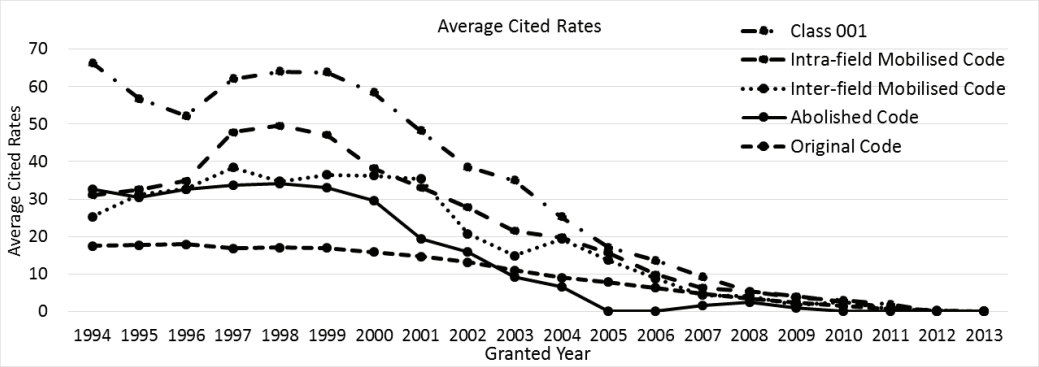

Figure 2. Average cited rates of USPC reclassified patents.

USPC reclassified patents among fields

Table 2. Patent counts in technological fields with USPC Reclassification.

	Patent Reclassified to Current Tech Field (%)						
Original Tech Field	**1.**	**2.**	**3.**	**4.**	**5.**	**6.**	**Sum**
1. Chemical	3,303	62	276	816	684	252	**5,393**
	(61.25)	(1.15)	(5.12)	(15.13)	(12.68)	(4.67)	**(100)**
2. Computer & Communication	135	11,649	16	1,201	81	1,913	**14,995**
	(0.90)	(77.69)	(0.11)	(8.01)	(0.54)	(12.76)	**(100)**
3. Drugs & Medical	958	13	6,260	44	23	96	**7,394**
	(12.96)	(0.18)	(84.66)	(0.60)	(0.31)	(1.30)	**(100)**
4. Electrical & Electronic	155	1,627	49	1,187	124	1,273	**4,415**
	(3.51)	(36.85)	(1.11)	(26.89)	(2.81)	(28.83)	**(100)**

	(22.18)	(2.76)	(3.26)	(4.67)	(9.48)	(57.66)	**(100)**
Sum	**6,286**	**16,482**	**6,786**	**3,579**	**4,008**	**5,736**	**42,877**
	(14.66)	**(38.44)**	**(15.83)**	**(8.35)**	**(9.35)**	**(13.38)**	**(100)**

Table 2 displays the U.S. utility patents granted from 1994 to 2013 with USPC reclassified inter/intra-field. It was found, through calculating the variances in the patent count in the original and current technological fields that patents in C&C were reclassified most among all the USPC reclassified patents. Among the patents in original technological fields in C&C, 77.69% belonged to the main class in the Primary USPC Intra-field Mobilised Code, with 12.76% reclassified to Others. Another variance occurred to D&M. 84.66% of the patents belonged to the main class in Primary USPC Intra-field Mobilised Code, with 12.76%

reclassified to Chemical. The last variance occurred to Mechanical. 38.13% of the patents belonged to the main class in Primary USPC Intra-field Mobilised Code, with 41.76% reclassified to C&C. 36.85% of patents in E&E were reclassified to C&C, 28.83% reclassified to Others, and only 26.89% reclassified intra-field.

Statistical differences among five patent groups

Six one-way between subjects ANOVAs were conducted to compare the effect of patents with different USPC reclassification types on patent performance in TCT, NPR, Patent Reference, USPC Count, Patent Term Extended, and Patent Claim. There were all significant differences of indicators on patent performance at the $p<.001$ level for the five types of patents with/without USPC reclassification. Post hoc comparisons using the Dunnett T3 test (Dunnett, 1980) showed significant differences in the mean scores of the six indicators for the patents in different types of the USPC reclassification.

- **TCT Performance:** When the value of TCT is lower, it means a patent involves more fast-moving technologies and a patent tends to cite recently issued patents. Results derived from statistical tests showed: B. Abolished Code (5.7 year) < C. Inter-field Mobilised Code (6.3 year) < E. Original Code. (7.8 year). Short TCT of the patents with Abolished Codes indicated that patents of this kind involved the most fast-moving technologies and the speed of their technological innovation was clearly faster than patents with Inter-field Mobilised Codes. On the contrary, patents with Original Codes tended to be slower in term of their speed of the technological innovation.
- **NPR**: When the number of NPR is higher, it means the linkage of technology to science is stronger. Results derived from statistical tests showed: A. Class 001 (10.4), C. Inter-field Mobilised Code (11.7) & D. Intra-field Mobilised Code (10.7) > E. Original Code (7.9) & B. Abolished Code (5.5). When calculating Science Linkage, the more NPRs were, the stronger the linkage of technology to science was. Therefore, patents reclassified to Class 001, patents with Inter-field Mobilised Codes and Intra-field Mobilised Codes had stronger linkages to science, compared to patents with Original Codes and Abolished Codes.
- **Patent Reference:** When the number of Patent References is low, it indicates the novelty of technology is high. Results derived from statistical tests showed: B. Abolished Code (11.6) < E. patent with Original Code (14.2) < A. Class 001 (19.3) < C. Inter-field Mobilised Code (15.0). It can be inferred that the technological novelty of patents with Abolished Codes was much higher than that of patents with Original Codes. Clearly, the technological novelty of patents with Class 001 or with Inter-field Mobilised Codes tended to be low.
- **USPC Count:** Patents with more USPC counts indicate they involve broader technologies. Results derived from statistical tests showed: C. Inter-field Mobilised Code (5.2) > E. Original Code (4.4) > B. Abolished Code (3.9). The technology breadth of patents with Inter-field Mobilised Codes was the largest. The technology breadth of patents with Abolished Codes was smaller than that of patents with Original Codes.
- **Patent Term Extended:** When the term extension lasts longer, it indicates that a patent involves more complicated technologies. Results derived from statistical tests showed: A. Class 001 (416) > C. Inter-field Mobilised Code (341), D. Intra-field Mobilised Code (307) > E. patent with Original Code (300) > B. Abolished Code (168). It can be inferred that patents with Class 001 involved a higher level of technological complexity than patents with Inter/Intra-field Mobilised Codes. However, the term extension of patents with Abolished Codes was the shortest, indicating that they involved the lowest level of technological complexity.

- **Patent Claim:** When the value of patent claims is higher, it indicates that a patent's innovation scope is wider. Results derived from statistical tests showed: A. Class 001 (22.2) > C. Inter-field Mobilised Code (17.6) > B. Abolished Code (16.5), E. patent with Original Code (15.1). It can be inferred that the innovation scope of the patents with Class 001 or patents with Inter-field Mobilised Codes was obviously wider than that of patents with Abolished Codes and patents with Original Codes.

Technological evolution from the USPC reclassification perspective

This study divided patents granted in the last two decades into two groups, i.e. 1994-2003 and 2004-2013. Observations were made from the evolution of USPC codes as a result of the USPC reclassification. Table 3 shows the USPC with top three most patent counts in the two periods respectively. If a patent was reclassified to Class 001, it meant that there was no specific technology code suitable for the patent. To some extent, it indicated that the patent belonged to emerging technologies or original USPC codes assigned were not appropriate for the patent, which required a new code. Table 3 shows in both periods, the majority of patents reclassified to Class 001 came from Class 707 in the C&C field. This phenomenon reflected the technological uncertainty of patents originally assigned to Class 707, the majority of which were therefore reclassified to Class 001. In the first period, there were 19.7% of patents originally assigned to Class 395 and then reclassified to Class 001. However, due to the abolition of Class 395, their technological description remained unknown.

Table 3. Patents with USPC reclassified in the Class 001 and the Abolished Code groups.

USPC	1994-2003	2004-2013	USPC Description
Original class reclassified to 001 (Class 001)			
707	4,884 (79.6%)	9,684 (99.5%)	Data processing: database and file management or data structures
395	1,206 (19.7%)	0 (0.0%)	(Abolished)
364	19 (0.3%)	0 (0.0%)	(Abolished)
705	0 (0.0%)	18 (0.2%)	Data processing: financial, business practice, management, or cost/price determination
714	0 (0.0%)	7 (0.1%)	Error detection/correction and fault detection/recovery
Current class of original abolished (Abolished Code)			
438	4,895 (11.3%)	1 (4.3%)	Semiconductor device manufacturing: process
714	4,179 (9.6%)	0 (0.0%)	Error detection/correction and fault detection/recovery
710	3,448 (7.9%)	0 (0.0%)	Electrical computers and digital data processing systems: input/output
703	1,314 (3.0%)	2 (8.7%)	Data processing: structural design, modeling, simulation, and emulation
477	2 (0.0%)	2 (8.7%)	Interrelated power delivery controls, including engine control

For patents with Abolished Codes, it meant that their original codes did not align with the technological evolution any more, and thus the codes were abolished and the patents were reclassified to new codes. As shown in Table 3, the majority of patents with Abolished Codes

occurred in the first period, with only 23 patents of this kind in the second period. In the first period, the majority of patents whose original USPC codes were abolished were reclassified to Classes 438 (11.3%), 714 (9.6%), 710 (7.9%), and 703 (3.0%). Patents reclassified to Class 438 were about semiconductor device manufacturing in the E&E field, and those reclassified to Classes 714, 710 and 703 focused on technologies in the C&C field. Based on the patents reclassified to Class 001 and with Abolished Codes, it was found that the USPC reclassification tended to occur in the C&C and E&E fields in the first period and in the C&C field in the second period.

According to Table 2, patents with Intra-field Mobilised Codes mainly occurred in the C&C (77.69%) and D&M (84.66%) fields. Therefore, Table 4 focuses on the top three Intra-field Mobilised Codes, and Figures 3 and 4 present the flow of the patents between USPCs in the two fields, where the flow occurred more than ten patents. In the C&C field, the USPC reclassification in both periods mainly occurred from Class 345 to Class 715 (28.8% and 26.6%), which was about "Operator interface processing" and from Class 369 to Class 720 (11.8% and 5.1%), which was about "Information storage or retrieval". Additionally, in the first period, there remained 10.2% of patents reclassified from Class 707 to Class 715, which was also about "Operator interface processing". In the second period, there remained 6.2% of patents reclassified from Class 707 to Class 709, which was about "Multicomputer data transferring". In the D&M field, the USPC reclassification occurred from Class 128 to Class 600 (68.0%) which was about "Surgery" in the first period, and from Class 514 to Class 424 (76.4%) which was about "Drug, bio-affecting and body treating compositions" in the second period. The code mobilisation within the same field occurred due to the extension of the original USPC.

Table 4. USPC reclassification: the Intra-field Mobilised Code group.

Main Class of USPC		Count	
Original	**Current**	**1994-2003**	**2004-2013**
Intra-field Mobilised Code in C&C			
345	**715**	2,793(28.8%)	516(26.6%)
369	**720**	1,144(11.8%)	98(5.1%)
707	**715**	991(10.2%)	96(5.0%)
707	**709**	68(0.7%)	120(6.2%)
Intra-field Mobilised Code in D&M			
128	**600**	3,909(68.0%)	4(0.8%)
514	**424**	626(10.9%)	389(76.4)
606	**623**	227(3.9%)	18(3.5%)
514	**435**	17(0.3%)	26(5.1%)
435	**424**	49(0.9%)	21(4.1%)

345: Computer graphics processing and selective visual display systems; **369:** Dynamic information storage or retrieval; **707:** Data processing: database and file management or data structures; **709:** Electrical computers and digital processing systems: multicomputer data transferring; **715:** Data processing: presentation processing of document, operator interface processing, and screen saver display processing; **720:** Dynamic optical information storage or retrieval

128: Surgery; **424:** Drug, bio-affecting and body treating compositions; **435:** Chemistry: molecular biology and microbiology; **514:** Drug, bio-affecting and body treating compositions (an integral part of Class 424); **600:** Surgery (an integral part of Class 128); **606:** Surgery (an integral part of Class 128); **623:** Prosthesis (i.e., artificial body members), parts thereof, or aids and accessories therefor

Observed from the patents with Intra-field Mobilised Codes, it showed that in the C&C field those patents were related to "Operator interface processing" in both periods. In the D&M field those patents were related to "Surgery" in the first period and "Drug, bio-affecting and body treating compositions" in the second period. Observed from the patents with Inter-field Mobilised Codes, it showed that the USPC codes were mainly mobilised from the E&E and Mechanical fields to the C&C field, as seen in Table 2. Statistics on the top three USPC mobilisation were detailed in Table 5, and Figures 5 and 6 present the flow of the patents between USPCs among the three fields, where the flow occurred more than ten patents. In the first period, the USPC reclassification mainly occurred from the E&E field to the C&C field, for example from Class 348 to Class 375 (64.6%) about "Pulse or digital communications", and from Class 346 to Class 374 (20.6%) about "Thermal measuring and testing". However, in the second period, inter-field code mobilisation was not obvious. It can be seen that the topics of technological evolution were different in the two periods.

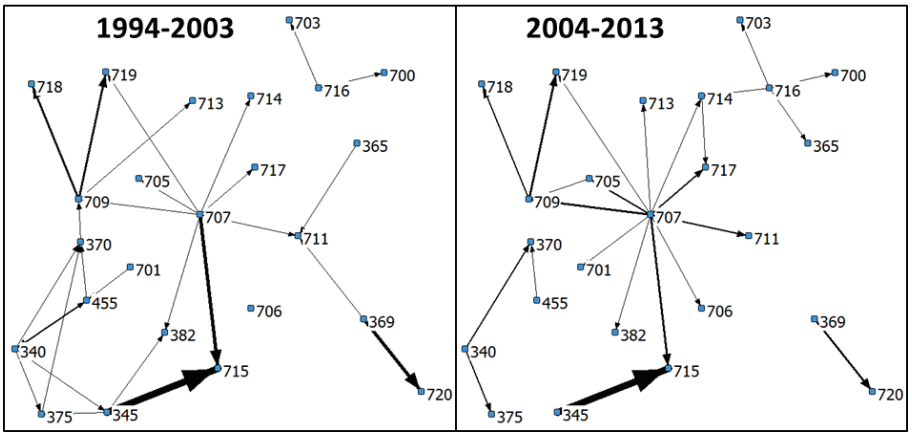

Figure 3. The flow of patents between USPCs in the C&C field.

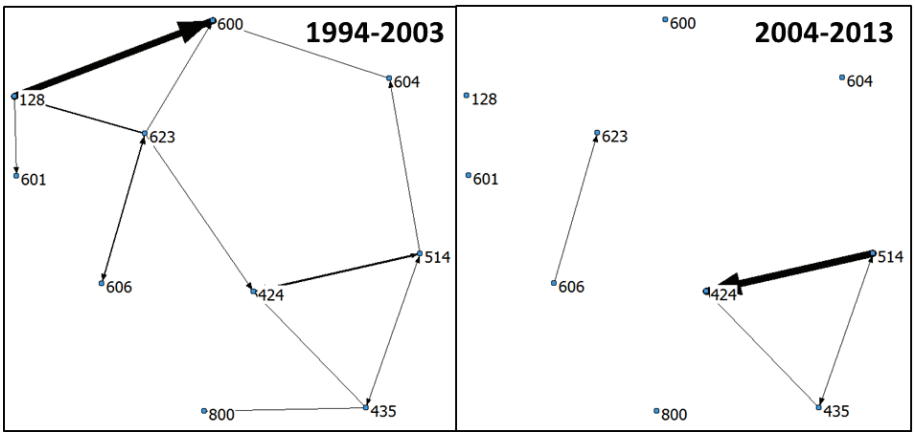

Figure 4. The flow of patents between USPCs in the D&M field.

Looking at patents with Inter-field Mobilised Codes from the Mechanical field to the C&C field, the flow of the mobilisation tended to occur from Class 359 to Class 398 (94.8% and 37.8%) about "Optical communications" in both periods.

Observed from the patents with Inter-field Mobilised Codes, it showed that patents with the USPC reclassification from the E&E field to the C&C field focused on the technology topics of "Pulse or digital communications" and "Thermal measuring and testing" in the first period, but focused on "Data processing: measuring, calibrating, or testing" in the second period. As

for patents with USPC reclassification from the Mechanical field to the C&C field, they tended to be related to "Optical communications" in both periods.

Table 5. USPC reclassification: the Inter-field Mobilised Code group.

Main Class of USPC		Count	
Original	**Current**	**1994-2003**	**2004-2013**
Inter-field Mobilised Code from E&E to C&C			
348	**375**	989(64.6%)	2(2.1%)
346	**374**	316(20.6%)	0(0.0%)
257	**365**	21(1.4%)	3(3.2%)
257: Active solid-state devices (e.g., transistors, solid-state diodes); **346:** Recorders; **348:** Television; **365:** Static information storage and retrieval; **374:** Thermal measuring and testing; **375:** Pulse or digital communications			
Inter-field Mobilised Code from Mechanical to C&C			
359	**398**	2,837(94.8%)	17(37.8%)
235	**705**	22(0.7%)	0(0.0%)
359	**369**	15(0.5%)	0(0.0%)
235: Registers; **359:** Optical: systems and elements; **369:** Dynamic information storage or retrieval; **398:** Optical communications; **705:** Data processing: financial, business practice, management, or cost/price determination

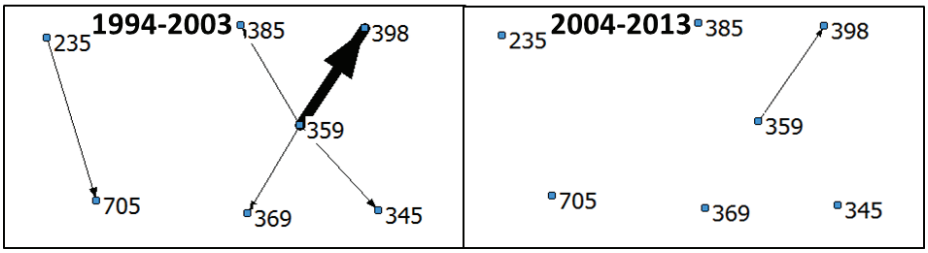

Figure 6. The flow of patents between USPCs from the Mechanical field to the C&C field.

Conclusion and Discussion

The majority of USPC reclassified patents occurring prior to 2000 and in the Computer & Communications field

With the advance of new technologies, the USPC system is updated quarterly in March, June, September and December (USPTO, 2012a). Newly granted patents were assigned with technology codes derived from the latest version of the USPC. Accordingly, their original USPC technology codes were less likely to be reclassified. This study found that the number of patents with main class in primary USPC reclassification hit the highest prior to 2000 and began to decrease every year after 2001. Patents with Abolished Codes accounted for 42.53%

and the majority of the patents were granted prior to 2000. Next were patents with Intra-field Mobilised Codes, which accounted for 26.55%. For the average citation rates every year, patents reclassified to Class 001 were ranked as top, and patents with Original Codes were ranked as bottom. Due to the USPC reclassification, patents with Intra-field Mobilised Codes occurred most frequently in the C&C field, and patents with Inter-field Mobilised Codes occurred most frequently from the Mechanical field to the C&C field.

USPC reclassified patents showing significant differences in patent indicators

Six one-way between subjects ANOVAs were conducted to compare the effects of patents in different groups by the USPC reclassification, according to their patent performance in TCT, NPR, Patent Reference, USPC Count, Patent Term Extended, and Patent Claim. Different results were obtained for the different types of patents, as below.

- **Patents reclassified to Class 001:** They got higher values of NPR, Patent Reference, Patent Term Extended and Claims Count, indicating that they performed better than other patents (whether they were reclassified or not) in novelty, linkage to science, technological complexity and innovative scope. Therefore, USPTO needs to re-examine appropriate USPC technology codes for them or assign appropriate codes to them when the new codes are created.
- **Patents with Inter-field Mobilised Code**: Compared to patents reclassified to Class 001, they got more USPC counts and longer TCT, indicating that they involved broader technology topics and therefore their codes assigned were mobilised inter-field. Their longer TCT meant that their technology had a low speed of innovation.
- **Patents with Intra-field Mobilised Code**: They tended to have low novelty and a small innovative scope; therefore, their codes assigned were mobilised intra-field.
- **Patents with Abolished Code**: They were mainly granted prior to 2000. Patens of this type and patents with Original Code performed similarly – their values of patent indicators were low.

Technological evolution from the perspective of the USPC reclassification

This study investigated different groups of patents based on the USPC reclassification. Statistical analysis was conducted on the technology codes and comparisons were made between two ten-year periods. Based on the results derived, different types of technological evolution were found.

- **Emerging technologies in Class 001:** In both periods, a large portion of the emerging technologies were about "Data processing: database and file management or data structures" in the C&C field. This reflects the uncertainty of the development of the emerging technology, and thus patents originally assigned to Class 707 needed to be continually redefined and reassigned with specific technology codes.
- **Technological transition in Inter-field Mobilised Code:** Technologies from the E&E and Mechanical fields tended to be transferred and applied to the C&C field. Technologies about "Television" in E&E was transferred and applied to "Pulse or digital communications" in the C&C field. Technologies about "Recorders" in E&E were also transferred and applied to "Thermal measuring and testing" in the C&C field. In the Mechanical field, technologies related to "Optical: systems and elements" were transferred and applied to "Optical communications" in the C&C field in both periods.
- **Technological cohesion or spread in Intra-field Mobilised Code:** Technologies in this group tended to focus on the C&C and D&M fields. In the C&C field, technologies related to "Computer graphics processing and selective visual display systems" and "Data processing: database and file management or data structures" were combined together and applied to "Data processing: presentation processing of document, operator

interface processing, and screen saver display processing". Figure 3 shows not only technological cohesion but also technological spread. For example, technologies about "Data processing: database and file management or data structures (Class 707)" were spread to other technologies in different fields. Patents with original USPC 707 were reclassified to eight different codes in the first period, and then spread to other ten codes in the second period.

- **Technological substitution in Abolished Code:** Technologies in this group tended to occur in the first period. This indicates that the USPC scheme in the second period has been adapted to the recent technological development. In the first period, technologies of this kind mainly occurred to those related to "Semiconductor device manufacturing", which were reclassified to Class 438 with their original USPC 437 being abolished. Technologies related to "Error detection/correction and fault detection/recovery" which were reclassified to Class 714 with their original USPC 371 and 395 being abolished. This indicates that the mature technologies have caused the biggest impact on the USPC scheme.

It is suggested that future research extend the sample to patents with reclassified USPC subclasses or patents with reclassified secondary USPCs in order to observe recent intra-field technological changes in great detail. The Radical (Leaps) Innovation of technologies is only applied to the minority, but the majority of patents are embedded with Incremental Innovation. Incremental Innovation tends to occur inside fields. Through extending the patent sample to subclasses or secondary of USPC, it helps understand more technological evolution within a field. Besides, understanding the establishment, abolishment and movement of technology codes recorded in the Classification Orders Archival Report (USPTO, 2013) helps understand the trajectories of technological evolution more detail. Although this study focused on the reclassification of USPC schemes, it is argued that the same research model could be applied to trace the changes in the class schemes in International Patent Classification (IPC) or Cooperative Patent Classification (CPC) and changes in classification codes in their counterpart patents.

Abstract
Despite large numbers of empirical studies are conducted on examiner patent citations, few have scrutinized the cognitive limitations of officials at patent offices in searching for prior art to add citations during patent prosecution. This research takes advantage of the longitudinal gap between International Search Reports (ISRs) required by the Patent Cooperation Treaty (PCT) and subsequent examination procedure in national phase. It inspects whether several kinds of distances actually affect the probability that a piece of prior art is caught at the time of ISRs, which is much earlier than national phase examinations. Based on triadic PCT applications for all of the triadic patent offices (EPO, USPTO, and JPO) between 2002 and 2005 and their citations made by the triadic offices, evidence shows that geographical and organizational distances negatively affect the probability of prior patents being caught in ISRs, while lag of prior art positively affects the probability. Also, technological complexity of an application negatively affects the probability, whereas the size of forward citations of prior art affects positively.

Conference Topic
Patent Analysis (foundation of examiner patent citations, in particular)

Introduction
Patent citations have been widely utilized for empirical studies of patent systems, particularly for such issues as economic value and knowledge flows. Several empirical studies have examined whether examiner citations are different from inventor citations. One of the studies on the subject was conducted by Alacer and Gittleman (2006), who showed the similarity between examiner citations and inventor citations with respect to geographical distance in particular. While previous studies have compared examiner citations and inventor citations in other aspects such as the relationship with renewal rates, there have not been enough analyses concerning how patent offices are influenced by several kinds of "distances" that can limit cognitive boundary during prior art search. This study focuses on ISRs as a basis for measuring the search obstacles of the triadic patent offices, and tests how officials are bounded by "distances," including similar kinds of cognitive obstacles against prior art search, without relying on comparison with inventor citations. In conducting the analyses, we consider applicants' self-selection, since applicants from the U.S. and Japan can choose the European Patent Office as their search agency, where the EPO has reputation for its complete search (applicants who seek stringent search may choose the EPO ex ante).

The methodology: PCT and ISR as the basis of empirical measurement
This project proposes and implements a method of measuring the search obstacles, namely binding conditions on search capability, of the triadic patent offices by focusing on ISRs issued by different ISAs, specifically the patent offices in Europe, the U.S. and Japan, according to the PCT. In particular, binary choice models are employed for each of cited patents (which are added in the national phase in all of three jurisdictions) about whether or not they were already caught at the earlier time of ISR issued by the triadic offices. We limit our samples to those PCT applications made to and examined at all of the three offices. There are advantages to employ this methodology.

First, ISRs are issued under the common search criterion imposed by the WIPO under the PCT system. Under the PCT, "an applicant must file an application with a receiving office and choose an international searching authority to provide an international search report and a written opinion on the potential patentability of the invention." "The applicant generally has at least 30 months from the filing (priority) date to decide whether to enter the national phase in the countries or regions in which protection is sought" (WIPO, 2014). The guideline at the WIPO applies to every ISA when issuing ISRs, whereas applicants in some countries are allowed to choose ISAs. The same criterion for prior art search is applied over different patent offices, while national phase examinations do not have such standardized rules.

Second, the lag mentioned above between ISRs and national phase examinations allows a "level" testing ground for search completeness. While ISRs are issued at an early stage, more searches are conducted in national offices later. Since knowledge is geographically localized (Jaffe et al. 1993; 1999), and knowledge diffusion takes time, additional time between ISRs and national phase search facilitates more complete search in the later stage. We limit our samples to those PCT applications that are examined at all of the three triadic offices, meaning that localized knowledge in any of these areas at the time of ISRs is more likely to be caught by the offices at the national phase in a less localized way. See Figure 1 below for the lag and collective searches made at later stages in national phase.

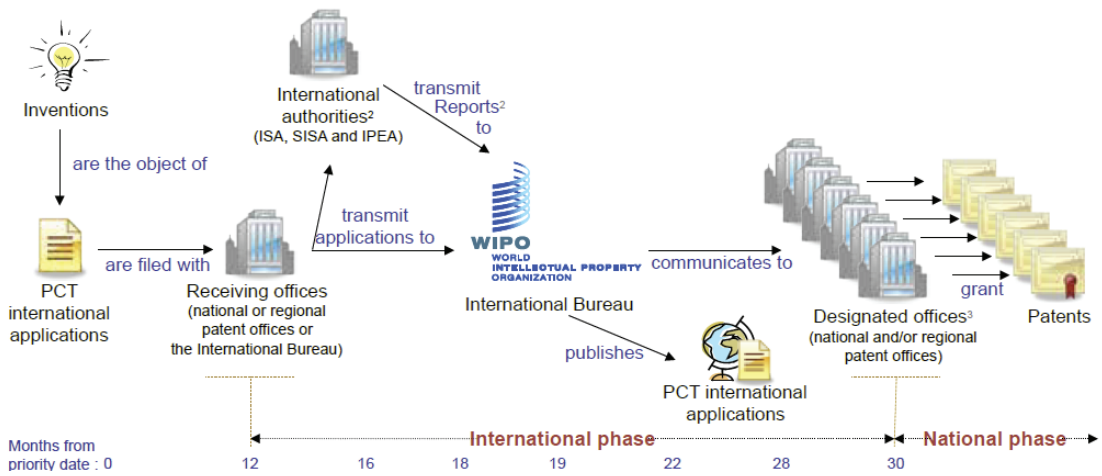

Figure 1. PCT procedure (replicated from WIPO, 2014, p.13).

Following the logic above, we retrospectively define the probability of every cited patent depicted in national phase, identified at the INPADOC family level, to have been already caught in the ISR of the originating PCT application. Taking this probability (a binary variable *found_in_ISR*, empirically) as the dependent variable, we implement PROBIT analyses at INPADOC family level with explanatory variables representing the various "distances" between citing and cited patents, including technological complexity of originating applications, and other related indicators.

Applicants' (inventors') citations are excluded from the analysis, since the objective is to evaluate the determinant of search completeness by the ISAs. However, self-selection of the U.S. and Japanese applicants to choose the EPO as their ISA is considered in the analyses, since the EPO has high reputation of examination standard and therefore applications with higher quality from the U.S. and Japan may choose the EPO as the ISA.

Although actual ISR search is sometimes outsourced to non-PTO agencies, we consider ISRs as a basis of evaluating PTOs, since they are issued under the name of the patent offices, not private search agencies. Only citations made by the triadic offices are considered in the current analyses. Since PATSAT, our primary data source, records non-patent literature in

non-standardized formats, we could not consolidate the same non-patent literature across different records. For this reason, we employ patent citations only at this time.

Hypotheses

Since ISR searchers (examiners/searchers for patent offices) are affected by cognitive obstacles from various "distances," we hypothesize that a prior patent (that was found in ISR or national phase) is more likely to be found in ISR when "distances" are less problematic, i.e.,
H1) a relevant prior patent is closer in geography (physical distance),
H2) prior patent is older (knowledge diffusion time),
H3) prior patent is from the same applicants (organizational distance),
H4) prior patent has more number of forward citations (knowledge diffusion probability), and
H5) application for which an ISR is issued has less scope, less number of claims, less number of inventors, and less number of international family (complexity against diffusion).
In addition, we consider if applicants' self-selection of ISAs affects the outcome variable.

Data source

The empirical domain of analysis is the triadic patent applications through PCT, with their earliest priority date within its international family between 2002 and 2005. Triadic PCT patent applications are defined here as INPADOC families that contain all of EPO, USPTO and JPO applications recorded on EPO's PATSTAT database, with only one "WO (PCT)" application in a family, meaning that a single PCT application initiates international phase for all applications in a family. The number of international families for the analysis is 97,828. Although international applications to and from China and Korea has increased dramatically in the last ten years, the triadic patent offices of the EPO, the USPTO and the JPO represented the vast majority before 2005, which is our observation period.
EPO PATSTAT (2013 OCT version) is used, and INPADOC family is the unit of analysis. Citation data also comes from PATSTAT (2013 OCT), although JPO citation data is augmented by Seiri-Hyojunka data (JPO's standardized patent prosecution data). US citations are not complete as well on PATSTAT, since citations for rejected applications are not registered on PATSTAT. The lack of the US citations for rejected applications may affect the result of the analysis, but this has not been verified yet. Applicant identifiers are consolidated by the EEE-PPAT database developed by ECOOM (Du Plessis et al., 2009; Magerman et al., 2009; Peeter et al., 2009).

Variables

We employ several categories of explanatory variables, representing each of hypotheses above, in PROBIT analyses taking the probability of a cited patent being caught in the previous ISR as the binary dependent variable ("*found_in_ISR")*. The unit of analysis is a pair of citing and cited international families, both consolidated at INPADOC family level.
For H1, three variables of *euro_cited* (cited family has its 1st priority, i.e., the earliest date, in EPC countries within a family, derived from tls201 and tls219 tables of PATSTAT), *us_cited* (cited family has its 1st priority in the U.S.), and *jp_cited* (cited family has its 1st priority in Japan) are defined. When a cited family has its origin in the same region where ISR is issued, the ISA of the region is expected to have geographical advantage over the relevant technology. Expected sign is positive for each region, e.g., positive *jp_cited* coefficients for applications originating from Japan.
For H2, citation lag between the 1st priority of a citing family and that of a cited family is defined as *fam_cite_lag* (derived from tls201 and tls219 tables of PATSTAT). The longer the lag is, the easier the prior art will be to be found at the time of ISR.

For H3, *self* is defined as a binary variable, taking the value of one if one of patents in a cited family and one of patents in a citing family belongs to the same applicant, based on PATSTAT (tls207) combined with EEE-PPAT, using "L2" id. Patent office will find it easier to locate prior relevant art within the same applicant.
For H4, *fwd_cite_of_the_cited* is defined and obtained from PATSTAT (tls217) as the number of forward examiner citations, counted at publication level (but consolidated at family level), and made out to the cited patent family.
For H5, we first use scope indicators. *IPC4_count* is the total net count of IPC subclasses (4-digit IPC, derived from tls209) assigned in a citing INPADOC family. Since patent classification of an application may change during prosecution process both in international phase and in national phase, we include all IPC subclasses to capture the breadth of a family. The number of claims of a patent is correlated with the complexity of the technological content. As an indicator of the number of claims, we obtain *publn_claims_max_tls211*, which is the maximum number of claims registered on PATSTAT (tls211 table) in a citing INPADOC family. We do not simply rely on claims data from a single office such as from the EPO, since an application can be modified during its prosecution internationally. We also employ *invt_nr*, the maximum number of inventors in an application included in a citing INPADOC family, from PATSTAT (tls207). The size of international family, *family_size*, is a count variable of applications in different countries in a citing INPADOC family (tls211/219).
In addition to the variables above, which are used to test hypotheses directly, we define three variables to address self-selection of ISAs by applicants. The first two represent the potential of the applicant. The first of the two is *total_count*, which is the number of total applications that an applicant has made, taken from EEE-PPAT. The second one is *applicant_avg_cited*, which is the number of average forward citations that an applicant has received, calculated by PATSTAT (tls212) and EEE-PPAT. Both are supposed to represent the experience level of the applicant, and are used as instrument variables for instrumented PROBIT on the variable *ISA_CHANGED*. This binary variable *ISA_CHANGED* indicates that the U.S. and Japanese applicants choose the EPO as their ISA (the EPO can be chosen from the U.S. and Japanese applicants, but not vice versa). This information can be obtained for PCT applications on PATSTAT, since the citation table tls212 has a field on "citation origin" where "ISR" is shown for PCT applications. Since first application country (RO) in a family is available from tls201, switching from RO to a different ISA can be coded. The correlation coefficient between *ISA_CHANGED* and the dependent variable *found_in_ISR* is low at 0.0348.
Control variables for originating areas, which are *JP_app* and *US_app* (applications from Japan and the U.S., respectively), are used. Technology class is controlled by thirty-five WIPO technology classification dummies (results not shown for space reason).

Estimation results

The result shown in the Model 1 of Table 1 employs all samples from the triadic regions. As is evident from the negative sign for *JP_app* and *US_app*, the baseline ISA (EPO) is found to be advantaged in finding prior art at the time of ISR. The positive sign of *ISA_CHANGED* also indicates that prior art is easier to be identified at the time of ISR if applicants from the U.S. or Japan choose the EPO as their ISA (for which robustness is checked in Model 4 and 5). These are consistent with the EPO's good reputation from international applicants. H1 is supported from the positive sign of *euro_cited*. Likewise, H2, H3, H4 and H5 are all supported o this model, except that the number of inventors has an insignificant coefficient.
Model 2 uses applications from Japan only in order to examine the locality of knowledge in Japan. As is expected in H1, *jp_cited* has a positive and significant sign, whereas *us_cited* has negative and significant sign. Other variables show similar results with the Model 1 and are consistent with hypotheses, except *self* indicates the negative sign. Model 3 uses U.S.

applications only, and the results are just consistent with the hypotheses. Model 4 and 5 limit the citation data to non-self citations only for robustness checks, while employing two instrument variables on the variable *ISA_CHANGED*. For Japanese applications, the coefficient for *ISA_changed* lost the significance in the Model 4, suggesting that the advantage provided by the ISA change from JPO to EPO is due to the applicants' self-selection. However, this effect is not observed for the U.S. applications in the Model 5.

Table 1. PROBIT analyses on the probability of ISR coverage; dep. var.=*found_in_ISR.*

Model 4 and 5 use "*total_count*" and "*applicant_avg_cited*" as instruments for "ISA_CHANGED."

Discussion and further development

Overall results are consistent with the hypotheses, suggesting that examiners (and searchers working for the PTOs) are bound by various kinds of "distances," including technological complexity of applications. These are intuitive, and are supported by the novel methodology for the first time. An interesting interpretation is that examiners (unlike inventors) are

required to find prior art by law, but that they are naturally bound by informational horizons they have. This has policy implications, since Patent Prosecution Highways (PPH) rely on outcomes from previous patent offices. Most prior studies using examiner citations do not incorporate these informational obstacles born by examiners, but they cannot be ignored. For example, prior studies on the difference of examination outcomes between patent offices (Jensen et al., 2005; Webster et al., 2007, 2014) do not explicitly consider them, but the cost of prior art search may affect the results. The results with instrument variables suggest the self-selection is working, but is evident for the Japanese samples only. Further scrutiny is needed.

Acknowledgments

This interim output is drawn from the collaborative project with Professor Setsuko Asami (Tokyo University of Science) and Professor Yoshimi Okada (Hitotsubashi University). The entire project is supported by RISTEX/JST. The comparison of search quality between PTOs at aggregated level was previously presented at the International Workshop on Patent System Design for Innovation at Hitotsubashi University (Wada and Asami, 2014) and at the 2014 Annual Conference of the Asia-Pacific Innovation Network. The idea of the probability of ISR coverage of this paper evolved out of the idea of aggregate ISR coverage ratio, which Professor Asami first thought of. The author also acknowledges the support from the MEXT/JSPS (Grant #22330122) for the analyses of citations and firm boundaries.

A Collective Reasoning on the Automotive Industry: A Patent Co-citation Analysis

Manuel Castriotta and Maria Chiara Di Guardo

{manuel.castriotta, diguardo}@unica.it,
University of Cagliari (Italy)

Abstract
While collective cognition has received increasing attention in the broader field of organization, academic research has largely overlooked its potential role on shaping innovation trajectories and technological change adaptation at a firm and industrial levels. Through a strategic lens and based on the patent bibliometrics and patent co-citation methods, we integrate and extend the cognition and technology strategy literatures by proposing an invention behavior map of leading companies and groups in the automotive industry. How collective cognition influence patent strategies? How economic trends impact on patent paths? Empirical evidence for these reasons is drawn from a longitudinal patent analysis quantitative approach of the period 1991-2013 considered overall and consequently subdivided into three sub periods of seven years each 1991-1997, 1998-2004, 2005-2013. About 443.000 patents, 1.108.356 citations and 1.234.623 co-citations of 49 automotive assignees were collected from Derwent Innovation Index (DII), the largest world patent and innovation database. Multi dimensional scaling and cluster analysis techniques are employed to detect embryonic cognition homogeneity measures and provide an overview of groups technology composition and companies innovation strategies trends. Finally, explorative findings are discussed below with suggestions about how they might be translated into managerial implications.

Conference Topic
Patent Analysis

Introduction
The empirical literature on technological regimes argues that firms within an industry behave in correlated ways because they share sources of information and technology (suppliers, universities, other industries), and perceive similar opportunities for innovation. The existence of a collective cognition shared by firms within a sector can also influence how inventions arise and how quickly and completely they diffuse, and can give us another key to better understand the collective failure of some industries as a result of surprisingly unexpected technological changes, or the innovation trajectories that have characterized some sectors. Yet, while collective cognition has received increasing attention in the broader field of organizational theory (Johnson & Hoopes, 2003; Nadkarni & Narayanan, 2007), research on innovation and patent strategies has been largely silent about the cognition's role (Kaplan, 2011, 2012; Kaplan & Tripsas, 2003, 2008) and empirical studies thus far have not questioned how industry boundaries truly define patent strategies and how economic trends impact on technological trajectories.

To take the first steps at going beyond these limitations and embryonically understand how industry structure and interaction among players can shape technological trajectories, we examine the case of the automotive sector from 1991 to 2013 and identify the dynamic evolution of patent paths among the principal actors in this sector. We chose the automotive sector for several reasons: first, the ability of firms to innovate is crucial to commanding a competitive advantage in this industry (Norhia & Garcia-Pont, 1991); second, all relevant players in this industry must routinely patent their innovations; and third, the automotive market is characterized by high entry barriers able to isolate new entrants and incumbents' dynamic noise.

In order to understand the phenomenon at stake, we analyze the evolution of the technological trajectory in the automotive sector by utilizing bibliometric information such as patent co-citations (Lai & Wu, 2005; Wang, Zhang & Xu, 2011). This approach displays a larger picture of the overall innovation structure and the patent linkages among players and groups' technology positioning, thereby shedding light on the patterns of patent strategies within an industry.

In total, a 21-year period, subdivided as three sets of years in seven-year time spans from 1991 to 1997, 1998 to 2004, and 2005 to 2013, are visualized. About 443.000 patents, 1.108.356 citations and 1.234.623 co-citations of 49 automotive assignees were collected from Derwent Innovation Index (DII), the largest world patent and innovation database. Multidimensional scaling and cluster analysis techniques are employed to detect the embryonic cognition homogeneity measures and to provide an overview of the groups' technology composition and companies' innovation strategy trends.

This study adds to the literature in multiple ways. First, it contributes to the patent literature showing the evolutionary patterns of patent strategies inside a specific industry using patent co-citation analysis. Second, it contributes to innovation literature by enhancing our understanding of how technological firms and group positioning evolve and are influenced by collective cognition. Third, it also contributes to the still-inadequate understanding of the drivers of patent strategies and innovation trajectories.

The paper is organized as follows. In section two, we describe the patent co-citation methodologies employed; in section 3, we present the bibliometric results and provide a graphical representation of firms' and groups' proximities performed by multidimensional scaling (MDS) and cluster analysis; in section 4, we discuss embryonic results and offer some conclusions;

Theoretical background

Bibliometrics and patent citation analysis

Patent citation analysis is an academic set of bibliometric methods directly derived from methodology that seeks to link patents in the same way that science references link papers. Papers and patents are both research instruments that adopt citation-count measurement systems (Narin, 1994). Moreover, in bibliometrics, the use of a citation approach for the assessment of similarity for the classification of documents is a mature methodology, and for this reason, it is feasible to apply the citation analysis of bibliometrics to patent analysis (Zhao & Guan, 2013).

Patent co-citation analysis

Co-citation analysis is a measure of the frequency of how many times A and B units are co-cited by third earlier units such as papers, authors, institutions, and in our study patents, inventors, or assignees (Lai & Wu, 2005; Wang et al., 2011). The assumption of co-citation analysis is that documents that are frequently cited together cover closely related subject matter (Small, 1973; Narin, 1994). In this vein, the co-cited frequency of patents can be used to assess the similarities or relatedness and to post evaluation and less-subjective unobtrusive patent maps and classification systems (Lai & Wu, 2005). In bibliometrics, it is used to assess document similarities in order to analyze the intellectual structure of science studies and identify cluster specialties and sub-fields (McCain, 1990; Di Guardo & Harrigan, 2012; Di Stefano, Gambardella & Verona, 2012).

Methodology

Sample and unit of analysis selection

Our analysis, following the bibliometric co-citation and patent co-citation methods prescriptions (McCain, 1990; Wang et al., 2011; Di Guardo & Harrigan, 2012) and in order to correctly select the unit of analysis started by tracing the history of most relevant M&As and alliances automotive industry milestones. This allow us to consequently identify in Derwent database the standard and non standard assignees codes for the overall and intermediate periods and correctly formulate compound Derwent Innovation Index and Derwent World Patent Index search queries (Wang et al., 2011). We retrieved assignees patent bibliometrics and assignees patent citation counts and finally co-citation frequencies. Operationally, the compilation of the raw co-citation matrix and its conversion to correlation matrix allow us to run multivariate analysis and consequently interpreting the findings. In the case of academic bibliometric studies, the unit of analysis may consist of scientific articles, authors and institutions (Small, 1973). Symmetrically, in the study of citation behavior in the patent analysis, the unit of analysis can be identified by single patents, inventors, institutions or assignees (Lai & Wu, 2005). Our research aims to show the strategic positioning and similarities between the leading automotive companies by displaying and then comparing the entire period of time with three different timespans. For these reasons we adopted assignees as unit of research.

Starting from the OICA 2013 report ranking, we selected the top 80 global companies in the automotive industry of manufacturers based on the number of commercial, passenger, and industrial vehicles produced. We examined the companies' websites and identified the number of brands for each company and its automotive groups. In the Derwent database, we checked individually for brands, single companies and groups, and the number of patents of the application date for the period 1991 to 2013. In this way, we divided the commercial brands by independent enterprises capable of producing technology. Then we looked back across the brands' histories, alliances, and M&As that occurred in the years between 1991 and 2013. In addition, in order to avoid the traditional limitations due to strategic and formal changes in companies and group structures, Derwent provides a comprehensive data set of joint ventures drawn up within industries in the period considered. From the operational point of view and following the correct search strategy proposed by Wang et al. (2011), we did a screening of all potential Derwent codes, including those with a different denomination than the main automotive group, related to joint ventures and M&As. In the research, we took into consideration 14 joint ventures formalized during the period among 18 companies.

Then, we launched an investigation of patent bibliometrics and identified the number of citations of the top 60 car manufacturers. Furthermore, in the hope of exploring the potential effects of the crisis in the strategic positioning of technology groups, we considered these in conjunction with the Asian crisis of 1997 - 98 and just before the start of the crisis of 2007–2008. Moreover, we took into account the M&A histories that showed that in these three periods, the most influential automotive group changes were concentrated. By analyzing the three periods, it was possible to visualize the structural change trends of automotive world industry. Finally, through the multidimensional scaling, a methodology that reduces the complexity and allows the matrices of proximity of certain objects to be studied (Mc Cain, 1990), we displayed the shape and measure the density of automotive sector conformation.

Discussion of results

Patent co-citation

The analysis of co-citations highlights the strategic positioning of the 49 major technological automotive companies in the global market in the period 1991 to 2013, 28 of the main groups in the periods 1991 to 1997 and 1998 to 2004, and finally the 34 major groups between 2005 and 2013. During the full period, the unit of analysis is the single automaker, while in the three time spans it is the automotive group through the extraction of aggregate data. The analysis of the complete map and the trends and changes in technology portfolios in the three time spans, considering the M&A histories and joint ventures, are discussed below through the results of multidimensional scaling and cluster analysis.

MDS and Cluster Analyses

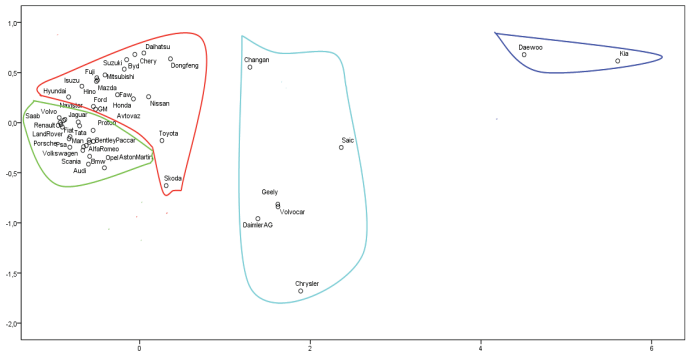

Figure 1. 1991-2013.

On the left of Figure 1 shows an area of high concentration and high technological similarities, while on the right, the distances among firms increase. In this scenario, cluster analysis clearly highlights four groups. The Japanese firms Toyota, Honda, and Nissan are the most central companies and belong to a larger international group comprised of Japanese, Chinese, Korean, and US companies. On the bottom left of the map, European manufacturers emerge, such as Volkswagen, Fiat, Porsche, Renault, BMW, PSA, and MAN, among which are India's Tata and the Soviet Avtovaz and the Malaysian Proton and its Lotus brand. Ford, GM, and Hyundai represent a technological bridge between the two areas. An important peculiarity of some company outliers such as Chrysler, Daimler AG, Geely, Volvo, and Chinese Saic and Dongfeng that belong to cluster 3 is seen, while peripheral positioning is occupied by Daewoo and Kia at the top right.

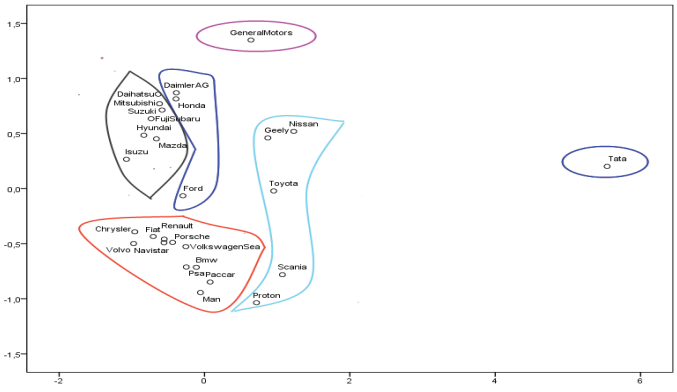

Figure 2. 1991-1997.

Figure 2 shows a major cognition concentration among firms, with the exception of the Indian company Tata on the right side. Ford, Toyota, and Renault are the major groups of centrality. Geely is the only Chinese enterprise present. Cluster analysis clearly shows six groups. General Motors is highly decentralized, a symptom of the uniqueness of its patent portfolio. Daimler and Hyundai are central, positioned in the two groups at the top along with the major Japanese companies, while at the bottom are MAN, Navistar, Volvo, and Paccar, which are all specialized in truck production, just below the European Union automakers. Interesting is the proximity of technology for Fiat and Chrysler, now belonging to the same group, and vice versa, the distance between Toyota and Daihatsu as separate companies at that time and since 1999 part of the same group. Of note is the proximity between Porsche and Volkswagen. Finally, the Volvo Group, at this stage not yet divided between truck and car production, is positioned at the left side near Navistar.

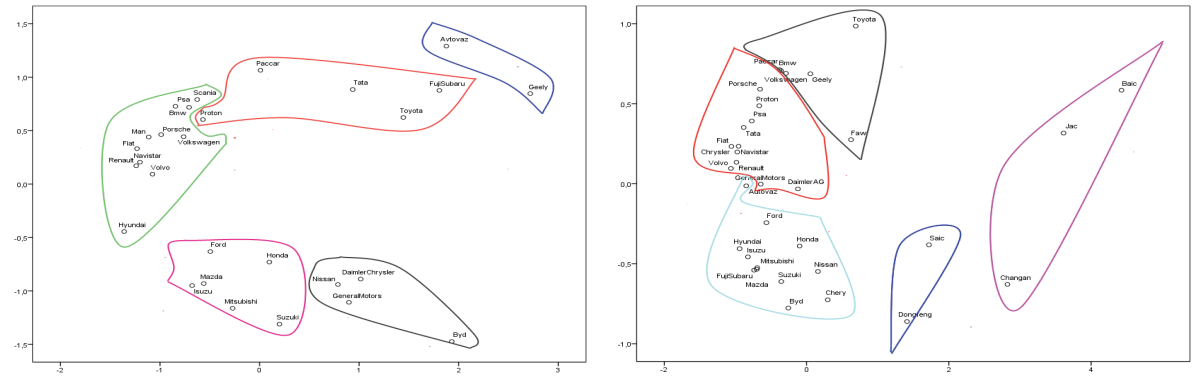

Figure 3. (a) 1998–2004. (b) 2005-2013.

Figure 3(a) transposes the effects of the Asian crisis of 1997-1998 and has a strong dispersion compared to the previous period's technology structures. The distances between companies are larger. To highlight the lack of a technological leader and a high level of technological heterogeneity, the central part of the map is empty.

Figure 3(b) includes the effects of the strong economic performance and global sales of the previous five years to have a stronger concentration symptomatic of technological proximity than in the previous period. During this period, Daimler AG, Ford, and GM occupy the most central locations on the map. General Motors, in particular, takes a decidedly opposite path in the three periods compared to Toyota. The American company tends to centralize its positioning technology, while Toyota tends to move within the confines of the map.

Conclusion and Limitations

This exploratory study increases the awareness of scholars by detecting and visualizing the cognitive structure, operationalized as companies' technological distances, of the automotive sector between 1991 and 2013. It reveals innovation similarities, technology positioning, and trends of assignees and groups, and makes it possible to hypothesize patent strategies and latent relationships among them. A contribution to the patent strategy and cognition literature has emerged on the basis of differences in positioning among companies and groups during the entire period and divided into time spans. In the overall map, this has emerged as some groups are composed of firms with heterogeneous positioning and consequently heterogeneous patent portfolios, while other groups have steadily increased over the years by acquiring high map closeness with companies with similar technological characteristics.

Second, the analysis of the three subdivided periods has highlighted how the level of similarity or distance among the groups, namely the collective cognition, changes continuously. The high concentration level that characterizes the first period is changed in the

second, which is more dispersed and where there are not central or technological leader groups. Yet the third one returns to a concentration level similar to the first period. Such behavior of the map, if considered in relation to the economic performance of the production and sales of the industry, reveals how, in times of crisis, companies tend to look for a heterogeneous technology portfolio to obtain competitive advantages, while in positive economic periods, conformity tends to prevail. It is as if the collective cognition profoundly affects the technology positioning and behavior of firms at the expense of objective assessments of patent strategy decisions. Third, research has highlighted significant strategic differences in positioning in the various periods in which such central enterprises move to the suburbs and vice versa, and some change their technology cluster membership by moving into another and finally emerge or disappear because of a failure or because of an M&A.

Fourth, an explorative contribution originates from the evaluative study of the groups' conformation in terms of brands and partnership formal contracts. In fact, it opens new horizons to researchers who want to analyze the impact of M&As or JVs on technological map positioning and, for example, in Foreign Direct Investments (FDI) and technology strategy literature. Finally, explorative findings of this study might be translated into managerial implications from the point of view of the companies strategic positioning planning. In fact, by detecting the heterogeneous technologies adoption (displayed by the more distant nodes in MDS), manager can potentially create innovative patent recombination strategies and consciously determine innovative future technological positioning scenarios.

Key words

nano photovoltaic technology (NPT); patent analysis; review; photoelectron device; semiconductor material; industry layout

Introduction

As one of leading core technology in the 21th century, nano photonic technology (NPT) is highly interdisciplinary, involving physics, chemistry, biology, materials science, and the full range of the engineering disciplines (Picraux, 2014). NPT is a study of the interaction of electrons and photons and its components in nano structure based on the great development and popularization of nanometre semiconductor materials (Liu, 2005). In 2011, NPT was identified as one of Key Enabling Technologies (KETs) for its vital role in strengthening Europe's industrial and innovation capacity (European Commission, 2011). It is widely used in telecommunications, optical interconnects, display, lighting, photovoltaic, sensors, data storage, imaging, and testing, etc (AIRI/Nanotec IT, 2008).

Patent analysis, which involves statistical, analytical, and comparative methods for examining information in patent documents, has been widely applied in studies examining R&D capacity, technological fields, industrial departments, and company levels (Pavit, 1988). Careful analysis of NPT-related patents can assist in elucidating technological details and relationships, identifying business trends, inspiring novel industrial solutions, and developing investment policies. Therefore, this study performed a statistical analysis of patent data to explore the technological developments of NPT. The technology life cycle and regional distribution of the patents were studied, and the top ten patent assignees were also explored.

Methodology

The searching for NPT patents from the Derwent World Patent Index (DII) database, keywords search were performed for the term appearing in titles, abstracts, or claims. The search strategy of DII database based on NPT was as follows: TS=(((solar or photovoltaic or "optoelectronic integrated device" or OEIC or "optic switch" or "holographic memory" or "light amplifier" or "optical amplifier" or ROADM or "optical add-drop multiplexer" or "optoelectronic display") and nano) or (optoelect* and (semiconductor or GaAs or "gallium arsenide") and nano) or (("quantum well" or "quantum wire" or "quantum dot") and (laser or "photoelectric effect")) or "micronano laser" or "nano laser" or Nanophot* or "Nanowire laser" or "Uv nm laser" or "microcavity laser" or (nano same LED) or (nano same "light emitting diode")). After querying, filtering, and organizing the search results, 8168 NTP-related patents were obtained on December 12, 2014, and the data were analyzed using Thomson data analyzer (TDA).

Results and discussion

Figure 1 showed the evolution of the number of patents relative to the assignees, which is a typical value for exploring the technology life cycle base on patent data. It was showed that the number of patents and assignees increased gradually before 2000, indicating that the technology life cycle was in the introductory stage. This trend implied that few manufactures and institutions were investing in the R&D of NPT before 2000. By contrast, the number of patents and assignees increased rapidly after 2000, particularly during the 2007-2013 periods, indicating that the technology had entered the growth stage. Specifically, the number of patents (assignees) increased from 378 (558) in 2007 to 1006 (843) in 2013.

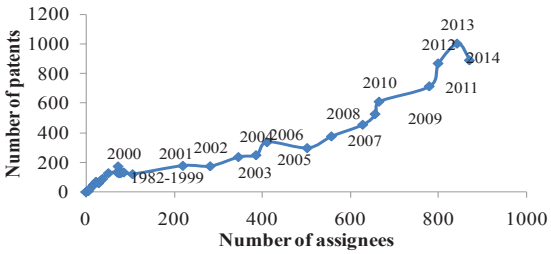

Figure 1. Technology life cycle

Figure 2 showed the number of patents filed in various countries/offices, as well as the trend of the number of patent applications. China (CN), Japan (JP), United State (US), WIPO (WO), and Korea (KR) were the top five countries/offices, with the number of patent applications of 2133, 1964, 1946, 970 and 656. The number of patent applications filed in CN was the highest, indicating that the NPT market in CN might offer the most potential for future development. Compared with other countries, the filing of NPT-related patents commenced only recently in CN, although the number of patent applications increased markedly in 2004-2014.

Moreover, the NPT-related patents were filed earliest in US and WO, and the number of patent applications of these two countries grew rapidly since the beginning of 2004.

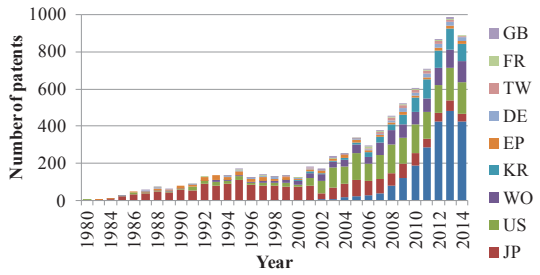

Figure 2. Number of patents and its evolution by country/office. The initialisms "WO" and "EP" indicate that the patent was filed in the WIPO and EPO, respectively.

Table 1 showed a summary of the top ten patent assignees. It was found that all of top ten patent assignees were from JP except *Semiconductors Institute of Chinese Academy of Sciences* and *Samsung Electronics Company, Limited*. In addition, the JP assignees were all companies, and these JP companies had already manufactured commercial NPT products. Furthermore, the JP and KR assignees were filed their patents in many countries/offices for the global layout of NPT. By contrast, *Semiconductors Institute of Chinese Academy of Sciences* filed patents only in CN.

Table 1. Top 10 patent assignees.

Assignee (nationality)	No. of patents	No. of application countries	Times cited (average)
NEC Corporation (JP)	280	4	425 (1.5)
Mitsubishi Denki K.K. (JP)	188	7	402 (2.1)
Fujitsu Limited (JP)	179	5	210 (1.2)
Sharp KK (JP)	170	6	430 (2.5)
Hitachi Limited (JP)	156	4	187 (1.2)
Samsung Electronics Company, Limited (KR)	153	6	137 (0.9)
Semiconductors Institute of Chinese Academy of Sciences (CN)	143	1	71 (0.5)
Furukawa Electric Company, Limited (JP)	138	6	423 (3.1)
Nippon Telegraph & Telephone Corporation (JP)	132	3	30 (0.2)
Matsushita Denki Sangyo KK (JP)	115	5	286 (2.5)

Conclusion

This study analyzed patent data to explore the technological developments of NTP. After querying, filtering, and organizing the search results, this study analyzed 8168 NTP-related patents. The primary findings of this study were detailed as follows.

(1) Based on the analysis results, the technology life-cycle status of the NPT is currently in the growth stage, indicating that many products were sufficiently developed for commercialization.

(2) US assignees were the most prominent assignees, although the most patent applications were filed in CN, indicating that the market for NPT in CN might offer the most potential for future development.

(3) All of the top ten assignees were from JP, KR, or CN. The JP and KR assignees were all companies, and the assignees were filed their patents in many countries/offices for the global layout of NPT and products. By contrast, *Semiconductors Institute of Chinese Academy of Sciences* is academic institution and filed patents only in CN.

Future studies should consider evaluating the current state of NPT developments in a specific field to identify application areas for new patents.

Acknowledgments

We deeply appreciate the financial supports to this research from Youth Innovation Promotion Association of Chinese academy of sciences.

No.16, Nan'erduan, Yihuan Road, Chengdu (China)

Introduction

The Subject-Action-Object (SAO) structures are composed of Subject (noun phrase), Action (verb phrase) and Object (noun phrase), which can represent technology information with more details in a simple manner and have been widely applied in patent text mining (Cascini, Lueehesi, & Rissone, 2001; Sungchul et al., 2012; Zhang et al., 2014a). This paper presents an approach for technology evolution analysis based on SAO. SAO structures are extracted and cleaned from patent text. The technology information of patents such as problems, solutions, functions and effects are stated by SAO. By calculating the distributions of problems over solution groups, a technology evolution map of problems can be drawn. Graphene sensor patents are selected as a case study.

Methodology

Extracting SAO Structures

After collecting patents, some national language processing (NLP) tools are used to extract raw SAO structures from patent text fields. Normally, the fields such as "Title" and "Abstract" are precise and meaningful for NLP (Sungchul et al., 2012).

Cleaning SAO Structures

The number of raw SAO structures is huge and they need to be cleaned. Text mining tools and domain thesauri are used to carry out Subject and Object cleaning by following a term clumping framework (Zhang, et al., 2014b). The verb phrases of Action are normalized and categorized by experts.

Tagging SAO Structures

According to a classification model learned from a training data, the cleaned SAO structures are tagged with 4 kinds of labels of *problem*, *solution*, *function* and *effect*.

Clustering SAO of Solution

After tagging the semantic type of each SAO, those with *solution* label are clustered into different *solution* groups. Each solution group with similar SAO can be considered as a *solution* topic.

Drawing technology evolution map of problems

Kim, Suh and Park (2008) approached a method that can be used to draw technology evolution map of keywords by calculating the distributions of keywords over the keyword cluster groups. We draw technology evolution map of problems based on Kim, Suh and Park's (2008) research. Firstly, we calculate the distributions of problems over the *solution* groups. If the co-occurrence frequency of two problems is above a threshold, we draw a directed line segment between them to show their relevance. Then the occurrence frequency of each problem in *solution* groups is counted. Finally, by adding the earliest filling date of each problem, a technology evolution map of problems with horizontal axis of timeline and vertical axis of frequency can be drawn.

Case Study

Extracting SAO Structures

We selected Derwent Innovations Index (DII) as data source and invited experts to determine the patent retrieval strategy for graphene sensor patents. After eliminating irrelevant patents, we got 196 patents. We extracted raw SAO from the "Title" and "Abstract" fields and got 4,823 raw SAO structures using an NLP tool named ReVerb (Anthony, Stephen & Oren, 2011).

Cleaning SAO Structures

We cleaned Subject and Object by using a commercial text mining tool, VantagePoint (Nils, 2011) and domain thesauri. We followed the term clumping framework to clean them, which includes general cleaning, terms pruning and terms

consolidating processes. After term clumping, we got 628 terms of Subject and Object. We normalized and categorized the verb phrases of Action based on a rule table made by experts. After the cleaning steps, we got 2250 SAO structures.

Tagging SAO Structures

We chose 167 SAO structures from 20 patents as a training set. We picked up Subject, Action as the classification features and C4.5 decision tree as the classifying algorithm to build a classification model which helps to categorize SAO to 4 classes of *problem*, *solution*, *function* and *effect*. Among the classified SAO structures, there are 208 tagged with *problem* label, 746 with *solution* label, 824 with *function* label and 472 with *effect* label. A sample of SAO is shown in table 1.

Clustering SAO of Solution

We clustered the SAO structures with *solution* label into *solution* groups using *k*-means algorithm. By comparing the cluster results, we set the *k*-value 20 and got 20 *solution* groups.

Drawing technology evolution map of problems

By calculating the distributions of problems over each *solution* group, a technology evolution map of problems in graphene sensor patents was drawn. A part of the map is shown in Figure 1.

Table 1. A sample of SAO after tagging.

Type	Subject	Action	Object
Problem	method	synthetize	graphene oxide
Solution	method	use	ultrasonic oscillation process
Solution	graphite powder	mixed with	sodium nitrate
Function	graphene oxide	used for	thin film transistor

Conclusions

The technologies in the upper left corner of Figure 1 appeared in many different *solution* groups and were applied for patents in earlier time, which can be considered as the basic problems in graphene sensor, such as ***producing carbon nanotube***, ***synthetizing graphene oxide***, etc. The technologies in the lower right corner of Figure 1 appeared in fewer *solution* groups and were applied for patents lately, which can be considered as the latest technologies or emerging technologies, such as ***manufacturing sensor array***, ***detecting nucleic acid***, etc**.**

We can draw a technology evolution map of solution, function or effect by following a similar process. The separate technology evolution maps of problem, solution, function and effect can be combined to a more comprehensive technology evolution map of graphene sensor. This study is ongoing.

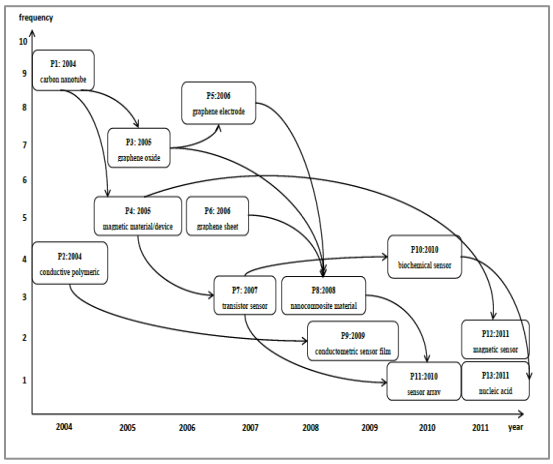

Figure 1. A part of technologies evolution map of problems in graphene sensor patents.

Prediction of Potential Market Value Using Patent Citation Index

HeeChel Kim[1,2], Hong-Woo Chun[2], Byoung-Youl Coh[2]

{kim, hw.chun, cohby}@kisti.re.kr

[1]University of Science and Technology, 305-350, 217 Gajeong-ro, Yuseong-gu, Deajeon(South Korea)

[2]Korea Institute of Science and Technology Information, Dept. Of Technology Intelligence Research, 130-741, 66 Hoegiro, Dongdaemun-gu, Seoul (South Korea)

Introduction

Patent statistics have frequently been used as both technological and economic indicators, however, in order to fully utilize patent data in economic analyses, we must link patents to economic activity at a level of industry or product.

Many previous pieces of research showed the effectiveness of patents citation index (PCI), containing annual citation information, on economic indicators of respective firms. Hall et al. (2005) have studied the relation between a market value and PCI using the Tobin's q approach, and Patel and Ward (2011) have compared the stock market value of firms with the patent citation using the event study methodologies. Both studies showed that Patent statistics can be effectively used to micro-level economic analyses and the increase of PCI has the positive effect on the corresponding market value.

Meanwhile, our study aims to prove the effectiveness of PCI on the economic value of industry, so-called Meso-level study and, in this case, it is essential to develop technology-industry concordance method.

Method

The correlation analysis between Potential Market value (PMV) and PCI for the respective industry is carried out in three stages.

(1) Data concordance process. The market data was collected from Annual Survey of Manufactures (ASM) [1] in the US Census Bureau (http://www.census.gov) and PCI [2] data was collected from the patent set registered USPTO.

Next, we created an annual concordance matrix of IPC (international patent classification) 4-digit to NAICS (North American industry classification system) 6-digit (rev.2002, 2007, and 2012) by Algorithmic Links with Probabilities (ALP), ALP (Lybbert & Zolas, 2013), concordance method of the WIPO (http://www.wipo.int/). ALP is the most up-to-date method compared with those of YTC (Kortum & Putnam, 1997), OECD (Johnson, 2002) and DG (Schmoch et al., 2003).

Each IPC 4-digit is connected to multiple NAICS 6-digit probabilistically via a text mining-based matching rule.

PMV was calculated by model 1 as follows, and consequently, 593 annual pairs of PMV-PCI for each IPC were generated.

$$PMV_{ij} = \frac{\sum_{k=1}^{476} a_{ijk} \times b_{ik}}{\sum_{i=1}^{593} \sum_{k=1}^{476} a_{ijk} \times b_{ik}} \times \sum_{k=1}^{476} b_{ik} \quad \text{..... Model 1.}$$

a = Probability of IPC 4-digit to NAICS 6-digit
b = Value of shipment by NAICS in ASM
i = Year (2002 to 2013)
j = IPC 4-digit code (A01G, A01H, …, H05K)
k = NAICS 6-digit code (311111, 311119, …, 339999)

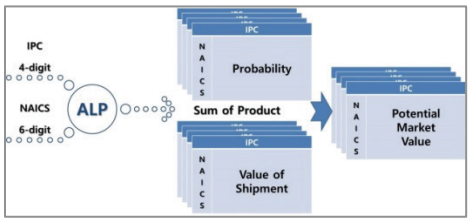

Figure 1. Process of IPC-NAICS Concordance and PMV Calculation.

(2) Statistical correlation analyses for all industry fields. We performed a statistical correlation analysis between the annual incremental of PMV and PCI. We used the Spearman's rho correlation analysis, a nonparametric correlation analysis algorithm, useful to calculate the correlation between the ranked variables (IBM, http://k:5172/help/index.jsp?topic=/com.ibm.spss.statistics.tut/introtut2.htm).

(3) Statistical correlation analyses for 4 major industry fields. The correlation analyses between the annual incremental of PMV and PCI for 4 major industry fields - electrical engineering, instruments, chemistry, and mechanical engineering – were also performed.

Result

Figure 2 shows annual trends of PMV, PCI, and Patent registered. All kinds of variables are trending upward in an accelerating degree.

[1]ASM is estimated sample statistics issued annually for more than one people employees firms in the manufacturing sector. ASM is classified industries by NAICS. In this study, using field of the value of shipment at the 2004 and 2006 edition of ASM that follow the revised NAICS 04 and 2008 to 2011 edition of ASM that follow the revised NAICS 07.

[2]PCI data was used granted patent of USPTO. During the year of from 2002 to 2013.

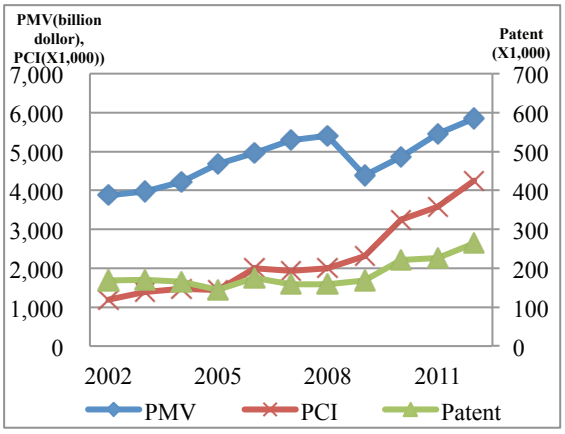

Figure 2. Structure of PMV, PCI and Patent.

PMV of each IPC

Table 1 shows the result of the PMV of each IPC calculated from model 1. It has a significant meaning that a set of patents can be expressed to market value.

Table 1. PMV (unit: million US$).

No.	IPC	2002	2003	…	2013
1	A01G	282	301	…	229
2	A01H	3,057	3,831	…	15,227
...	…	…	…	…	…
593	H05K	6,556	6,166	…	5,055

Correlation Analyses

In the analysis results over the entire industry fields (Table 2), we could find out that significance of correlation and direction varies depending on the Lagging time (differences in data collection year between PMV and PCI). It has a relatively weak positive correlation when the lagging time is 0, meanwhile, it showed relatively strong negative correlation when the lagging time is "PCI+1" – the data collection year for PCI is one year after to that of PMV - . And in case of the lagging time of "PCI-1", it has relatively strong positive correlation, which reveals patent citation activity's positive relation to the corresponding market value "one year later".

Table 2. Results of PMV-PCI rate's correlation analyses (all fields, **significance level 0.01).

Lagging time(year)	Correlation coefficient	p-value (two-tailed)	N
PCI-1	0.136**	0.000	5337
0	0.093**	0.000	5930
PCI+1	-0.323**	0.000	5337

The analyses results of 4 major industry fields showed similar tendencies to all-field-analysis except electrical engineering field.

Table 3. Results of PMV-PCI rate's correlation analyses (4 major fields, **significance level 0.01).

Field	Lagging time(year)	Correlation coefficient	p-value (two-tailed)
Electronic	PCI-1	-0.013	0.747
	0	0.143**	0.000
	PCI+1	-0.513**	0.000
Instrument	PCI-1	0.209**	0.000
	0	0.011	0.795
	PCI+1	-0.360**	0.000

Conclusion

In this research, we made a systematic way for describing the technological impact on industry sector by using some indices, which has a significant meaning that a set of patents can be expressed to market value. We also had confirmed the potential of PCI to predict PMV of the industry. Experimental results showed that PMV in all industry fields was related by the corresponding field's patent-citation activity in one year before or after. After this work, we will deal with enhanced concordance approach to find out relationships between IPC 7-digit and NAICS 7-digit. Also, the self-citation ratio of patent-citation activity may affect economic activity at a level of industry or product, which is now on a study.

Introduction

This paper presents an analysis of knowledge flows in the pharmaceutical innovation process. Backward citations, citations to non-patent literature (NPL), and forward citations that link patents, scientific publications, and pharmaceutical pipelines data on drug developments are analyzed and visualized to provide a more holistic understanding. Results show that patents linked to drugs tend to be technically specialized when compared to patents without linkages to drugs. Moreover, patents linked to drugs tend to cite older patents and scientific publications and impact wider technological and scientific fields than pharmaceutical patents not linked to drugs.

Diverse studies have been conducted to study the origin, trajectory, and destination of knowledge flows and the delays in the science and technology system. Patents and citations between patents and to non-patent literature (NPL) are analyzed to understand knowledge spillovers (Lukach & Plasmans, 2002) or to measure patent quality (Squicciarni et al., 2013). The OECD Science, Technology and Industry Scoreboard 2013 (OECD, 2013) uses comprehensive and up-to-date data to report on knowledge flows via collaboration networks (e.g., derived from co-authored publications and co-inventors on patents), international migration of researchers (e.g., estimated from changes in author's addresses on publications), but also flows of royalty and license fees for technologies. Recently, the OECD introduced a new indicator, called "Patent-Science Link," that aims to measure knowledge flows between the science base and the innovation system (OECD, 2013). According to this new indicator, patented pharmaceutical inventions account for the majority of citations made from patents to scientific publications. That is, the distance between the science base and the innovation system is much closer in pharmaceutical fields than it is in other technological fields. Pharmaceutical innovation is particularly important for drug discovery, as research and development (R&D) costs are huge and major challenges exist for arriving at cost-effective new drugs. In fact, there is a steady decrease in R&D productivity over the last number of years (Booth & Zemmel, 2004).

The structure of the paper is as follows: The next Section details data acquisition and preparation. This is followed by a description of the methodology and results. The paper concludes with a discussion of key insights and their comparison to prior work.

Data Acquisition and Preparation

Five datasets by Thomson Reuters covering 1981 to 2011 are used in this analysis. (1) Publication data from the *Web of Science (WoS)* database. (2) Patent data from the *Derwent World Patents Index (DWPI)* and associated citations from the (3) *Derwent Patents Citation Index (DPCI)*. (4) Linkages between publications and patents come from the *WoS-DPCI Linktable* computed by Thomson Reuters and JST that provides information on backward citations from patents and to the non-patent literature (NPL), i.e., scholarly publications, derived from the *DPCI*. (5) Drug pipeline data was retrieved from the *Cortellis for Competitive Intelligence* database including detailed information of exactly drugs a patent is associated with. Data was compiled on December 11, 2013.

Interested to identify patents and their linkages to the NPL in pharmaceutical fields, we extracted all 833,376 patents with the International Patent Classification (IPC) code "A61P: Specific therapeutic activity of chemical compounds or medicinal preparations" from the *DWPI* with their citations from *DPCI*, called "Pharma_Patents." Then, we extracted 57,800 patents linked to pipeline data from the *Cortellis for Competitive Intelligence* database, called "Drug_Patents." Next, the *Drug-Patents* were subtracted from the *A61P-Patents* resulting in a dataset of 325,576 "Non-Drug Pharma Patents" that have the A61P code but are not linked to drugs.

Finally, all 115,252 NPL for *Drug_Patents (DP)* and 718,269 *Non-Drug_Pharma_Patents (NDPP)* were retrieved using the *WoS-DPCI Linktable*.

Methodology

Four metrics were computed: (1) *citation lag*; (2) *generality index* computing the diversity of patents that are cited by a given focal patent as well as the diversity of patents that are citing the focal patent;

(3) *subject index*, a new indicator based on the generality index but computed for NPL; (4) *patent scope*, often associated with the technological and economic value of patents with broad scope patents having a higher value (Lerner, 1994).

Results

Using the four metrics, a number of novel results can be computed.

Technology Delays: Citation Lag

Comparing citation lag data for *DP* and *NDPP* reveals the temporal dynamics of knowledge flows. Table 1 shows that forward citations from *NDPP* come from patents that were published on average 2.17 years later while *DP* are cited faster—after 1.89 years on average. Backward citations from *NDPP* go to patents that were published on average 3.4 years earlier and they go to much more recent NPL—published only 1.69 years earlier on average. Interestingly, *DP* cite older works than *NDPP*: Cited patents are 5.64 years old and cited NPL are 2.5 years old on average. All values are statistically significant at the 1% level. In sum, they show that *DP* cover larger temporal ranges and are cited more quickly than *NDPP*.

Table 1. Forward and Backward Citation Lags.

	NDPP	DP
Forward Cites by Patents	2.17	1.89
Backward Cites to Patents	3.40	5.64
Backward Cites to NPL	1.69	2.50

Technology Diversity: Generality & Subject Index

The generality index was calculated for 4- and 6-digit IPCs for forward and backward citations for *NDPP* and *DP*, see Table 2. *DPs* have higher generality index and subject index than *NDPP*. That is, on average, *DP* draw on more diverse technology "base knowledge" and are cited by a more diverse set of patents that have more varied IPCs. All values are statistically significant at the 1% level.

Table 2. Generality Index for Forward Citations (FC) and Backward Citations (BC).

		NDPP	DP
Generality Index (4-Digits)	FC	0.36	0.37
	BC	0.40	0.54
Generality Index (6-Digits)	FC	0.46	0.50
	BC	0.52	0.73
Subject Index	BC to NPL	0.22	0.28

Technology Value: Scope

The patent scope was computed for *NDPP* and *DP*, see Table 3. The scope of *DP* is lower than that of *NDPP*. This is unexpected as patents linked to drugs are presumably more valuable than those not linked to drugs.

Table 3. Scope.

	NDPP	DP
Scope (4-Digits)	0.13	0.11
Scope (6 Digits)	0.16	0.15

Conclusions

This paper compared and contrasted patents that are linked or not linked to drugs to understand knowledge flows and delays in pharmaceutical innovation. The results indicate that *Drug_Patents* draw from a more diverse set of technologies and are cited more widely across the technology landscape. However, they tend to be more technically specialized (lower scope) than *Non-Drug_Pharma_Patents*. Concerning citation lag, *Drug_Patents* tend to refer to older patents and scientific publications and are cited faster than *Non-Drug_Pharma_Patents*.

In our prior work, we introduced new drug-patent indicators for identifying patents related with pharmaceutical entities' R&D progress (Jibu & Osabe, 2014) and that IPC count, forward citations, and citations to NPL are efficient drug-patent-indicators. The work presented here is novel is that it shows that citation lags and the generality of backward citations are statically significantly different for *Non-Drug_Pharma_Patents* and *Drug_Patents*.

Acknowledgments

We would like to thank Fernando Galindo-Rueda for his expert comments and support of this research. This work was partially funded by the National Institutes of Health under awards P01AG039347, U01GM098959, and U01CA198934.

Abstract

Using the accumulative publication data on HER-2 and its trend line, we draw the accumulative curve of the publication data. We discuss the characteristics of the accumulative publication curve, and how these characteristics change with respect to the different trend lines. We find that the points that regression line and the publication curve intersect with each other and the minimum points with respect to the trend lines do not change very much in both exponential trend line and linear trend line even if the exponential trend line raises itself much faster than the linear trend line. These data points are formed around the time when the significant discoveries are made and the related regulations are executed. These significant discoveries and regulations impact how and where the research should go and how the basic discoveries influence their application. The accumulative publication curve itself tells us very little about science. However the change of the accumulative publication curve with respect to the trend lines may tell us how science evolves. The content in the publications with significant scientific value may change the direction and trend of research, while research may change the publication trend the other way round. We may say that important scientific discoveries and regulations on clinical practice act as tipping points or act as drivers of change in the rates of scientific publications on the topic of HER-2. This induces us further to explore how scientific events drive the publication process. We may expect that through the publication process, we can monitor the scientific process.

Conference Topic

Theory

Introduction

The number of publications is widely used to measure the output or the productivity of researchers or their affiliated institutes. Hence, it is also used to compare the output of different countries (Bornmann & Marx, 2013; Zhu et al., 2004; Inglesi-Lotz & Pouris, 2011; Garfield, Pudovkin, & Paris, 2010). (China is ranked the second in terms of output of scientific research measured by the number of publications.) It is normally regarded as a quantitative indicator. The number of citations is supposed to measure the impact or the visibility of the researchers or their affiliated institutes that are investigated (Garfield, 1955). Sometimes it is even referred to as the indicator that measures the quality of the research in the cited article that a researcher has performed.

However, these measurements arouse a heated debate. In the December 16, 2012, the concerned scientists gathered in the Annual Meeting of the American Society for Cell Biology developed a set of recommendations referred to as the *San Francisco Declaration on Research Assessment* (DORA). DORA aimed to stop the use of the "journal impact factor" (JIF) in judging an individual scientist's work. They invited interested parties to indicate their support by adding their names to this declaration. Later the editor-in-chief of *Science* Bruce Alberts published an editorial to support this declaration. He thought the evaluation based on JIF was destructive and just encouraged "me-too science" and hence blocked innovation and created a strong disincentive to pursue risky and potentially groundbreaking work. Many leading scientists and scientific organization endorsed in this declaration (Alberts, 2013). JIF, a scientometric indicator based on the number of publications and the number of citations,

was originally created as a tool to help librarians to select journal to purchase, but later it is frequently used as a measure of the scientific quality of research in an article published in this journal and act as the primary parameter with which to compare the scientific output of individuals and institutions. Some academic institutes even use it to decide if a researcher should be funded or promoted as a tenure member (Garfield, 1999; Alberts, 2013). However, this practice arouses the fierce objection by scientists who are evaluated.

Bibliometricians also gave their voices to this phenomenon. Wouters, Glänzel, Gläser, & Rafols (2013) call for the urgent debate on the dilemmas of performance indicators of individual researchers. The Higher Education Funding Council for England (HEFCE), which distributes public money for higher education to universities and colleges in England and ensures that this money is used to deliver the greatest benefit to students and the wider public, carry out a work to review the role of metrics in the assessment and management of research. (http://www.hefce.ac.uk/whatwedo/rsrch/howfundr/metrics/). In the review, the working group launched a call for evidence to gather views and evidence relating to the use of metrics in research assessment and management. Elsevier and SPRU responded to the call. Ismael Rafols, Paul Wouters and Sarah de Rijcke organized a special session on the quality standards for evaluation indicators: Any chance for the dream to come true? (STI program). This session initiated to make the Leiden manifesto on the research assessment. van Raan, a scientometrics pioneer and gatekeeper (Garfield, Pudovkin, & Paris, 2010), will coordinate among different aspects so that this manifesto could be accepted widely. All these principles and responses, without exception, mention that quantitative information provided by metrics must be complemented by qualitative evidence to ensure the most complete and accurate input to answer a question. Even DORA recommended that the funding agencies should consider a broad range of impact measures including qualitative indicators of research impact, such as influence on policy and practice. DORA also recommended the publishers should make available a range of article-level metrics to encourage a shift toward assessment based on the scientific content of an article (DORA).

Garfield (1979, p. 62) illustrated that:

> "If the literature of science reflects the activities of science, a comprehensive, multidisciplinary citation index can provide an interesting view of these activities. This view can shed some useful light on both the structure of science and the process of scientific development."

However, can metrics drawn from publications and citations provide qualitative indicators that reveal the contents of the publications so that metrics can measure the way the contents of the publications influence policy and practice? Liu & Rousseau (2013, 2014) expounded that citation in essence is the interaction of the perspectives on a specific scientific phenomenon, hence can be used to reveal how the scientific phenomenon is understood. With the help of the regression line and a detrended curve, Liu & Rousseau (2012) show that the citation diffusion curve of an article containing a really original idea has an S-shape similar to the standard innovation diffusion curve. The convex part corresponds to the academic phase of the field that Kao's idea initiated, while the concave part corresponds to the technology dominated phase. The curve in the post-technology phase paralleled the regression line. The points of inflection correspond to the phase transition from academic to application research, while minima indicate a breakthrough in academic phase, and maxima indicate a breakthrough in the technology dominated phase. This implies that breakthroughs may directly influence the rate of change of the diffusion process while phase transfers may influence the rate of change implicitly. They claimed that the theory of diffusion process expounded in this article have the potential use of discerning breakthrough and turning points in an S & T area and finding social, technological, political and economic factors influencing the development of science. Can we use the number of publications on a specific topic to

observe the research trend? How the regression lines and the detrended forms of the publication curve tell us about the development of science? Can we discern the breakthrough and turning points between the academic phase and applied phase? Can we find social, technological, political and economic factors influencing the development of science? In this article, we will use the publications on Biomarker Her 2 to illustrate how the scientific activities on a specific research topic influence the publication process. With the help of the regression line and the detrended forms of the publication curve, we try to identify the breakthrough in this area and trajectory of translating research finding into diagnostic tools, medicines, procedures, policies and education. We will combine descriptive material on the development of the research domain with the publication growth - presents a model of interconnections of the publication and citation process, we analyze the cumulative publication curve and compare it to major events in the field. We will show that important scientific discoveries and regulation of clinical practice act as tipping points/ drivers of change in the rates of scientific publications on the topic of HER-2.

Data

After comprehensive literature research, we determined our search string:
TS=("CerbB2*" OR "CerbB-2*" OR "Cer-bB2*" OR "C-erbB2*" OR "Cer-bB-2*" OR "C-erbB-2*" OR "C-er-bB2*" OR "C-er-bB-2*" OR "Cerb B2*" OR "Cerb B 2*" OR "erbB2*" OR "erbB-2*" OR "er-bB2*" OR "er-bB-2*" OR "erb b2" OR "erb b 2" OR "HER2" OR "Epidermal growth factor receptor 2" OR "EGFR2" OR "CD340" OR "her 2")
These words include all the spelling variants related to the biomarker Human Epidermal Growth Factor 2. Among these words, “Her 2” is the only word that is not specific which may bring us some noising results because “her 2” can be used as in “her 2 children” which has nothing to do with Human Epidermal Growth Factor 2. Worse, children can be replaced by any nouns. Between her 2 and the nouns, any adjectives can be added in between. Even worse, since the Web of Science (WoS) ignores all punctuations, any punctuations can be added in between. Also one item that has “her 2 children” does not necessarily mean it is not what we need. Even the articles which deal with Human Epidermal Growth Factor 2 do not exclude the expression “her 2 children”. These situations make it very difficult for us to formulate an effective search string. However, we use the position information and its follow up to judge if these articles are related to the topic that we are searching by a program (Chavarro & Liu 2014, Lang, Liu & Chavarro, 2015), if it cannot be judged by a program, we judge it manually. We have got 98 articles that are not related to our topic. We downloaded all these data in 27 May 2014 and then excluded these 98 articles. Hence we get 30,056 articles. Since the gene of Her2/neu did not have a uniform name at the beginning when the scientists found this gene, we picked up some articles from the reference list of the early articles. And we exclude the articles published in 2014, and then we get 29,210 publications. Using these 29,210 records we do some bibliometric analysis.
The numbers of publications per year increase in roughly linearly. It is said that when a research topic turns to the application science, fewer and fewer publications will be published, instead, more and more patents will be approved. But in our case, it is the opposite, the research topic on HER-2 has already been applied in the diagnosis and therapy, the numbers of the publications on this topic do not decrease at all.

Table 1. Cumulative numbers of publications, the first and the second order differences.

Year	*cumulative numbers of publication*	*the first order difference*	*the second order difference*
1981	1	1	
1982	1	0	-1
1983	1	0	0
1984	3	2	2

Methodology: Regression Trend Lines and Detrended Curves of Time Series Data

Table 1 is a time series data. A time series is a sequence of data points, typically consisting of successive measurements made over a time interval. In informetrics, the time interval can be defined in different shift (Liu & Rousseau, 2008). Normally we make a scatter diagram to see whether data change linearly or nonlinearly. Then we make a regression analysis to find the best-fitting curve to see how the data change over time. We can get a regression equation to explain the

degree of association or the relationship between the data and time. Based on the equation that fits past data as well as possible, we can predict values of the variable at points other than the observation points.

The linear regression is the straight line. The curves of the nonlinear regression curves, depended on the regression equations, have different shapes. For example, the curve can be exponent curves if the regression equation is exponent function. The other possible curves can be logarithmic curve, power curve and multinomial curve. The straight line from the linear regression and the curve from the nonlinear regression are also called trend lines. Figure 1 show the exponential, multinomial, power, linear and logarithmic regression curves of data in Table 1.

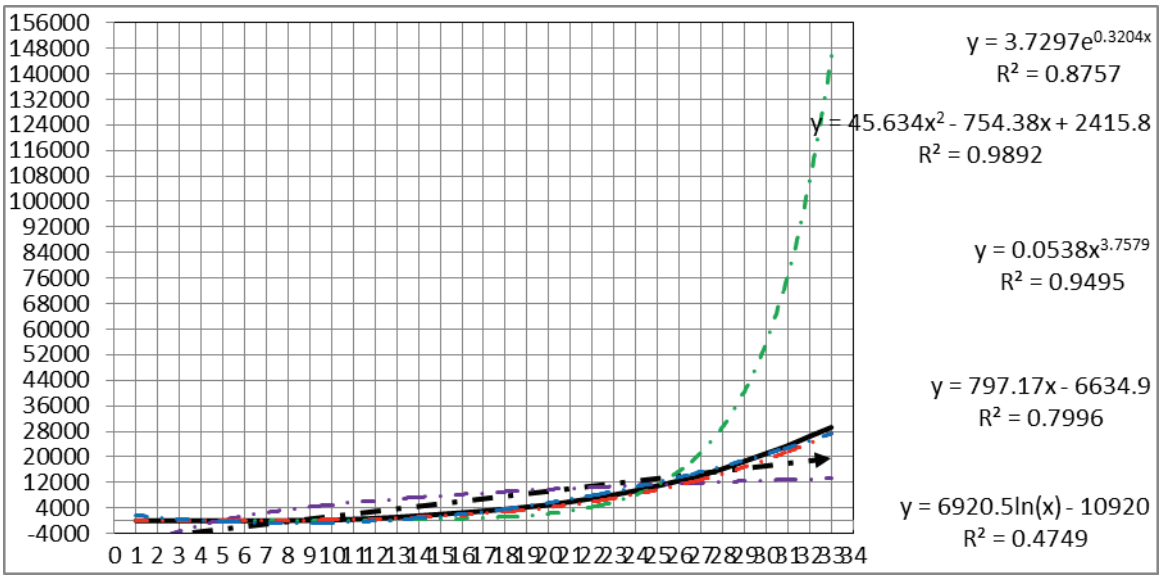

Figure 1.The exponential, multinomial, power, linear and logarithmic regression curves of data in Table 1.

Detrended curve (Shiavi, 1991) is a detrended description of the data. In order to draw a detrended curve, we find a trend line first and then calculating the difference between the overserved data and the trend line. It will give us a view on how the data change in terms of trend line. Peng et al. (1994, 1995) introduce the detrended fluctuation analysis. It is a scaling analysis method used to estimate long-range temporal correlations form. In other words, if a sequence of events has a non-random temporal structure with slowly decaying auto-correlations. It hence can eliminate the trend that self-affinity. By discerning long range correlation, it can help us understand what dominates the change of the data in the time series.

In this article, instead of calculating the difference between the observed data and the trend line, we will rotate abscissa to the paralleling line of the regression line and make the line touching the edge of the scatter diagram. The ordinate will pass through the first observation point so that all the numbers are positive. We then establish a new coordinate system. We will see how the data change with respect to the regression line

Results

We can choose different regression trend lines. In this article, we choose the best fitted straight line. Figure 2 shows the cumulative curve of the numbers of publications on her 2, its regression line and its minimum with respect to the regression line. We can see that the cumulative curve of the numbers of the publications on HER-2 is convex. The regression line intersects with the original data around 1987-1988 and 2007-2008. The minimum with respect to the regression line is around 1998-1999 (1 is the year 1981, 2 is 1982 and so on).

Now we know gene HER-2 was identified in 1981 by transfection studies with DNA from chemically induced rat neurogliobalstomas by Shih, Padhy, Murray and Weinberg (1981). From 1981 to 1987, several groups identified this gene independently (Schechter et al., 1985; Coussens et al., 1985; Semba, Kamata, Toyoshima, & Yamamoto, 1985; Fukushige et al., 1985). Slamon, Clark, Wong, Levin, Ullrich, and McGuire (1987) found correlation of relapse and survival with amplification of the HER-2 oncogene. HER-2 became a significant prognostic factor. Since then Slamon started to do research on binding to the HER-2 protein and prevents it from relaying a signal that stimulates the cancer cell to divide (Pioneers, 2007). In 1998, Herceptin was approved by FDA. Since then a revolutionary treatment started its journey in the history of human being to conquer the disease, based on the gene analysis, personalized treatment appear in the horizon that people can see. In 2007, American Society of Clinical Oncology (ASCO) and The College of American Pathologists (CAP) developed guidelines for when and how the status of HER-2 should be tested (Wolff et al., 2007). This guidelines were updated in 2013 (Wolff et al., 2013). Since then the test for the statues of HER-2 and clinical treatment with Herceptin become a standard test and treatment. However, as Herceptin did not take effect in some patients, the subpopulation remains to be defined, and side effects including cardiotoxicity need to be solved (Kumler, Tuxen, & Neilsen, 2014), HER-2 is still a topic that needs more investigations. We indicate these important events in Figure 2.

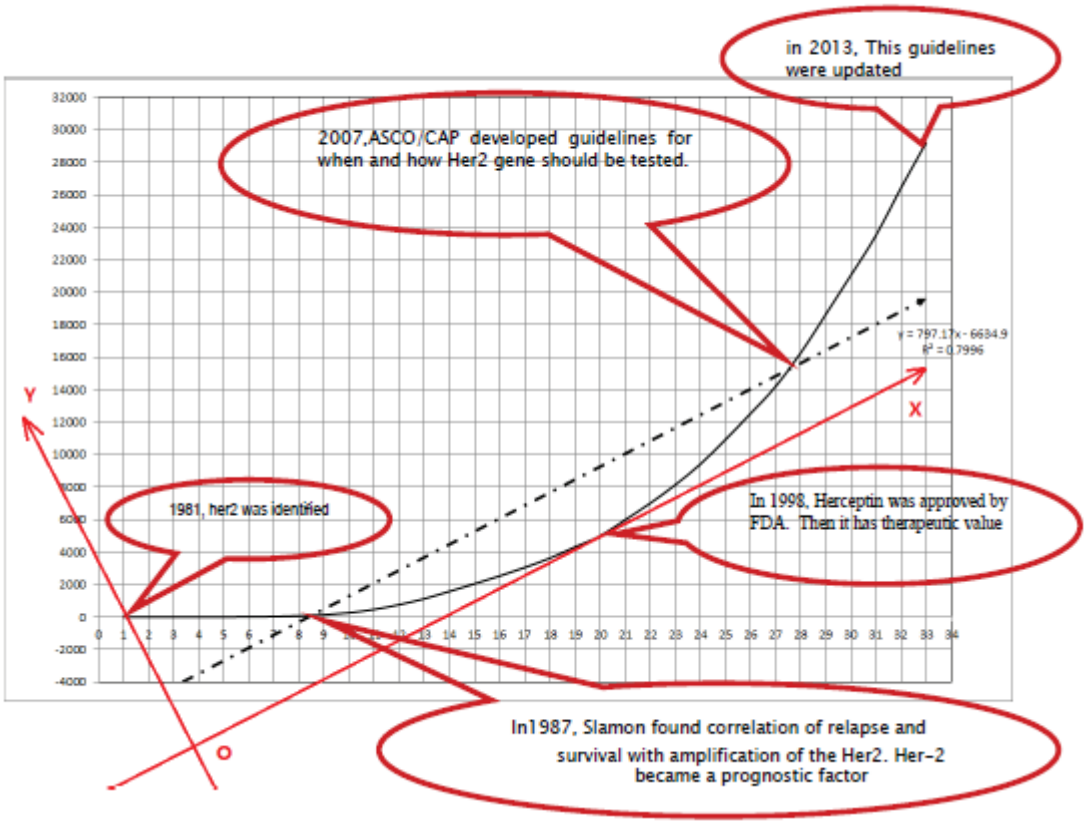

Figure 2. The cumulative curve of the numbers of publications on her 2, its regression line and its minimum with respect to the regression line.

We know that the minimum is a key point where the first-order derivative changes from negative to positive. If a curve shows the status of a thing that changes over time, we say it describes a kind of motion. The motion described by this curve changes from decreasing to increasing in the minimum point. A motion may have a different appearance as viewed from a different reference frame. If we choose the actual data as reference frame, to see how the trend changes, we can see that the discovery of the correlation of relapse and survival with amplification of her-2 oncogene in 1987 changes the trend reflected with publication data. This discovery made the amplification of her-2 a significant predictor and prognostic factor.

The numbers of publications start to increase significantly, the passion on this research topic is activated. Though with respect to the trend line, the original data curve decreases monotonically; the curve did not begin to increase until 1998 when Herceptin was approved by FDA. It is similar to the minimum point in cumulative number of citations curve of Kao when optical fiber was invented by Corning Glass Works in 1970. The crucial material problem, optical fiber, which Kao said in his conclusion "appears to be one, which is difficult but not impossible" was solved. This invention helped Kao realized his dream that no one believed it at the beginning (Liu & Rousseau, 2012). It is a coincidence that no one believed that the method Dr. Slamon used would work and the drug he created would be approved by FDA. On the contrary, everyone thought Dr. Slamon was crazy and he could not even find a student assistant majoring in science at the beginning (see the movie: Living proof and Bazell, 1998). In 2007, HER-2 test in breast cancer was recommended by ASCO-CAP, HER-2 research entered into another stage. The second order difference decreases after 2008. It dropped tremendously in 2010 and 2011. But in 2012, it went up tremendously which probably was caused by the fact that the recommendation guideline was challenged by the clinic practices and the new progresses. In 2013, ASCO/CAP convened an Update Committee that included coauthors of the 2007 guideline to conduct a systematic literature review and update recommendations for optimal HER-2 testing. In 2013, the second order difference become negative. Does the curve reach the point of inflection? We know the negative second order difference means the curve change from convex to concave. So far we cannot get to this conclusion. More observations are needed, at least we need to know how many publications on HER-2 will be published in 2014 so that we can judge whether it is an innate trend or just an occasional fluctuation. However, since major debate was settled down, though HER family oncogene (erbb1 erbb2, erbb3, erbb4) need to be dually blocked, and relative subpopulation needed to be defined and side effects refrain the use of some new developed medicine. For the moment there is an urgent need for prospective biomarker-driven trials to identify patients for whom dual targeting is cost effective (Kumler, Tuxen, & Neilsen 2014), we say it is not a major obstacle. We expect that the year when the breakthrough will make on these obstacles will appear in the maximum point on the curve drawn by the numbers of the publications on the HER-2. But it would depend on whether the research topic HER-2 gives rise to the other research topic.

The predictive, prognostic and therapeutic value of HER-2 are what changes the trend of research. The discoveries of these values of HER-2 influence the diffusion of the knowledge on HER-2 in the landscape of human intellectual space.

Selection of Trend Lines and the Different Implications that Detrended Line can Give Us

We can choose exponential, linear, logarithmic or power function as the trend lines to see what the data can tell us. Intuitively these trend lines are totally different, we hence imagine that the different trend lines can tell us totally different stories. But Figure 1 tells us the points that the different trend lines cross the data are slightly different, all around 2005-2008 even if the exponential trend is a much faster trend than the linear one. However, it is difficult to establish a new coordinate system to see clearly what the data tells us. Since the exponential curve is a straight line in semi-logarithmic system, we draw a scatter diagram in semi-logarithmic system (Figure 3). The data curve is concave upwards with respect to the exponential trend line. We can see the extremum with respect to the exponential trend line is around 1994, a little bit earlier than the time when the Herceptin was approved. However, it is in 1994 that Prof. Slamon finished phase 3 trial and was waiting for the decision of FDA. The first point that the trend line crossed the data is the same, but the second point is a little bit earlier. But the 2007 guideline was accepted for publication in September 27, 2006. The

expert panel was convened in 2005 and started to work on the guideline. It seems as if the shift of time is still in the acceptable region.

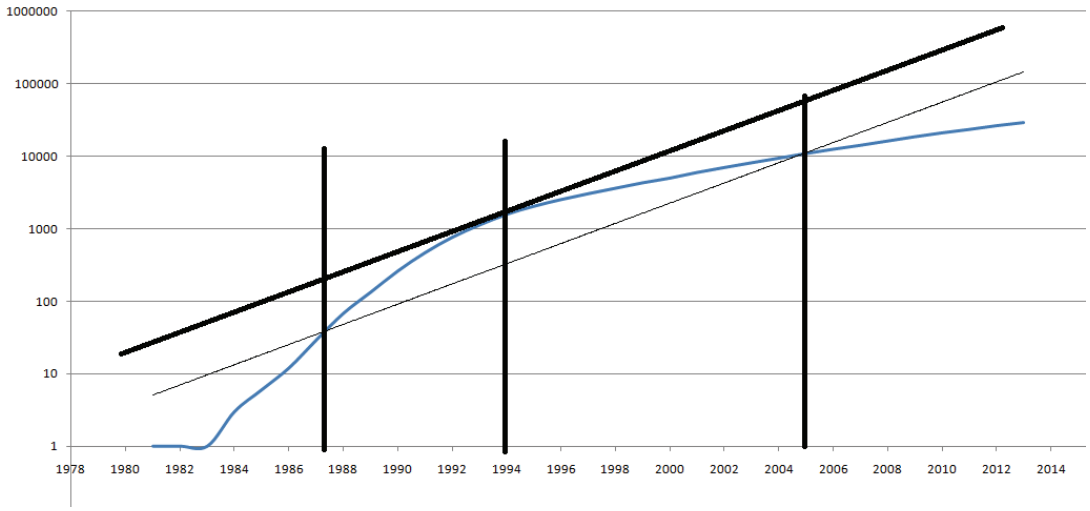

Figure 3. Cumulative publication data curve and its exponential trend line in the semi-logarithmic framework.

Publication and Citation Diffusion Process

Liu (2011) and Liu and Rousseau (2012, 2013, 2014) explore the determining factors that influence the citation process, and link the citation to the cognitive process of a scientific phenomenon under investigation. Through these articles, we illustrated the interaction of different perspectives on the phenomenon under investigation and how it is that the new ideas are accepted by academia determine the citation diffusion process.

In this investigation, we show that publication data curve with respect to the trend line can reflect how the important scientific events such as scientific discoveries and the release of government regulations in the clinical practice can change the trends of the publication process. Obviously, the primary knowledge creation process influences not only the citation process but also publication process. The change of research trends can show themselves in the publication data curve with respect to the trend line.

Liu and Rousseau (2010) studied two forms of diffusion, namely diffusion by publication and by citation. They tried to illustrate that publication diffusion is dominated by the internal diffusion mechanism that originates from the fact that a group of scientists expands their own (field) border. The citation diffusion is dominated by the external diffusion mechanism that the publication of the group of scientists, published in more and more fields, have potential to be applied in the other fields. Obviously, the publication diffusion process and citation diffusion process are interlinked with each other in that publication diffusion process determines the citation diffusion process.

As a matter of fact, publication process is entangled with citation process. Figure 4 shows how these two processes are entangled. Once the scientist(s) are interested in the scientific phenomenon, on the one hand they observe this phenomenon and get some preliminary impressions, and from these impressions they formulate some scientific ideas. On the other hand, they read the literature, which discusses this phenomenon and the perspectives to interact with the ideas that they formed by their observations to help them to get new insight into the phenomenon, and they then begin to make a thorough investigation. From these investigations scientists get new perspectives on the phenomenon. They articulate the new perspectives into a publication. When they write the manuscript they cite the old perspectives in the literature (perhaps they also read the other literatures for new evidence to convince the

readers). Publication and citation are thus born. In this process, scientific phenomenon is more and more clearly cognized.

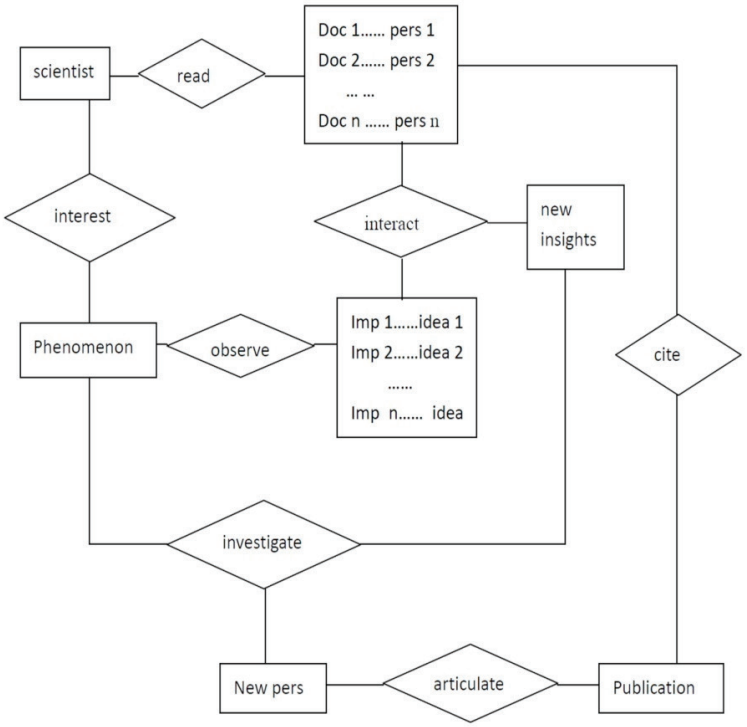

Figure 4. Entangled publication and citation diffusion process.

We can see from Figure 4 that the citation and publication processes are dynamic movement processes driven by the cognitive process of a phenomenon under investigation. The cognitive process is constituted (was led) by a series of scientific events. In this sense we may say that scientific events act as an engine to drive the evolution of science. Some events can lead the cognitive process to another direction. For example, the research in the publication Slamon, Clark, Wong, Levin, Ullrich and McGuire (1987) led HER-2 research from basic research to applied research. This event will change the research trend. Some events have no significant influence on the research trend.

Every scientific event could be represented by some publications on this event. In this sense, the scientific events drive the publication process, this process then drives the citation process. Scientific ideas that the publications convey are then diffused into the human intellectual landscape. So publication diffusion process may give us a deeper insight into the scientific events. The relationships between different publications are not as clear as that in citations, though through co-authorship or co-keywords we can establish different networks. But co-authorship or co-keywords did not reveal how the idea in one publication is diffused into the other publication. We cannot trace how the ideas in different publications interact with each other. Probably the mechanism of publication diffusion process needs to be explained via the citation diffusion process communicating different perspectives of the phenomenon under investigation. Therefore, citation and publication have a potential to reveal the cognitive process of the phenomenon under investigation.

However, we must understand how a scientific idea is diffused in the abstract intellectual landscape. This is the academic movement. In order to describe the academic movement we need to know where an idea comes from, where it will go, how fast the diffusion process is, how long is the distance from its start point to its destination. However, we face a lot challenges. First of all, we must mark the landscape with these scientific events. We have the

classification system such as the Library of Congress Classification System, Chinese Classification System, the WOS subject areas and the ESI fields. However, these systems alone cannot mark the scientific event. Because of the inaccuracy of this system, this kind of research does not give us more sense about the cognitive process of a research topic. Trochim and his colleagues (2011) proposed to identify "markers" in the translation process. They then assess the time that it takes for outputs to move across markers (Molas-Gallart, Este, Llopis & Rafols, 2014). Maybe this kind of mark system that embedded in a concrete scientific investigation will give us more information about the cognitive process of a scientific research.

Secondly, the distance in the human intellectual landscape may change over time and the destinations for the diffusion process are uncertain. These will make it very difficult to describe the scientific cognitive process via publication and citation diffusion process. These research questions deserve our effort. We would understand the scientific process more accurately if we could describe publication and citation diffusion processes more precisely. We can even anticipate what drives the evolution of science.

Conclusion

With the numbers of the publications on HER-2, we drew the accumulative curve of the publication data. We discuss the characteristics of the accumulative publication curve with respect to its trend lines and how its characteristics change in different trends. We find out the intersect points through regression line and the publication curve. These points are around the time when significant discoveries and regulations are made. These significant discoveries and regulations dominate how and where the research should go and how the basic discoveries influence their application. The accumulative publication curve itself tells us very little about how the science is evolving, but the change of the accumulative publication curve with respect to the trend lines may tell us more about the science. The content in the publication that has significant scientific value may change the direction and trend of research, hence change the publication trend reversely. We may say that important scientific discoveries and government regulations on clinical practice act as tipping points or act as drivers of change in the rates of scientific publications on the topic of HER-2. This makes us go further to explore how scientific events drive the publication process.

Abstract
Building on the concepts of the reward system of science and social capital, Blaise Cronin brought forth the idea that rewards in science are threefold, forming a triangle built from authorship, citations, and acknowledgements. Of these, acknowledgments are the hardest to grasp and evaluate. After nearly 45 years of multidisciplinary research on acknowledgments and a corpus of over 80 scientific contributions, there is still no consensus on the value of acknowledgments in scholarly communication. This study aims to further acknowledgments research with a meta-synthesis of the literature, establishing the theoretical framework for the use of acknowledgments as bibliometric indicators. Based on in-progress content analyses, broad categories emerge revealing contextual information crucial to the understanding of acknowledgments. Applying our framework on data from the Web of Science, further phases of this study will provide large-scale findings based on a multidisciplinary sample. From there, it will be possible to envision recommendations for the standardization and use of acknowledgments as indicators. However, grounding the study of acknowledgments in their underlying theoretical considerations and conceptual foundations will ensure these recommendations respect the diverse traditions of the scientific field.

Conference Topic
Theory

Introduction and background
It is a broadly recognized fact that the scientific field has a very "high degree of codification", to borrow the Bourdieusian phrase (Bourdieu, 1996, p. 226). How and when one is admitted into the academic community, how a researcher acquires credibility within the scientific realm, and what contributions turn a researcher into a renowned scholar are endlessly evaluated, measured, and scrutinized. This high degree of codification helps to both foster and assuage the paradox that underlies the use of empirical measures to define what remains an intrinsically nuanced and contextualized concept: scientific "success".

Merton (1973) presented the sociology of science with the reward system of science, its recognition paradigm, and the nepotistic undertones of the Matthew effect; Bourdieu reframed the concept of recognition to befit the concept of symbolic capital. Blaise Cronin brought forth the idea that these rewards are threefold, forming a triangle built from authorship, citations, and acknowledgements (Cronin, 1995; Cronin, 2005; Cronin & Weaver-Wozniak, 1993). These are all part of the *illusio*, which encompasses the stakes of the academic "game", its rules, and the very fact that its rewards are worth pursuing (Bourdieu, 1988, p. 56).

Of these rewards, acknowledgments are the hardest to grasp and evaluate; reasons range from lack of standardization to name-dropping and ambiguous wording (Cronin, 1995; Cronin, 2014), as well as the placement of acknowledgments, which can vary from in-text mentions to paratextual elements situated outside the body of the text (Genette, 1997). Researchers have also called for stricter policies to inform the use of acknowledgments, prescribe their form, offer conditions for inclusion, or establish their ethical ramifications (Brown, 2009; Chubin, 1975; Pontille, 2001). For example, while Cronin's research (Cronin, 1995) showed that in

most researchers' view, obtaining permission to thank is unnecessary, certain current editorial policies (e.g., PLOS ONE, 2015) require any acknowledging party to obtain the acknowledged party's permission. Extricating one aspect of acknowledgments is also not always straightforward. The "Funding Text" (FT) field of the Web of Science (WoS) database, indexed since 2008, is a telling example, since it often contains all things and people acknowledged, not just the agencies or institutions that provided funds to the project. That being said, the FT field of the WoS has opened new avenues for this research by making massive datasets available.

However, the literature heeds one important and overarching warning: after nearly 45 years of multidisciplinary study and a corpus of over 80 scientific contributions, there is still no consensus on the value of acknowledgments, no potential for meta-analysis within this corpus, and, despite common questions, no shared framework for further analysis, nor any clear recommendations for standardization. Given this situation, this study aims to further acknowledgments research with potential contributions to scientific policy guidelines (editorial and institutional) and research assessment (individual and disciplinary) in the scientometrics field, which has shown ongoing interest for acknowledgments as a potential indicator (Cronin & Weaver-Wozniak, 1992; Cronin, 2005; Díaz-Faes & Bordons, 2014).

In order to gain an understanding of where acknowledgments research had emanated from and where it is currently situated in the scientific ecology, an initial overview of the literature on acknowledgments was conducted, leading to the retrieval and document-level analysis of 115 scientific publications, which became the subject of a chapter submitted for inclusion in a book on theories in informetrics (Desrochers, Paul-Hus, & Larivière, in press).

This phase of the research established that the reward triangle can and should be studied, not only for its three constituting factors, but also for the relationships between them. It showed that the meeting point of citation and authorship is the apex of the reward triangle. Acknowledgements, however, are foundational in that they reveal the inner workings of the scientific *illusio* (Bourdieu, 1988) that support this apex and that have, historically, supported key conceptual frameworks: the "invisible college" (Crane, 1972), "trusted assessors," encountered before and during the peer review process (Mullins & Mullins, 1973), and the categorization of authors vs. acknowledged contributors (Patel, 1973).

Methodology

Following this initial review, it became clear that a meta-analysis of acknowledgments research would not be possible; however, the range of complex and varied approaches could form the basis for a meta-synthesis (Rousseau, Manning & Denyer, 2008) of the literature. This will: extract knowledge on the perceptions of acknowledgements across a variety of disciplines (e.g., Information Science, History, Astronomy, Literature, and Psychology); provide scientometricians with information pertaining to the nuances and contexts of research creation in various disciplines; and yield the conceptual framework necessary to undertake acknowledgements research on a larger scale using multidisciplinary datasets. The following research questions were thus devised:

1. What does "acknowledgment research" look like?
    a. Throughout history? (1970-present)
    b. What were its founding concepts and considerations?
    c. How are acknowledgments perceived and positioned in the acknowledgments literature itself?
2. Who is concerned with acknowledgment research?
    a. Scientists from what fields conduct acknowledgment research?
3. What aspects of acknowledgments are studied in acknowledgment research?

Using approaches based in the Social and Health Sciences (Rousseau et al., 2008; Dixon-Woods et al., 2005; Mays, Pope & Popay, 2005) and recommendations specific to the use of evidence-based literature in Information Science (Urquhart, 2010), a protocol for meta-synthesis was established using the PRISMA model for systematic literature reviews (Moher et al., 2009). The most recent searches place the corpus at 80 relevant documents. This paper presents preliminary findings and initial theoretical considerations.

Preliminary Findings and Discussion - Foundations for a theoretical framework

Based on in-progress content analyses, broad categories are emerging; they reveal contextual information crucial to the understanding of acknowledgments as potential bibliometric indicators.

Paratextual Status: Acknowledgements can be elusive, especially in structure-driven datasets. Standardized locations, conventions, separate paragraphs, in-text allusions, database fields defined as pertaining to one aspect but including others are all intrinsic to understanding their value.

Disciplinary Contexts: The literature stems from various disciplines, yielding a broad range of methods and reporting styles. It also approaches the topic from various angles: a discipline (e.g., Cronin, 2001), a culture or a group (e.g., Woolf, 1975), a linguistic community (e.g., Al-Ali, 2010), a specific journal or set of journals (e.g., Rattan, 2013), dissertations (e.g., Gesuato, 2004), or direct enquiry (e.g., Heffner, 1979), quantitative (e.g., Costas & van Leeuwen, 2012) or qualitative (e.g., Bashtomi, 2008). These differences do provide a spectrum of perspectives that need to be part of any standardization process of these scholarly rewards into contextualized indicators.

The Thankers and the Thanked: At its core, acknowledgments research is based on the basic questions of who or what gets thanked by whom and for what. From the expression of gratitude towards spouses to the mention of support from grant agencies, scientific acknowledgments reflect the same diversity as acknowledgments from other types of writers, such as literary writers (Desrochers & Pecoskie, 2014) and can be seen as a "'ledger' where debts are acknowledged" (Weber & Thomer, 2014, p. 84). Inconsistencies abound: people are thanked without specification of tasks, tasks are listed without names; financial capital is embedded with social capital and with messages of a highly personal nature (Coates, 1999).

Cloak and Dagger Reveals: The previous two categories show that scientific acknowledgments are sometimes as much a puzzle as they are clear; this in itself is information. Indeed, the last decades have shown interest in the fact that acknowledgments can expose the invisible college and pre-publication readers, including unknown reviewers, thereby setting boundaries between groups who know their identities and those who do not. This is obviously problematic in terms of using acknowledgments as indicators; yet abolishing this practice would mean revoking a practice that pays homage to the peer review process as it currently exists.

Language and Ethics: The acknowledgments genre has been studied in Linguistics and alluded to in other disciplines, including Information Science (Cronin, McKenzie & Stiffler, 1992). "How" entities are thanked is closely linked to prescribed funding-based requirements, cultural and disciplinary practices, and editorial guidelines, the latter being related to the ethics of thanks: securing permission to thank someone, paying 'lip service' to key players, and name-dropping (Cronin, 1995; Hollander, 2002)—angles reminiscent of the Matthew effect.

Value and Perception: Finally, acknowledgments research has the ingrained quality, seen elsewhere in science but perhaps rarely to this extent, to turn on itself. Numerous papers oscillate between two positions: perceiving acknowledgments as suitable for study and as potential indicators, true to the Merton-Bourdieu-Cronin theoretical continuum; and

criticizing them as problem-laden, lacking standardization, and fickle. Context and processes have come under scrutiny in the use of other indicators in research assessment; yet acknowledgment studies have a particular penchant for self-deprecation while relying on what is now four decades of research to insist upon the fact that there is something to this paratext.

Conclusion and Upcoming Phases

Quantitative content analysis will help weigh these concerns throughout the history of acknowledgments research. Qualitative analysis will help nuance these findings through context, history, and disciplinary boundaries. Together, these analyses will provide a meta-synthesis of the existing literature, from which the conceptual framework outlined here will be refined for use in further studies. The goal is to use this framework on data from the WoS and to provide large-scale findings based on a multidisciplinary sample. From there, it will be possible to envision recommendations for the standardization and use of acknowledgments as indicators.

However, since the literature provides many important warning signs, heeding them and grounding the study of acknowledgments in their underlying conceptual foundations will ensure these guidelines respect the multiple traditions of the scientific field and work within the boundaries of the evolving high stakes of codification. Furthermore, they will help take into account the fact that acknowledgments have long had a special standing in academia as the place where the *homo academicus* (Bourdieu, 1988) can make the invisible visible, but also vice-versa. This, in itself, is a stake of the *illusio* that deserves to be better understood.

Introduction

Is there any regularity in scientists' research activities? For example, does there exist a period when a scientist makes his most contributions? If so, which period is the most productive period? To answer the questions above, many scholars have been contributed their efforts on studying the relationships between productivity and age, such as: (1) age distribution of scientists' creativity or productivity (Liming et al., 1996; Bonacarsi & Daraio, 2003; Jones 2010); (2) the relationship between the longevity and scientist's outputs (Levin & Stephan, 1991; Jonesa & Weinberg 2011; Todorovsky, 2014); (3) the effects of age on researcher's productivity (Bonacarsi & Daraio Costas & van Leeuwen, 2010). However, the previous research still leave some gaps need to be filled. One of them is what about the age distribution of an individual researcher's achievements in his research career. Our research efforts in this paper would contribute to this topic. Particularly, the object of our study is Academicians of the Chinese Academy of Science. And we explore the age distribution of publication by these academicians.

Data and Method

The website of Academic Divisions of the Chinese Academy of Sciences provides academicians' brief introduction and research experience, which including their birth day and affiliated institutions. We choose total 139 Academicians in field of *Mathematics & Physics*, and total 85 Academicians in field of *Information Technical Science* as our research data. *Mathematics & Physics* is an ancient and classical subject, and *Information Technical Science* is a rapid development subject. In order to analyze the age distribution of these academicians' publication, the academician's name and affiliation were used as joined retrieval terms to get their publications both in China National Knowledge Infrastructure (CNKI) and web of science (SCI) database. CNKI is the largest authoritative digital publishing platform and knowledge services platform in China. To get their whole publication output, the repetitive or mistaken publication data of these academicians were deleted.

The average age of 224 academicians is 74 years old, and all of these academicians are now alive until the retrieval day (11/2014). The number of the scientists' publications was selected as the scientific productivity indicator, but the co-author situation was equally considered. This paper considers age distribution of scientists' publication from the scientists' physiological age view.

Age distribution of academicians' publication

Firstly, we count the number of every individual academician's publication according to his physiological age. After that we sum the number of publication up according to the same physiological age of all academicians in the same field. So we can get the physiological age distribution of publication of total scientists in one field. We named papers indexed in SCI/CNKI as "SCI/CNKI" paper for short.

Age distribution of academicians' publication in Mathematics & Physics

The publication age distribution curve of CNKI paper and SCI paper of academicians in *Mathematics & Physics* are shown in Figure 1(a). The publication age distribution curve of total paper (sum of number of CNKI paper and SCI paper) is presented in Figure 1(b). Just as shown from the folder part of the two publication age distribution curves in Figure 1(a), we can see the period between the age of 50 and 65 is the same publication peak period of CNKI paper and SCI paper. Scientists published 61% of their total publications between the age of 50 and 71, the highest peak point is at the age of 68.

Age distribution of academicians' publication in Information Technical Sciences

The publication age distribution curve of CNKI paper and SCI paper of academicians in *Information Technical Sciences* are presented in Figure 2(a). The age period from 60 to 70 is the same publication peak period of CNKI paper and SCI paper. As Figure 2(b) is shown, scientists published 51% of their total publications between the age of 62 and 76, and the highest peak point is at the age of 67. In detail, there is a smaller publication peak period between the age of 45 to 51 before the higher one.

Significant differences test of academicians' productivity before and after tenure

Paired-Samples T Test was used to test if the scientists' productivity would be different before and after tenure. We sum up the number of publications for five years of every individual academician before and after tenure. Before testing, we assume that there is no significant difference of academicians' productivity before and after tenure, then we use the Paired-Samples T test to test the hypothesis. According to the analysis results, the assumption is rejected, which means that the number of publication is obviously different before and after tenure. After tenure, academicians are more productive than before in overall.

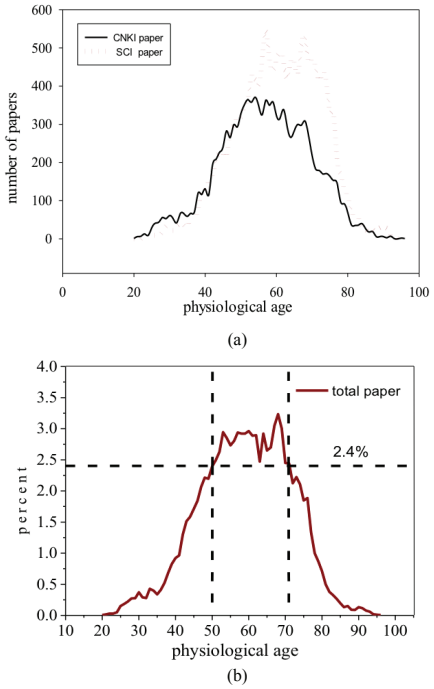

Figure 1. Publication age distribution of academicians in *Mathematics & Physics*.

Discussion and conclusion

The final results show that age distributions of academicians' publication have some regular features. The entire publication age curve of *Mathematics & Physics* shows a single peak distribution. The publication peak period is between the age of 50 and 71. However, publication peak period of academicians in *Information Technical Sciences* is between the age of 62 and 76. Moreover, it is different from *Mathematics& Physics,* which has a small publication peak period between 45 and 51 in publication age curve of *Information Technical Sciences'* academicians. Additionally, our results also reveal that there is significant difference of the scientists' productivity before and after tenure. The publication age distribution law on academicians of the Chinese Academy of Science brings us useful enlightenment. We should pay more attention to middle-aged scientists to improve their research input-output ratio.

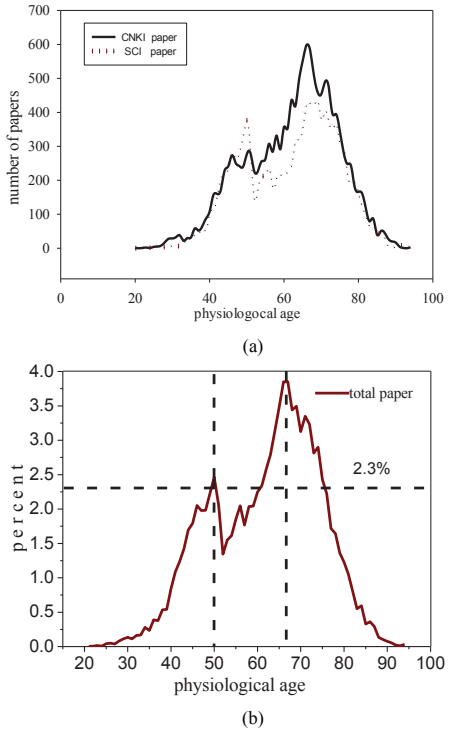

Figure 2. Publication age distribution of academicians in *Information Technical Sciences*.

Introduction

The concept of the core of documents had originally been introduced in connection of co-citation analysis (Small 1973). The term *core documents* has later been re-introduced in the context of bibliographic coupling (BC; see Glänzel & Czerwon, 1996) and hybrid BC and text based similarities (Glänzel & Thijs, 2011) in order to identify strongly interlinked papers that form important nodes in the network of scholarly communication. In order to study stability and dynamics of core-document sets we apply two different methods to h-index related literature in the period 2005–2013 for illustration.

Data Sources and Processing

Data were retrieved from Thomson Reuters Web of Science Core Collection (WoS) following the strategy of Zhang et al. (2011), with extension of the period 2005–2013. We also added citing papers but removed duplicates and papers with less than 5 references to avoid biases in BC similarities. We obtained a final set of 3,270 documents. Figure 1 shows the annual increment of papers in this set.

Research Questions, Methods and Results

In this study we apply two different methods to determine core documents, (Method I) the traditional one according to Glänzel & Czerwon (1996) with a fixed number of links ($n = 15$) and Method II using the h-core of the network (Glänzel, 2012). In both cases we applied a *hybrid approach*. We used link strengths of 0.5 and 0.4 according to Salton's cosine measure. Using these parameters, we analysed the dynamics of core documents along the following questions.

- How is evolution of core documents reflected by the two methods?
- Do the two methods provide stable results?
- Do core documents adequately represent the evolution of the topic?

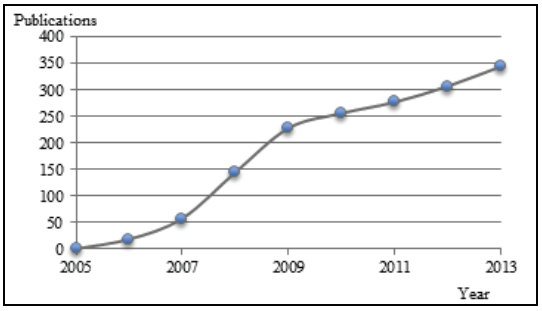

Figure 1. Distribution of h-related publications during 2005-2013.

Core document are by definition strongly interlinked with a large number of other documents in the set under study and thus represent the very core of the set. As expected, their number increases with expanding time spans, the average annual growth rate of the cumulative set amounted to 46% (Method I) and 25% (Method II), respectively. Not only the number of nodes in the network but also the number of their links is growing, however at a different pace. Indeed, we found that the complete h-related set increased at a large constant pace of 11% while the growth of the core sets was faster (see above), but its growth slowed down. This might in part be a consequence of the increasing age of references. In 2013 the core reached a representation of 2.0% and 2.4%, respectively. This characterizes the evolution of the core set with respect to the topic dynamics. The second question that arises from these figures is in how far do both methods mirror the same "core" of literature. In order to check the robustness of these methods, we compared the overlap of the sets of core documents obtained from the two methods. To this end we used BC with fixed number of links as reference standard. Concordance with Method I ranged between 83.8% and 95.2% with increasing trend from 2005–2007 to 2005–2013 and using Method II the shares ranged between 96.8% and 80.7%, however with decreasing trend.

In order to answer the third question, we analysed the core sets obtained from the two methods on the basis of authors and topics of the individual papers. The evolution of the core-document sets according to Method II is shown at three different stages in Figure 2 using Pajek with Kamada–Kawai layout (Batagelj & Mrvar 2003).

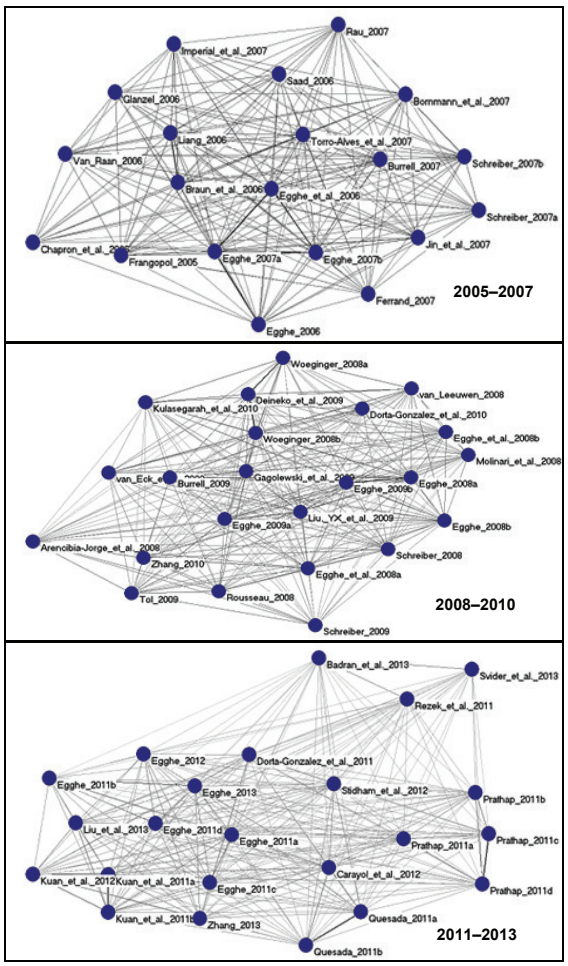

Figure 2. The evolution of the core-documents set (II).

Core nodes in Figure 2 are based on BC but hybrid similarities are used to measure the links between the nodes. This can be done because of the strong concordance between the sets obtained from the two methods. The links between core nodes in Figure 2 are denser and stronger than in the BC approach, which is due to the inclusion of textural information. The interpretation of Figure 2 is not straightforward, but the structural changes of the networks during different periods presented here are quite clear and noteworthy. The network in the first sub-period (2005–2007) comprises above all theoretical publications. The network of 2008–2010 already reflects a different picture. While most theoretical papers are still located in the centre of the network, also 'applied studies' started to appear in the core-documents set. These are distributed at the periphery of the network, which indicates that the topic starts to expand from pure theory to more application. The network of the last sub-period (2011–2013) reflects the clearest structure, where we could distinguish several sub-networks. As the most stable contributor, Egghe's six papers are found in one strongly interlinked sub-network, with the most theoretical roots. Unlike the network in 2008–2010, where some 'applied studies' were still scattered at the periphery of the network, we found more distinct sub-networks on 'applied' research in the network in 2011–2013. In this sense, core documents appear to follow the trend of the topic that is moving away from 'hard-core' informetrics towards research evaluation at different levels of aggregation and for various purposes.

Discussion and Conclusions

In the present study we focussed on 'core documents' with their evolution in publication networks using the example of a specific but nonetheless heterogeneous paper set. The two applied methods proved robust and representative. Their coverage amounted to about 2% of the topic literature, which is in line with the expectations (cf. Glänzel, 2012) but their links lead to related documents that represent a much broader coverage of the topic h-related literature.

The evolution of the core-document network represents the general tendency of shifts in topic, authors and application in an adequate manner. This gives also evidence that Hirsch-type indices have become a tool that is used also outside the informetric community.

Abstract
Using a dataset of 26,228 Psychology document surrogates from Elsevier databases, we compare author relatedness measure outcomes for 125 authors based on topic modelling to more traditional approaches that rely on direct citation, co-citation and collaboration. Outcomes for the author topical similarity measure are compared to existing co-authorships in the dataset using UCINET/NetDraw. We demonstrate how author topical similarity outcomes provide a similar, but more complete, picture of author relationships than the co-authorship network. Nonparametric correlation analysis results of author topical similarity, co-authorship, citation, and co-citation were also compared for thirty author pairs of differing author topical similarity values. There is a significant correlation between author topical similarity and co-authorship and direct citation-based measures for high similarity author pairs, but not with co-citation measures. The author topical similarity measure, therefore, may serve as a reasonable predictor of collaboration or direct citation for authors with high topical similarity. The measure may also identify potential collaborators based on high author pair similarity values, where there is a lack of existing collaboration, and serve as a complement to author relatedness based on co-citation analysis.

Conference Topic
Methods and techniques

Introduction
Understanding the relationships between authors is of great interest to researchers in scholarly communication and informetrics. Author relatedness can be revealing of the membership of research communities and potentially hidden similarities among authors that may not be readily apparent. The relatedness of authors is a multi-faceted concept that can be determined from different data sources, which include direct author citations, author co-citations (White & McCain, 1998), author bibliographic coupling (Zhao & Strotmann, 2014), author topical similarities (Lu & Wolfram, 2012), author collaborations (Glänzel & Schubert, 2005), and other derived measures (Jacobs & Wolfram, 2014; Jeong, Song, & Ding, 2014). These measures can be discursively categorized into three groups: citation-based (author citation or co-citation), content-based (author topical similarities), and collaboration-based measures (co-authorship). Among developed measures, citation-based measures, especially based on author co-citation analysis, are most influential and well-studied in the literature. The emergence of topic modelling techniques (Rosen-Zvi et al., 2010) has reheated the interest in content-based measures. Co-authorship has been widely used to understand scientific collaborations and reveal research communities. It is well understood that these measures focus on different aspects of author relationships and reveal different types of relatedness. However, the inter-relationships among the different measures have been rarely researched. Are authors with higher topical similarities more likely to collaborate with each other? Do they tend to cite

each other more often? Are they more likely to be co-cited by others? These questions are not adequately addressed in the literature. The purpose of this study is to examine the inter-relationships among several measures of author relationships, including citation-based measures, content-based measures, and collaboration-based measures. More specifically, the research aims to address the following questions:

1) Does author relatedness assessed by author topical similarity reveal similar relationships as a more traditional assessment approach based on co-authorship?
2) What is the relationship between author citation, author co-citation, author collaboration and author topical similarity?
3) Can author topical similarity be used as a predictor for other relatedness measures such as author collaboration, author direct citation or author co-citation?

Author topic modelling (Rosen-Zvi et al., 2010) will be used to determine author topical similarity using bibliographic records for the field of Psychology. Understanding the inter-relationships among the different author relatedness measures contributes to the better use of them in revealing scientific structures.

Literature Review

The present study builds on existing research examining author similarity comparison by employing topic modelling techniques and comparing outcomes to citation and co-citation-based measures.

Measuring the relatedness between scientific entities (e.g. articles, authors, and journals) has been studied for years. Typically, most similarity measures between units are based on quantifiable assessments arising from citation practices that link authors or through direct collaboration or other co-occurrence similarities (Börner, Chen, & Boyack, 2003). To date, the relatedness or similarity between authors has been investigated mainly through five perspectives: direct citation, bibliographic coupling analysis, co-citation analysis, co-authorship analysis, and co-word analysis. Direct citation relationships are built on citation behaviour when one author cites others' work (Boyack & Klavans, 2010). Bibliographic coupling relationships are measured by counting the same references two authors share in their publications and have been studied recently by Zhao and Strotmann (2008, 2014). Moreover, the most widely studied approach, co-citation analysis, assesses the association between two authors by the frequencies they were co-cited by others (White & McCain, 1998). A co-authorship relationship results from a direct collaboration (Glänzel & Schubert, 2005). Each of these methods relies on an explicit connection arising from citation or collaboration. Without these connections, no relationship can be identified. Implicit relationships can be revealed by comparing the content of documents authors have published. Until recently, this has taken the form of co-word analysis, where words or index terms from documents are used to determine how closely related entities of interest are (e.g., Law & Whittaker, 1992).

Although previous studies have used content-based methods to approach the relationships between authors, documents and disciplinary areas, topic-based methods have rarely been applied to date to capture the relationships between authors (Lu & Wolfram, 2012). Topic modelling seeks to automatically reveal the latent topics from a set of documents through machine learning. Hofmann (1999) first proposed a generative data model—called the Probabilistic Latent Semantic Indexing (PLSI)—that represented each document as a probability distribution over a set of topics. While Hofmann's work provided some advantages for document indexing, it may lead to serious problems of overfitting (Blei, Ng, & Jordan, 2003). To overcome the limitations of PLSI, Blei, Ng, and Jordan (2003) presented a three-level hierarchical Bayesian model, which is known as Latent Dirichlet Allocation (LDA). In the LDA model, each document is modelled as a finite mixture over an underlying

set of topics, where each topic is modelled as a mixture over an underlying set of terms (Blei et al., 2003). Follow-up efforts to extend content-level LDA modelling have been investigated using different approaches, such as the Author-Conference-Topic (ACT) model (Tang et al., 2008), correlated topic model (CTM) (Blei & Lafferty, 2006), interactive topic modelling (Hu, Boyd-Graber, Satinoff, & Smith, 2014), and supervised Latent Dirichlet Allocation (sLDA) (Mcauliffe & Blei, 2008). Most topic modelling studies explored the relationships between documents and topics. However, few studies have employed topic modelling methods to conduct author similarity comparison. The present study explores how topic modelling-based author relatedness assessment may complement existing methods based on citation and collaboration-based measures.

Method

Data collection

Elsevier, Inc. has provided a dataset consisting of selected data for 56,620 bibliographic records from 118 Elsevier Arts & Humanities journals. Initially, the authors explored the use of all the data, representing many disciplines within the humanities and social sciences. Outcomes using the author topic modelling approach outlined below resulted in inclusive topical assignments, likely due to the broad vocabulary represented that resulted in topical assignments that combined terms from different disciplines. The subset of the data assigned with Scopus subject classification code 3200, corresponding to "Psychology (all)", was used in this study. The Psychology subset represented the most frequent field appearing in the dataset.

The Psychology subset includes bibliographic records of 26,228 publications written by 63,695 different authors. The authors were identified using the *author_id* field included with the data. An Author-Topic LDA model (Rosen-Zvi et al., 2010) was trained on the title and abstract fields of the psychology subset. The number of topics (k) was set to 100 for exploratory purposes. Other parameters of the model were set as follows: alpha equals 0.5 ($50/k$), beta equals 0.01 and the number of iterations is 1000. All terms were normalized to lower case before processing. A standard list of English stop words were removed and Porter stemming was applied when processing the text. The descriptive statistics of the psychology subset are provided in Table 1. The document length is measured by the number of word tokens in the title and abstract after removing stop words (i.e. common words that were excluded). During the process, we found some authors were listed multiple times in an article because of their multiple affiliations. This was counted as one occurrence in the study.

Table 1. Descriptive statistics of the psychology subset (title and abstract fields).

Measure	*Frequency/Value*
# of documents	26,228
# of unique authors	63,695
Avg. document length	176.98
Title terms	349,410
Abstract terms	4,292,509

Author topical similarity measure

The author topical similarity measure is adopted from the topic-based author relatedness measure proposed by Lu and Wolfram (2012). The measure uses the cosine similarity between Author-Topic vectors from the training results of the Author-Topic modelling as the topical similarity between authors. Given the topic features of the Author-Topic modelling,

the author topical similarity measure is able to identify topical similarity even when the terms do not match. As is the case in any other probabilistic model, the Author-Topic modelling does not work well for authors with a limited number of publications. To ensure the quality of the topical similarity measure, we focused on authors with at least 10 publications in the Psychology subset. Higher cutoff values for the number of papers resulted in smaller numbers of authors for comparison. The cutoff of 10 papers resulted in 125 authors and 7750 author pairs. Table 2 provides descriptive statistics of the author topical similarities between the 125 prolific authors in the psychology subset.

Table 2. Descriptive statistics of the author topical similarity values (author publication count ≥ 10).

Measure	*Value*
# of author pairs	7,750
Mean	0.108
Standard deviation	0.166
Minimum	0.003
Maximum	0.997
Median	0.049

The similarity measures for the 7,750 author pairs were mapped using UCINET 6.0/NetDraw 2.1 network analysis software (https://sites.google.com/site/ucinetsoftware/home; Borgatti, Everett, & Freeman, 2002) and compared to a co-authorship map for the same authors using the data from the Elsevier Psychology dataset. The software allows the strength of ties between nodes to be represented by line thickness. Because each author topical similarity pair had essentially a non-zero similarity, the mapping of all possible author pairs resulted in an incomprehensible map filled with edges. Another advantageous feature of the software is that the display of edges may be controlled using a cutoff value. To allow the stronger relationships to be represented on the map, a similarity cutoff value of 0.5 was selected. The use of a cutoff value did not remove any data in the similarity calculation. It affected only the display of edges between author pairs by removing the edges for author similarity values below the cutoff value. Other cutoff values could have also been selected based on the strength of similarity sought. The 0.5 cutoff value resulted in 10 of the 125 authors not being included in the generated map. A co-authorship map of the Psychology authors was also generated from the Elsevier data and served as a comparison for similarity using a more commonly used measure of author similarity. There were far fewer co-authorship pairs generated from the dataset resulting in a much larger number of authors being excluded from the map because there were no collaborations present in the dataset to be represented in the map. Also, because the 0.5 cutoff value excluded 10 of the 125 authors, the same 115 authors were included in the co-authorship map. The map for the author topical similarity pairings and co-authorship relationships were compared visually for common groupings and differences.

Sampling and other data collection

To explore how the author topical similarity measure compares to other measures of similarity, a stratified random sample of 30 author pairs that spans the full range of author similarity measures was compared. Three pairs of authors were selected from each 0.1 similarity level stratum. The author topical similarity measure for each of these author pairs was compared to more commonly used similarity assessment measures including co-authorship, co-citation and mutual citations by the author pairs. The Elsevier dataset did not provide citation data and the authors did not have access to Elsevier Scopus. Citations between each author and co-citations were collected manually using Thomson Reuters Web of Science (WoS). Co-authorship data from WoS was also

incorporated because it included possible additional co-authored publications beyond those included in the Elsevier dataset. Nonparametric correlation outcomes were calculated for each measure due to the skewed distribution of the data.

Results

A histogram of the distribution of calculated author topical similarity values appears in Figure 1. Note that a logarithmic scale is used due to the large number of low similarity values. Approximately 25.7% of the similarity values exceed 0.1, and only 4.4% are above 0.5, indicating that high similarity measures may provide good discriminative capacity in distinguishing between author pairs with high and low levels of relatedness.

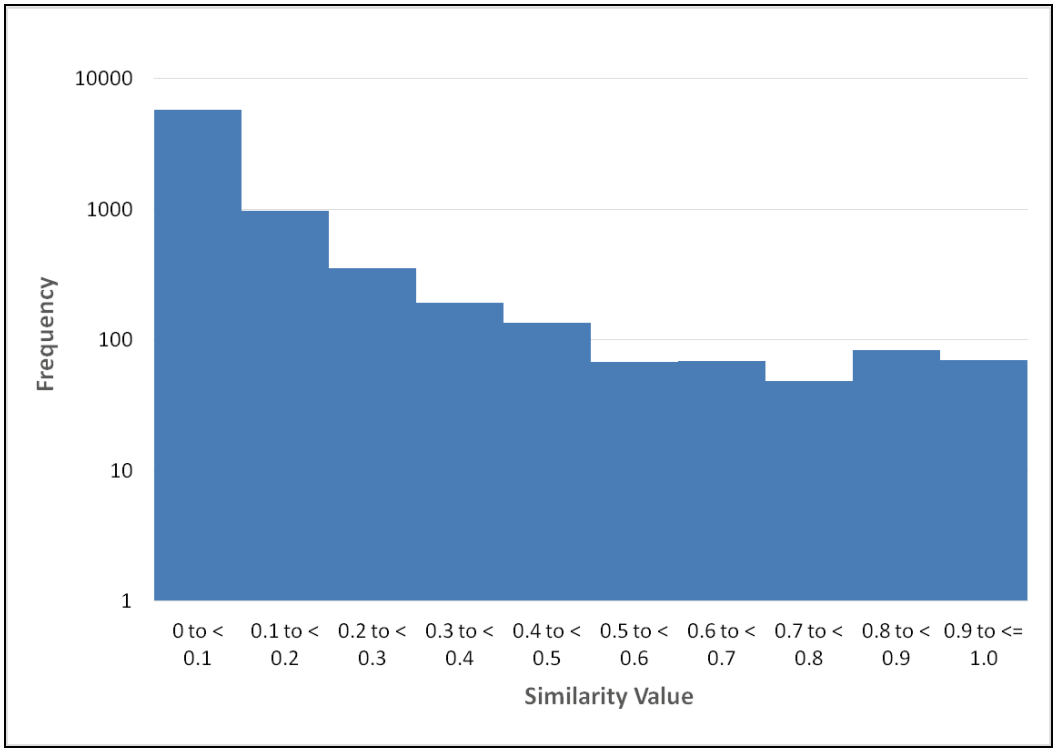

Figure 1. Histogram of calculated author topical similarity values

The UCINET map of the author topical similarity pairings with a 0.5 cutoff value appears in Figure 2. The node sizes and colours highlight comparable numbers of edges where the author similarity values are greater than 0.5. One can see that distinctive clusters of author groups are formed, with two relatively large clusters, a third mid-sized cluster and three smaller clusters with several authors. The large cluster on the right side of the map reveals an author, "Leino-Kilpi H.", who topically serves as a bridge between two parts of the cluster. The topical connection of this author to others in the cluster is missing in the co-authorship maps below due to a lack of collaboration evident in the dataset. The largest node with the greatest number of edges, "Keser H." near the centre of the large cluster to the left, indicates a high level of similarity with a large number of surrounding authors, which is also reflected in Figure 4 below.

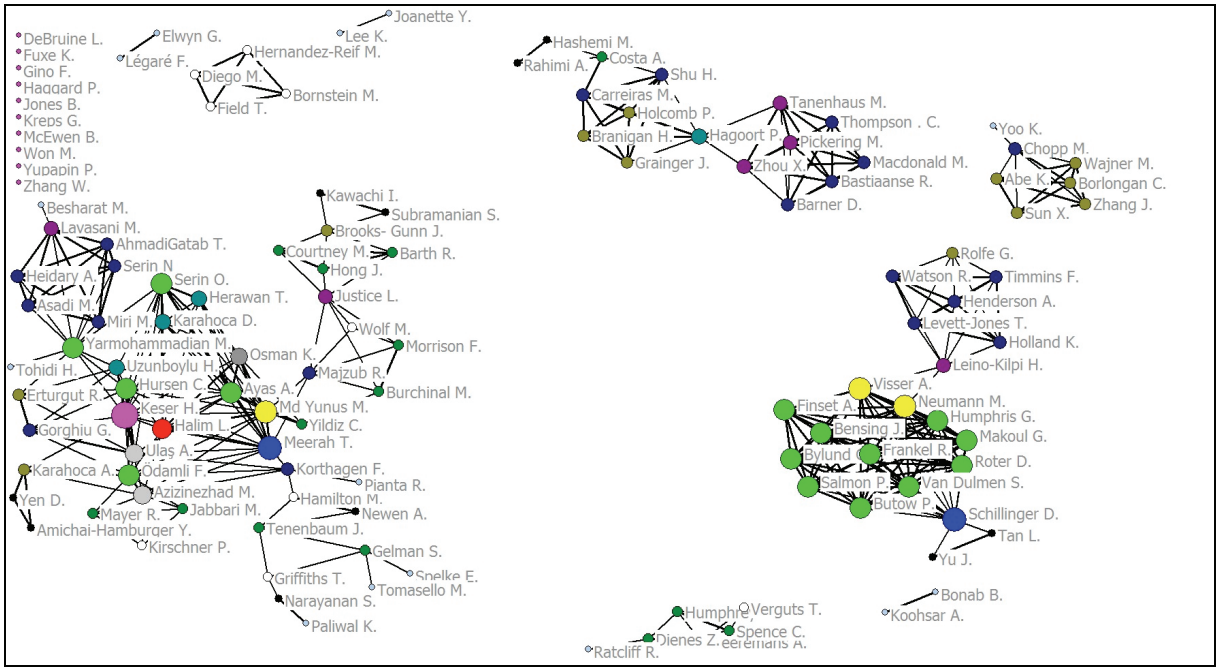

Figure 2. Author topical similarity map (similarity cutoff = 0.5).

Figure 3 summarizes the author collaboration map for the Psychology authors. One can immediately see one drawback of using co-authorship only to assess author relatedness. Fifty-six of the 125 authors were excluded because they did not collaborate with any of the other authors in the dataset. Those connections that do exist are much more limited than for the author topicality similarity outcomes, with two larger clusters and many smaller groups of two to six authors. The members of the two largest clusters in Figure 3 are almost identical to the two largest clusters in Figure 2, but represent only a fraction of the authors that appear in the Figure 2 clusters. Only three of the 10 authors excluded in Figure 2 are included in Figure 3, indicating that these three authors had no topical similarity values above 0.5 with the other authors.

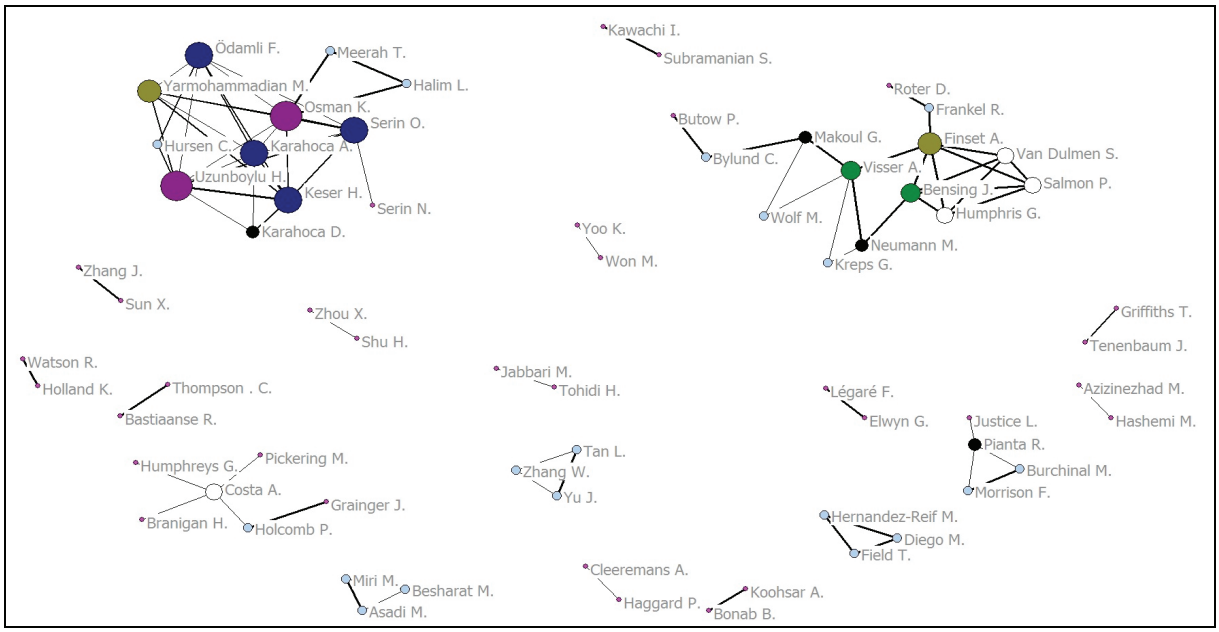

Figure 3. Co-authorship map for all author pairs

The map in Figure 2 shows relationships only for authors with a topical similarity of greater than 0.5. Figure 3 does not take into account the topical similarity of authors. Figure 4

provides the co-authorship map that includes only author pairs with a topical similarity of greater than 0.5. This eliminates a further 21 authors (77 total) from inclusion on the map. It is essentially the same map as Figure 3 flipped along the horizontal axis and, but with fewer edges arising from the removal of the additional authors.

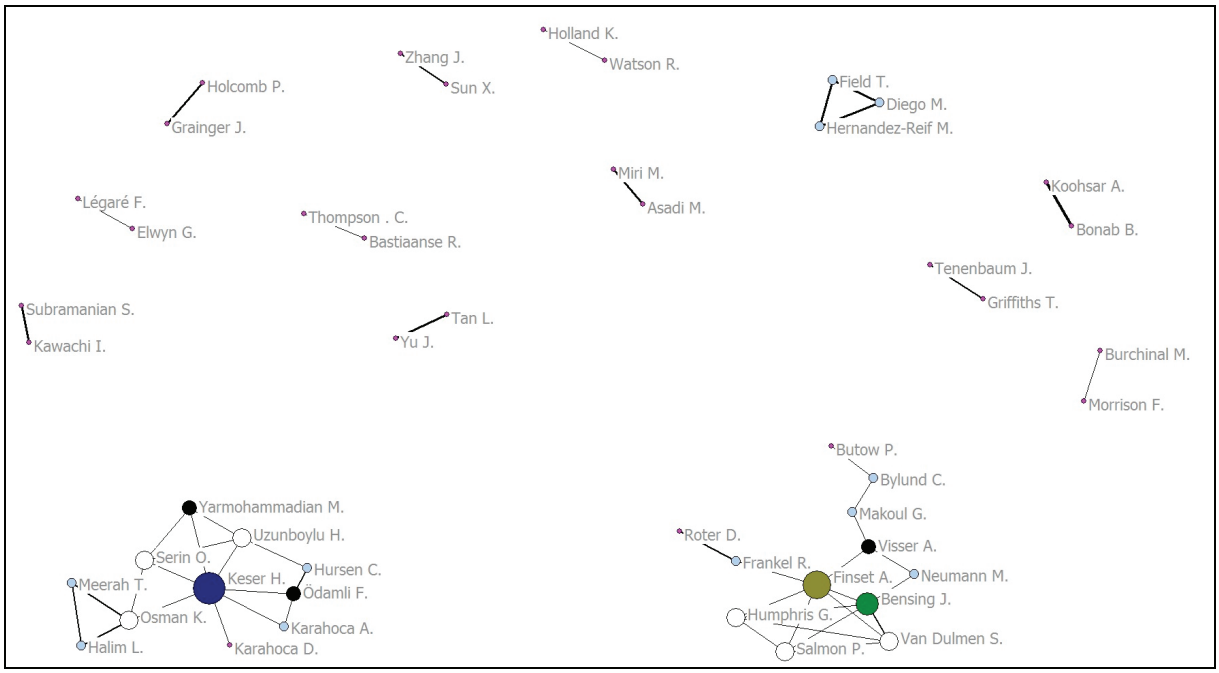

Figure 4. Co-authorship map for author pairs (Author topical similarity cutoff of 0.5)

To examine how the author topical similarity measure correlates to other author relatedness measures, 30 pairs of authors were randomly selected as described above. Outcomes for the author topical similarity, co-authorship, mutual author citing and co-citation values were compared using Spearman's rho nonparametric correlation coefficients (Table 3). There are significant, mid-level correlations observed between the author topical similarity measure and co-authorship for both the Elsevier and WoS data, as well as the mutual citing data for each author. However, there is not a significant correlation with the co-citation counts from WoS. Due to the lack of co-authorship observed for the selected author pairs for author topical similarity values below 0.5, the correlations were also run and included in Table 3 using the 15 similarity values above 0.5 (High) and the 15 values below 0.5 (Low). The positive correlations remained for high similarity author pairs but were not significant for low similarity author pairs.

Discussion

Outcomes of the author topical similarity measure provide a richer method by which author relationships may be mapped and assessed. Unlike co-authorship, direct citation and co-citation networks, where a linkage is created only through collaboration or citation behaviours. The lack of collaboration or citation does not indicate that there is no relationship between two authors; it may simply indicate that the research community has not yet recognized such a relationship. This is most evident when comparing the resulting edges based on author topical similarity and co-authorship. Even when limited to author topical similarity values of greater than 0.5, representing only 4.4% of all possible network connections, the resulting network is rich and demonstrates clusters of author relationships. The richness of the linkages in the resulting network may also be controlled by setting different cutoff values for the author topical similarity. The co-authorship map, conversely, is much sparser and only reveals explicit relationships. The relatively high correlation measure

implies that the author topical similarity measure may serve as a good predictor of existing collaboration. This is more evident for authors with higher topical similarities. Although one would expect there to be a high correlation between collaborating authors, in the Author-Topic model each word is generated from each author according to the author's profile, modelled as a distribution of topics. So, even though collaborating authors tend to be more similar, they may still be generating different words in the titles and abstracts. Excluding co-authored papers in these cases for topic modelling may be attempted, but this could result in less reliable outcomes if the majority of the text on which the models are based is removed.

Table 3. Spearman's rho correlation outcomes for author relatedness measures

		Author Topical Similarity	*Co-authorship Elsevier*	*Co-authorship WoS*	*A Cites B WoS*	*B Cites A WoS*	*Co-citation WoS*
Author Topical Similarity	All	1	.568**	.660**	.452*	.445*	.255

	High						1
	Low						1

** Correlation is significant at the 0.01 level (2-tailed).

* Correlation is significant at the 0.05 level (2-tailed).

In the absence of existing collaborations, high author similarity values could serve as an indicator for possible future collaborations. We recognize that the motivations for collaboration are complex and go beyond authors having similar interests. Collaboration may also be prompted by the complementary areas of expertise collaborators bring, which would not be reflected using topic modelling techniques alone. Still, the similarity measure may be used to identify research "birds of a feather" that may not be evident using similarity measures based on collaboration or citation data.

In answer to the research questions posed at the beginning of this paper: 1) mapping of author relatedness based on author topical similarity can reveal a richer network of relationships between authors not evident through a more traditional relationship assessment based on co-authorship and can identify topical bridges; 2) co-authorship, co-citation and mutual citation between authors are significantly correlated, in particular for authors with high topical similarity, so authors with similar topical interests may be more likely to collaborate or cite each other; 3) high author topical similarity values can serve as a reasonably accurate predictor of co-authorship and mutual citation, but not of co-citation activity. The lack of a significant correlation between author topical similarity and co-citation provides evidence that

the topical similarity measure offers a different perspective on author relationships that complements the more traditional co-citation approach. The significant correlations observed between the author topicality similarity and other citation and co-authorship measures indicate that topicality may be a weak to moderately strong predictor of these other more traditional measures for authors with high topical similarity. This positive correlation between author topicality and co-authorship is not unexpected given that co-authored publications would result in more similar topical assignments.

The findings of this study have implications for author relatedness assessment. As the author topical similarity measure does not depend on collaboration or citation behaviour, it can serve as an alternative author relatedness measure where there is a lack of collaboration or citation connections. Even if the collaboration and citation connections exist, the topical similarity measure can provide complementary evidence of relatedness from the content perspective. In addition, the significant correlations between author topical similarity and collaboration shed light on recent developments in predicting and recommending collaborations. Most existing methods for predicting and recommending collaborations are based on the topological features of collaboration networks (Yan & Guns, 2014). The level of correlations between topical similarity and collaboration, particularly for authors with high similarity, provide strong evidence of including content-based predictors for this problem.

Topic modelling offers the ability to reveal relationships between authors that may not be evident through more traditional methods of similarity assessment, but it does have its limitations. The computational overhead associated with topic-based author relatedness modelling is more substantial than for citation and collaboration-based data. Also there must be a sufficient body of text to train the topic model and to accurately represent author relationships; therefore, this method may not be suitable for authors with a more modest publication record. In this case, analysis using citation-based methods may be more fruitful. Other limitations arise from the dataset itself. In identifying works attributable to an author, we have relied on the supplied Scopus author identifier. We recognize that author name disambiguation, regardless of the method used, may not be 100% accurate. In addition, the present study has limited itself to data from a single discipline. Furthermore, the dataset itself was not complete for the discipline of Psychology, but rather a subset. We cannot conclude that the outcomes for other disciplines will be similar. Outcomes would depend also on the collaboration traditions and citing behaviours of those disciplines. The computational overhead and limited ability for topic modelling to be able to produce meaningful topics with multidisciplinary datasets may limit the application of this approach beyond the disciplinary level.

Conclusions

Author topical similarity provides a novel way to assess author relatedness that complements existing methods based on co-authorship, direct citation or co-citation. While other methods require an existing form of connection based on collaboration or citations, author topical similarity assesses author relatedness based on the language used by the authors themselves. The small percentage of author pairs with high similarity values indicates that the measure is discriminating in the assessment of author relatedness. The present study has demonstrated how author relatedness based on topic modelling can provide a richer method to assess how closely related authors' research contributions are. Although significantly correlated with co-authorship and direct citation measures, author topical similarity between authors was not found to be significantly correlated with co-citations, which has been commonly used to assess author relatedness. Author topical similarity outcomes may serve as a reasonably accurate predictor of existing collaborations between authors, or an indicator of potential future collaborators in the absence of existing collaboration. Future research may investigate

how author topical similarity measures compare to other existing author relatedness measures for other disciplinary areas including the humanities and sciences, where collaboration and citation patterns may differ.

Acknowledgments

The authors would like to thank Elsevier, Inc. for providing access to the dataset used to conduct this study.

Abstract
Bibliometricians are aware that the citation behavior of scientists varies across fields, and for this they carefully normalize citations by field. They are also aware of the different publication intensities across fields. This imposes that the research performance of a scientist must be compared with that of their colleagues in the same field. Every comparison of scientists in different fields should be preceded by the normalization of the performances, and the same holds for comparing multidisciplinary organizational units. If the Web of Science recognizes 251 subject categories, there should be a somewhat similar number of research fields for the classification of the scientists. The Italian academic system is quite unique in providing a classification of professors, into 370 fields, 192 of them in the hard sciences. In this work we measure the descriptive statistics on annual publication (full and fractional counting) by Italian academics in each of the 192 hard science fields. These statistics help recognize the extent of distortion from failing to normalize the research performance of scientists based in different fields. They could also serve as scaling factors for avoiding distortion in rankings, including in other nations.

Conference Topic
Methods and techniques

Introduction
The purpose of bibliometrics is to provide continuously better support for the policy-makers and administrators of research institutions, in the achievement of their specific objectives, through the provision of methods and indicators for the evaluation of performance that are themselves always more accurate, robust, reliable and functional. The principle obstacle to bibliometrics is the insufficiency of the data to meet such high standards. The practitioner is thus forced to resort to proxies in measurement, which cause varying degrees of distortion in the results.

Research organizations are likened to other productive organizations, but where the product is new knowledge, rather than some other good or service. An organization's performance is then better than that of another one if, at parity of resources, it produces more knowledge or if, at parity of output, it consumes less resources. It is the shortage of information on inputs (production factors) that presents the greatest problem to bibliometricians. The production factors are labor and capital. Capital embeds all those resources other than labor (facilities, technical instruments, materials, databases, etc.). When we wish to measure labor productivity we must thus normalize for capital. But who can really know the financial and technical resources available to all the different institutions, departments, and then individual researchers? The bibliometrician also frequently lacks information on the realities of labor, due to the absence of databases on the researchers, and on their institutional, discipline and field affiliations.

Given these obstacles, practitioners often use indicators that do not relate output to input. This means they produce ranking lists that are highly size-dependent. At that point we cannot

know what part of an organization's or nation's rank arises from its performance or is due to size. Examples of this are the CWTS Leiden[1] and SCImago[2] lists, which rank universities by publications and fractional publications. Others have proposed indicators that attempt to get around the problems by relating the impact or excellence of research not to input, but rather to the output itself. Examples of this are the "new crown indicator" (Waltman et al., 2011), which measures the average impact per publication, or the "proportion of highly-cited articles to total publications" (Waltman et al., 2012). However, with this type of indicator, even when the output of the scientist increases, other factors remaining equal, his or her performance could still decrease: a paradox and a violation of the fundamental principle of the measure of efficiency.

In those cases where an indicator does relate output to input, it is still often applied at levels of organizational aggregation that are too high, ignoring the differing intensity of publication across fields. Bibliometricians have been aware of this problem for many years (Butler, 2007; Moed et al., 1985; Garfield, 1979), and are also aware of the distortion that afflicts the resulting aggregate rankings (Abramo, D'Angelo, & Di Costa, 2008). However the task of finer aggregation is difficult to solve without a database that classifies the researchers by field of research. Where they exist, such databases are maintained at central levels. Apart from the Italian one[3], maintained by the Italian Ministry of Education, Universities and Research (MIUR), the only other large-scale one we are aware of is the Norwegian Research Personnel Register[4] compiled by the Nordic Institute for Studies in Innovation, Research and Education (NIFU).

The NIFU system classifies scientists in 58 scientific fields grouped in five main domains. Perhaps the lower number of scientists in Norway works against finer classification: in fact comparing the performance of small numbers of researchers per field creates serious problems of significance. However, on the other hand, the Web of Science (WoS) identifies a full 251 subject categories for the classification of journals. And if there are this many fields for classifying scientific journals, there must be at least that many fields for classifying scientific work, and the scientists. In smaller nations or emerging economies we could expect to see fewer number of these fields present, since research structures will be unable to deal with all the areas, and we would expect to see research in more concentrated fields. However, in larger, developed countries we can expect to see the full spectrum of research fields. In fact in Italy the MIUR manages a system for the classification of all professors into a total of 370 "scientific disciplinary sectors" (SDSs).[5] Each professor belongs to one and only one of the SDSs, which are grouped into 14 university disciplinary areas (UDAs). Further, 192 of the SDSs from 9 of the UDAs fall in the so-called hard sciences. In the following we refer to these SDS by their code or acronym.[6] These 192 SDSs compare to the 176 WoS subject categories identified in the JCR-Science Citation Index (see the Annex 1[7] for a conversion of SDSs to WoS subject categories.

As noted above, the lack of field classification of scientists means that measures of research performance will inevitably be affected by distortions in rankings, due to the different intensity of publication across fields. The higher the level of aggregation, the stronger these distortions become. The corollary is that, rising to international levels, it has been impossible

to correctly compare institutional or national research performance.

To date, in fact there is no international standard for the classification of scientists. Thus in this work we provide our colleagues and practitioners with descriptive statistics on yearly publications (both full and fractional counting) of Italian academics in each of the 192 hard science SDSs. Our intention is that these statistics might first permit recognition of the extent of distortions that occur when evaluations compare the research performance of scientists within the same discipline, but in different fields. For those nations lacking databases of researchers by field, our statistics could also serve as normalization factors, serving to reduce the distortions when comparing research performance of individuals, groups or entire research organizations.

Data and Methods

In the study we measure "publication rates" in 192 SDSs, meaning average yearly publications of individual scientists, over the period 2009-2013.[8] Data on Italian academics are extracted from the official database maintained by the MIUR. The database indexes the name, academic rank, affiliation, and SDS of all academics in Italian universities. At 31/12/2013 the entire Italian university population consisted of 56,600 professors employed in 96 universities, which are authorized by the MIUR to grant legally recognized degrees. It has been shown (Moed, 2005) that in the so-called hard sciences, the prevalent form of codification for research output is publication in scientific journals. For reasons of robustness, we thus examine only the nine UDAs that deal with the hard sciences,[9] including a total of 192 SDSs. Furthermore, again for reasons of robustness, we calculate the yearly average publication rates only of those professors who have been on staff for at least three years over the observed period.

Table 1. Dataset for the analysis: number of fields (SDSs), universities, research staff and WoS publications in each UDA under investigation

UDA	SDS	Universities	Research staff	Publications*
Mathematics and computer science	10	72	2,930	16,262
Physics	8	65	2,003	22,597
Chemistry	12	60	2,701	26,054
Earth sciences	12	49	974	6,066
Biology	19	67	4,423	34,406
Medicine	50	65	8,998	72,661
Agricultural and veterinary sciences	30	56	2,820	14,951
Civil engineering	9	54	1,394	7,462
Industrial and information engineering	42	73	4,791	40,572
Total	192	86	31,034	207,132†

* Figures refer to publications authored by at least one professor pertaining to the UDA.

† Total is less than the sum of the column data due to double counts of publications co-authored by researchers pertaining to SDSs of more than one UDA.

Publication data are drawn from the Italian Observatory of Public Research (ORP), a database developed and maintained by the authors and derived under license from the WoS. Beginning from the raw data of Italian publications[10] indexed in WoS-ORP, we apply a complex

[8] For the most appropriate publication period to be observed see Abramo et al. (2012b).

[9] Mathematics and computer sciences; Physics; Chemistry; Earth sciences; Biology; Medicine; Agricultural and veterinary sciences; Civil engineering; Industrial and information engineering.

[10] We exclude those document types that cannot be strictly considered as true research products, such as editorial material, meeting abstracts, replies to letters, etc.

algorithm for disambiguation of the true identity of the authors and their institutional affiliations (for details see D'Angelo et al., 2011). Each publication is attributed to the university professors that authored it, with a harmonic average of precision and recall (F-measure) equal to 96 (error of 4%). We further reduce this error by manual disambiguation. Because each professor belongs to one and only one SDS, we can then calculate the distribution of annual publication rates and the relevant descriptive statistics in each SDS.

The dataset for the analysis includes 31,034 professors, employed in 86 universities, authoring over 200,000 WoS publications, sorted in the UDAs as shown in Table 1.

Research projects frequently involve a team of researchers, a fact revealed in the co-authorship of publications. Various performance measures account for the fractional contributions of single co-authors to outputs. The contributions of the individual co-authors to the achievement of the publication are not necessarily equal, and in some fields the authors signal the different contributions through the ordering of the byline. The conventions on the order of authors for scientific papers differ across fields (Pontille, 2004; RIN, 2009), thus in the current study, the fractional contribution of the individuals is weighted accordingly.

Fractional contribution equals the inverse of the number of authors, in those fields where the practice is to place the authors in simple alphabetical order but assumes different weights in other cases, particularly in the life sciences. For these disciplines, we give different weights to each co-author according to their order in the byline and the character of the co-authorship (intra-mural or extra-mural). If first and last authors belong to the same university, 40% of citations are attributed to each of them; the remaining 20% are divided among all other authors. If the first two and last two authors belong to different universities, 30% of citations are attributed to first and last authors; 15% of citations are attributed to second and last author but one; the remaining 10% are divided among all others.[11] Failure to account for the number and position of authors in the byline would result in notable ranking differences, both at the individual level (Abramo, D'Angelo & Rosati, 2013a) and at the institution level (Abramo, D'Angelo & Rosati, 2013b).

Applying the above conventions, for each of the 192 SDS we will provide descriptive statistics on the intensity of annual publication: referred to as P for full counting and FP for fractional counting. We then examine further statistics on P and FP for the SDSs included in each UDA.

Results

Publication rates of professors in a specific field

The publication intensity of professors in a given field is known to be particularly skewed, with a small percentage of individuals authoring a large share of the total papers, and the others authoring a small share (Egghe, 2005; Kyvik, 1989; Lotka, 1926). Figure 1 provides the example of the field of Organic chemistry (SDS CHIM/06), showing the distribution of the average number of publications per year over the period under examination, for each of the 554 professors in the SDS. The distribution fits quite well a logarithmic curve, as indicated by the particularly high value of R^2 (0.974). Here, 10% of the professors have produced on average less than one publication per year, and six were totally unproductive. On the opposite front, we find 20 professors with over 10 publications per year, and one absolute outlier with 25.

The box plot (right side of Figure 1) refers to the same distribution. It shows a median of 3 publications per year and an interquartile range (difference between third and first quartile) of

[11] The weighting values were assigned following advice from senior Italian professors in the life sciences. The values could be changed to suit different practices in other national contexts.

2.6. It also brings out the presence of 30 outliers: hyper-productive professors with a performance that exceeds that of the third quartile by over 1.5 times the interquartile difference.

The distribution of frequencies by class of publication rates (Figure 2) shows a mode between 2 and 3 publications annually and a particularly long right tail, with a final peak for the hyper-productive professors.

The distribution of the average yearly publications measured by fractional counting (FP) shows a very similar situation: in Figure 3 the right tail is actually longer than that for only full counting (Figure 2).

The distributions seen for SDS CHIM/06 show structural elements that recur in the analyses of the other 191 SDSs. Most obvious is the skewness, although there are some interesting exceptions, for example as in VET/04 (Inspection of food products of animal origin). The 77 professors of this SDS have a publication rate that is almost uniform, as illustrated in Figure 4.

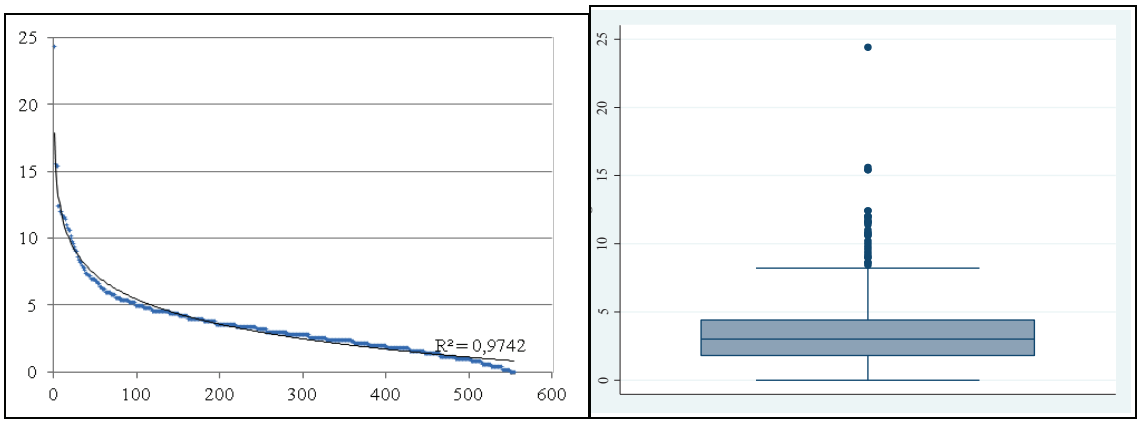

Figure 1. Distribution and box plot of annual publication rate P (full counting, 2009-2013) for 554 Italian professors in Organic chemistry (CHIM/06).

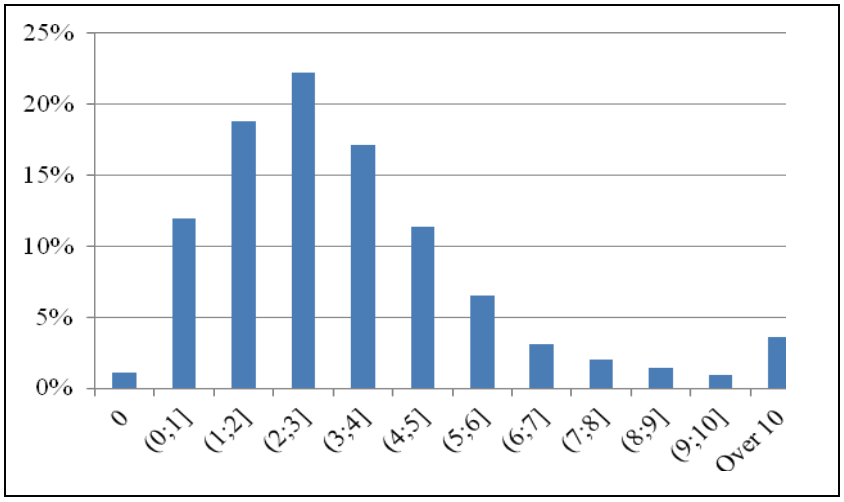

Figure 2. Frequency distribution for classes of annual publication rate P (2009-2013) for the 554 Italian professors in CHIM/06.

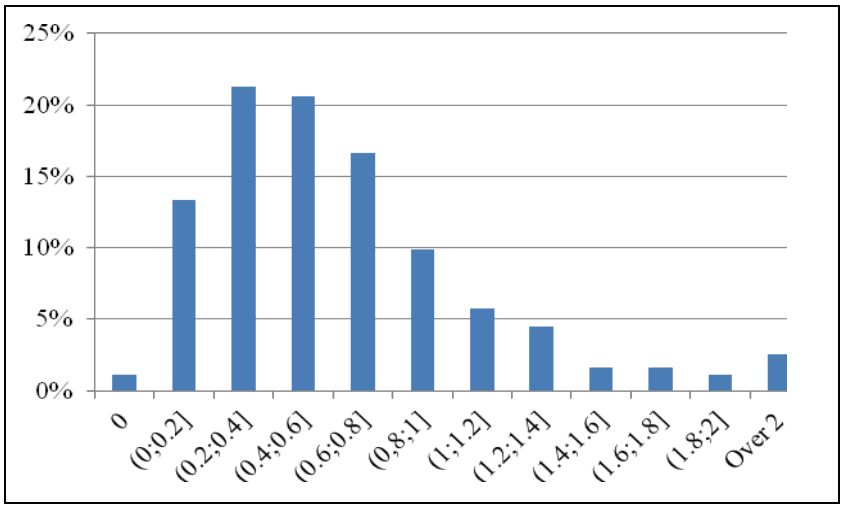

Figure 3. Frequency distribution for classes of annual publication rate FP (fractional counting, 2009-2013) for the 554 Italian professors in CHIM/06.

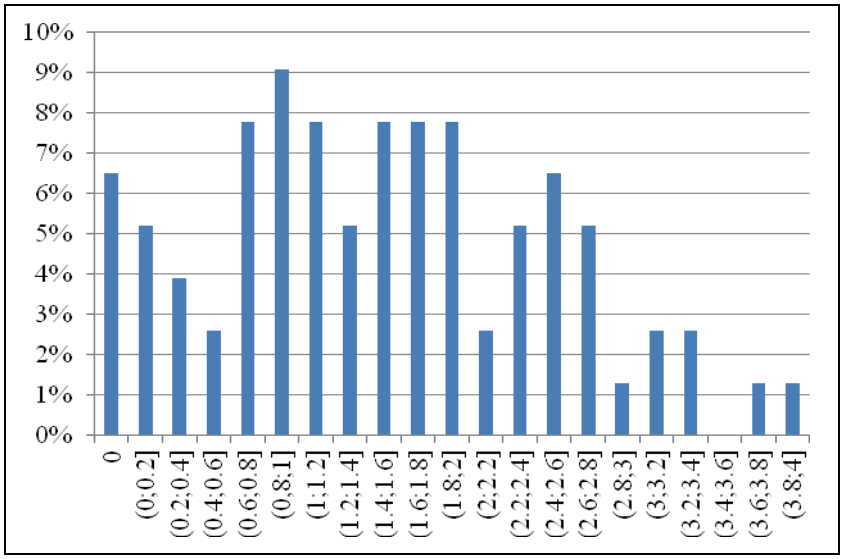

Figure 4. Frequency distribution for classes of annual publication rate P (2009-2013) for Italian professors in Inspection of food products of animal origin (VET/04).

Publication rates of fields within a discipline

As with the two examples above (CHIM/06 and VET/04), the publication rates in the various SDSs are never superimposable. Thus the calculation of the descriptive statistics for the SDSs provides useful benchmarks for the professors that work in them. Table 2 provides the statistics for all the SDSs in the Earth sciences discipline.

This UDA consists of a total of 12 SDSs with very different sizes in terms of national research staff, from a minimum of 17 professors in Applied geophysics (GEO/12) to a maximum of 137, in Palaeontology and palaeoecology (GEO/02). The intensity of publication is structurally very different. In Stratigraphic and sedimentological geology (GEO/03) only 2.2% of the professors (2 of 92) did not produce any publications over the five-year period under examination. On the opposite front there are 19 unproductive professors among the 121 of Physical geography and geomorphology (GEO/05), or 15.7% of the total. This SDS also registers the lowest average annual rate of publication, at 1.12 per year, followed by Structural geology (GEO/04), GEO/02 and Geophysics of solid earth GEO/11 (1.44, 1.48 and 1.49, respectively). In half the SDSs there is an average intensity of publication of 2 per year,

with a peak in Applied geology GEO/06 (3.09). Clearly, among all those of the UDA, this SDS has the greatest publication rate: the distribution of the performances shows all values in the highest quartiles. The top 25% of professors (3rd quartile) produce on average more than 4 publications per year, with the absolute record being a professor who produces almost 18. The dispersion of the performances in all the SDSs, indicated by the variation coefficients in the last column of Table 2, results as greatest in GEO/03 and GEO/05, where the coefficient is above 1.

The analyses of the distributions for fractional counting of the publication rate (FP) (Table 3) provide a picture similar to that for full counting. The average intensity of collaboration evidently does not vary in a substantial way between the SDSs, and thus the differential of publication rates between the SDSs does not vary in going from a full counting approach to fractional counting.

Table 2. Descriptive statistics for intensity of annual publication rate P (2009-2013) for the SDSs of Earth sciences.

SDS	Research staff	Unproductive	I quartile	Median	III quartile	Max	Average	Std dev.	Variat. coeff.
GEO/01	93	3.2%	0.8	1.6	2.2	8	1.76	1.40	0.80
GEO/02	137	7.3%	0.6	1	2.20	6.4	1.48	1.25	0.84
GEO/03	92	2.2%	1	1.8	2.8	22	2.40	2.69	1.12
GEO/04	116	6.9%	0.6	1	2	4.8	1.44	1.21	0.84
GEO/05	121	15.7%	0.2	0.8	1.4	8.2	1.12	1.22	1.09
GEO/06	76	1.3%	1.55	2.6	4.05	17.8	3.09	2.51	0.81
GEO/07	82	2.4%	1	1.8	2.75	8.2	1.99	1.46	0.73
GEO/08	67	3.0%	1.3	2.4	3.5	10.6	2.69	2.03	0.75
GEO/09	63	6.3%	0.8	1.8	2.9	11.4	2.21	2.04	0.92

GEO/12	0.19	0.32	0.60	0.90	0.38	0.28	0.74

For the descriptive statistics of the full 192 SDSs investigated, we refer the reader to Annex 2[12] for the full counting, and to Annex 3[13] for fractional counting. Below, in Table 4, we show for each UDA the SDSs with minimum and maximum values of some of the above statistics

[12] www.iasi.cnr.it/laboratoriortt/TESTI/Altro/ISSI-ANNEX%202_P.pdf, last accessed on April 8, 2015
[13] www.iasi.cnr.it/laboratoriortt/TESTI/Altro/ISSI-ANNEX%203_FP.pdf, last accessed on April 8, 2015

of P (full counting). The data indicate substantial variability in the intensity of publication between the SDSs in all the UDAs. In Mathematics the percentage of unproductive professors varies from a minimum of 3.9% in MAT/09 (Operations research) and a maximum of 43.2% in MAT/04 (Complementary mathematics). Such substantial variations also occur in Medicine, with 1.1% unproductive professors in MED/08 (Pathological anatomy) and 45.5% in MED/02 (History of medicine). In Agricultural and veterinary sciences, VET/02 (Veterinary physiology) does not have any unproductive professors, while AGR/01 (Rural economics and valuation) registers a share of 45.5%. More contained heterogeneity in unproductive professors is seen in some other UDAs: certainly in Earth sciences, which we have already examined, but also in Biology. In this UDA the maximum incidence of unproductive professors (11.8% of the total professors) is seen in BIO/08 (Anthropology) and the minimum (1.2%) in BIO/15 (Pharmaceutical biology). The median intensity of annual publication also presents high variability between the SDSs of a UDA. In Mathematics the median ranges from 0.2 publications per year in MAT/04 (Complementary mathematics) to 1.8 in MAT/09 (Operations research). In effect the interval of variation of the median values is very substantial in almost all the UDAs. Within Industrial and information engineering, the median intensity of publication registered in ING-INF/06 (Electronic and information bioengineering) and in ING-INF/02 (Electromagnetic fields) is more than 40 times that registered in ING-IND/01 (Naval architecture). In Medicine the two extreme situations concern MED/02 (History of medicine) and MED/16 (Rheumatology): the median intensity of publication registered in the first SDS (0.2) is $1/25^{th}$ of that for the second (5.0). The differences are more contained in Chemistry (2.0 vs. 3.4), Earth sciences (0.8 vs. 2.6) and Biology (1.1 vs. 3.3). The consistency of the outliers is also significantly different between the SDSs of a given discipline. In the Mathematics UDA, the most productive professor in absolute terms is one in INF/01 (Computer science), with an average of 28.6 publications per year, against the 3.6 of the most productive professor in MAT/04 (Complementary mathematics). In Medicine, a professor in MED/24 (Urology) registers a median of 76 publications per year over the five years examined; the most prolific in MED/47 (Nursing and midwifery) has barely 1.4 publications. In Industrial and information engineering the most prolific professor of ING-IND/01 (Naval architecture) authors an average of 1.4 publications annually, against the 33.2 of the most productive in ING-IND/34 (Industrial bioengineering). Finally, Physics FIS/01 (Experimental physics) includes a professor with an average of over 100 publications per year. In effect, this SDS consists of a range of subfields, including "high energy physics", where scientists regularly author hundreds of publications together with hundreds of co-authors. In this case (but not only in this case) a more opportune benchmark could be the distribution of the publication rate under the fractional counting method. Table 5 shows, for every UDA, the SDS with minimum and maximum values of the main statistics[14] of the fractional counting distributions. We see a level of superimposability with the data of Table 4, both in terms of the SDSs featured and for the intervals of variation in the main statistics of the SDSs, for each UDA.

[14] To avoid pointless duplication, the table does not show the incidence of unproductive professors, and instead provides statistics on average publication rate.

Table 4. SDSs with Min and Max values of descriptive statistics of intensity of annual publication P (2009-2013), for all UDAs.

	Unproductive (%)		Median		Max	
UDA*	Min	Max	Min	Max	Min	Max
1	3.9 (MAT/09)	43.2 (MAT/04)	0.2 (MAT/04)	1.8 (MAT/09)	3.6 (MAT/04)	28.6 (INF/01)
2	2.1 (FIS/04)	37.5 (FIS/08)	0.2 (FIS/08)	5.6 (FIS/01)	4.4 (FIS/08)	102.2 (FIS/01)

Conclusions

The great majority of the bibliometric indicators and the relative rankings lack fine-grained normalization of performance to the field to which the scientists belong. While bibliometricians intelligently field-normalize citations to account for the different citation behaviors across fields, they often close an eye when it comes to accounting for the different intensity of publication. At most they distinguish scientists as belonging to a few large disciplines, which cannot be sufficient if we accept the WoS as a true characterization, where scientific work is distinguished in 251 subject categories. Why would we normalize the citations for these 251 subject categories but then the scientists' performance for only a few disciplines? The answer is simple: in most cases the bibliometricians lack information about the field of research of each scientist under observation. Even at the national level the challenge of identifying the scientist's field is daunting, let alone for the task of international comparison.

Taking advantage of a particular feature of the Italian academic system, in this work we have provided descriptive statistics on the yearly publication rates of all Italian professors (over 30,000) in each of the 192 hard sciences fields, with both full and fractional counting method. Although the dataset refers to a specific nation, the very substantial size and the fine-grained field stratification certainly make it a useful reference system for the comparative evaluation of scientists in all the world. The only condition is that scholars recognize in which field of the Italian system the core of their scientific production falls. To this aim, in the Appendix, we have provided the reader with a conversion table, which establishes a link between SDSs and WoS subject categories, based on incidence of publications authored by Italian academics. Through this link, scientists outside Italy, knowing the distribution of their scientific production in the subject categories, can identify the corresponding SDS and select relevant statistic parameters as benchmark for comparative evaluation of their publication rates.

The statistics from the current analyses very clearly demonstrate the heterogeneity of publication rates even in the fields belonging to a single discipline. They help recognize the extent of distortions that occur when comparing the research performance of scientists from different fields, and could then serve as normalization factors to reduce such distortions when comparing the research performance of individuals, groups, or entire research organizations.

In future extensions of this work we could envisage a longitudinal analysis to assess the trends in publication intensity by field. We also know that publication rates of full, associate and assistant professors are different (Abramo, D'Angelo, & Di Costa, 2011). Gender differences in productivity have been demonstrated as well (Abramo, D'Angelo, & Caprasecca, 2009; Leahey, 2006; Fox, 2005; Pripić, 2002; Long, 1992). Because the composition of research staff by academic rank and gender varies across fields, a further extension of the analysis may then entail examining the differing publication intensity across fields by academic rank and gender.

Abstract
This paper constructs an Impelling Technology Foresight Model (ITFM) for foreseeing impelling technology in the field of life science, which is a comprehensive model consisting of four class indicators: international scientific environment, evolving of papers and patents, collaboration features of patent assignees' collaboration networks, and impacts. A case study was carried out in the field of life science. Recombinant DNA (RbDNA) and Monoclonal Antibody (mAb) were selected as impelling technologies to carry out the case study. ELISA Diagnosis (ELISA) and Fermentation Technology (FT) were defined as non-impelling technologies to be control group. Results revealed that impelling technologies have higher evolving rates from the stage of growth to maturity. Significant policies or programs usually boost the rapid progress of impelling technologies. Impelling technologies have much higher impact than non-impelling ones. Collaboration behaviour is much more broad and general for impelling technologies. To our knowledge, this is the first study carried out to date to foreseeing impelling technologies at this way.

Conference Topic
Methods and techniques

Introduction
Technology has made enormous contributions to modern society and many future social developments can be realized only through better technical developments and better management (Compton, 1939). Nevertheless, not all technical progress makes substantial contributions to social development. Only a few techniques brought revolutionary change to the human society, such as Transistor Technology and Recombinant DNA technique, which belong to the field of information technology and biotechnology, respectively. Information technology and biotechnology are also regarded as dominant technologies and will essentially impel the social development in the 21st century (Das, 2001).

Thus, it is an attractive topic all the time for scientists from many scientific fields to foresee what kind of technologies can become such impelling technologies, especially in the field of biotechnology. Impelling technology is defined in this paper as technologies that can bolster, lead and push the scientific development and technology progress in given fields, and that can drive the industry fast development and breed emerging industry. Transistor Technology and Recombinant DNA technique are just such technologies. However, people desire to know which technologies can become impelling technologies in the near future, especially for new technologies. For example, synthetic biology, which uses unnatural molecules to reproduce emergent behaviours from natural biology with the goal of creating artificial life (Benner & Sismour, 2005), is recognized as a powerful technique that can produce re-engineered organisms that will change our lives over the coming years, leading to cheaper drugs, green fuel and targeted therapies for diseases. The de novo engineering of genetic circuits, biological modules and synthetic pathways is beginning to address these crucial problems (Khalil & Collins, 2010). If that is true, synthetic biology could be regarded as an impelling technology. However, except for synthetic biology, there are still a large number of techniques emerging in the field of biology. Which can become impelling technology in the near future? Foresight analysis provides the idea of solutions.

Technology foresight, like technology forecasting, is the generation of reasoned statements about the future, the interpretation of such statements in terms of informed action, and the collective learning processes that are involved in responding to challenges of the future (Salo & Cuhls, 2003). Amanatidou (2014) pointed out that the major impacts of foresight belong to knowledge, network creation and promoting public engagement in policy-making. The scope of technology foresight comprises not only technologies and their applications but also public policies and societal challenges (Salo & Cuhls, 2003). UNIDO defined technology foresight as the most upstream element of the technology development process. It provides inputs for the formulation of technology policies and strategies that guide the development of the technological infrastructure. In addition, technology foresight provides support to innovation, and incentives and assistance to enterprises in the domain of technology management and technology transfer, leading to enhanced competitiveness and growth (UNIDO, 2014).

Indeed, similar forms of foresight technology also include technology intelligence, technology forecasting, road mapping and assessment (Firat, 2008). Many of these forms use similar tools and get similar results. Particularly forecasting and foresight are often confused in practice. According to the interpretation from the Technology Futures Analysis Methods Working Group 1 (TFAMWG), all these similar methods could be used in technology futures analysis (TFA). Technology foresight is used to analyse the effecting development strategy, often involving participatory mechanisms. Technology forecasting is to anticipate the direction and pace of changes. But there is a general tendency that forecasting usually focuses on specific technologies. Foresight studies usually bring together people with different expertise and interests, and use instruments and procedures that allow participants to simultaneously adopt a micro view of their own disciplines and a systems view of overriding or shared objectives (Firat, 2008). Some foresight related studies are introduced below and their findings contributed partly to the theoretical and technical basis of this study.

Based on the below related works analysis, we found that although many techniques have been used to answer many kinds of questions, impelling technology foresight works were lacking, especially by the method of model construction. Therefore, this study advanced the existing works by constructing an ITFM model to carry out impelling technology foresight analysis. ITFM model can be used for impelling technology foresight. To our knowledge, none of the existing studies has done such work as ever. The significance of this work is that if an impelling technology could be known before it becomes impelling technology or at the earlier stage of its life cycle, that would be very valuable for many kinds of scientists, policy makers and stakeholders to deal with it.

Related works

The term “Technology Foresight” was introduced by Irvine and Martin and took off in the 1990s as European, and then other countries (Miles, 2010). Until now, a lot of studies have been carried out to do such analysis in recent years, which could be divided into four aspects: function, subject areas of use, features of products and results, and techniques. Related works are discussed below.

Function

The focuses of technology foresight studies have been often motivated by the desire to shape S&T policies and analyse the challenges of education, services, health, and environment, etc. (Salo & Cuhls, 2003). For example, Carlson (2004) discussed the using of technology foresight to create business value. Sanz-Menendez (2001) made technology foresight as a useful tool for policy making. Havas (2010) analysed the impact of foresight on innovation policy-making. Weigand et al. (2014) studied collaborative foresight method to complement long-horizon strategic planning.

Subject areas of use

Based on the fields of science and technology, Linstone (2011) discussed the unique impacts of technology foresight on nanotechnology, biotechnology and materials science. Weinberger, Jorissen and Schippl (2012) carried out a study about technology foresight analysis in the field of environmental technologies with the purpose of supporting the process of identifying and recommending options for the prioritisation of future research funding. Furthermore, foresight has also been used in the field of education studies (Goldbeck & Waters, 2014; King, 2014), drugs discovery (Lintonen et al., 2014).

Features of products and results

From the aspect of products and results of foresight, the works of technology foresight usually have the following products: Strategic advice or guidance, particular technologies or their consequences, price or trends of markets, and production. For example, Cook, Inayatullah and Burgman (2014) concluded that foresight could play a more significant role in environmental decisions by the following ways: monitoring existing problems, highlighting emerging threats, identifying promising new opportunities, testing the resilience of policies, and defining a research agenda. Markus and Mentzer (2014) discussed the future consequences of ICT. Weinberger, Jorissen and Schippl (2012) used foresight methods to support the process of identifying and recommending options for the prioritisation of future research funding among the wide range of environmental technologies available that can contribute to progress in the field of environment.

Techniques

At the angle of techniques used for foresight, many kinds of methods have been used to carry out technology foresight analysis. One typical technique is bibliometric methods. Van Raan (1996) overviewed the potentials and limitations of bibliometric methods for the assessment of strengths and weaknesses in research performance, and for monitoring scientific developments. The study suggested that research performance assessment is based on advanced analysis of publication and citation data. While for monitoring scientific developments, bibliometric mapping techniques are essential. Actually, mapping has been widely used for technology foresight. For example, Yoon, Lee and Lee (2010) developed a keyword-based knowledge map to use to establish a policy to support promising R&D areas and devise a long-term research plan. Another typical method is modelling and system. For instance, Shiue and Lin (2011) developed a foresight MASA model for future technology evaluation in electric vehicle industry, which integrated the concept of vision, linking analysis planning, Markov chain, and Scenario analysis (SA). Chen (2012) proposed a structural variation model for answering what kinds of information may serve as early signs of potentially valuable ideas. Peer review and Delphi have also been used in foresight as in forecasting. For example, Lintonen et al. (2014) had done a drugs foresight analysis in 2020 through the method of Delphi expert panel study. Forster & Gracht (2014) had also assessed Delphi panel composition for strategic foresight based on company-internal and external participants.

Model of Impelling Technology Foresight Model (ITFM)

Definition and Hypothesis

As is stated above, impelling technologies are such technologies that could bolster, lead and push the scientific development and technology progress and drive the existing industry fast develop and bread emerging industry in given fields. However, this definition explains only the functional feature reflecting the results generated by impelling technologies, and lacks the

description of its inherent features, especially the features at the early stage of technology lifetime, which are much more important to foresee whether a technology at the early stage could become impelling technologies. Therefore, the inherent features of impelling technologies especially the features at the early stage could be used as indicators for reflecting impelling technologies. Thus, some hypothesises had been proposed as the theoretical base for constructing an Impelling Technology Foresight Model (ITFM) for foreseeing impelling technologies, particularly in the field of life science.

Hypothesis 1. Viewed by the concept of technology life cycle, technologies' development process can be divided into four stages (Little, 1981) of emerging, growth, maturity and saturation. Impelling technologies grow rapidly to the stage of maturity after short growth stage. Impelling technologies seldom show signs of turning to saturation stage for their competitive impact could remain much longer than non-impelling technologies. In order to evaluate the current stages of a technology, patents have been widespread used to do such analysis. For example, Patent analysis was applied by Zhou et al. (2014) to monitor the developmental stage of a particular New and Emerging Science & Technologies, dye-sensitized solar cells (DSSCs), and traced its potential evolutionary pathways. Some other related works have high impacts include Haupt, Kloyer & Lange (2007), Trappey & Wu (2011), Jarvenpaa, Makinen & Seppanen (2011), etc. This paper uses patent data to disclose the different/given features at the different stages of impelling technologies.

Hypothesis 2. During the development process of an impelling technology, pushing policies or programs usually would like to be attracted to boost the progress of impelling technology. For example, Human Genome Project has been the first major foray of the biological and medical research communities and it boosted the development of an array of new technologies (Collins, Morgan & Patrinos, 2003), among which Recombinant DNA technique have achieved considerable development and have also been generally recognized as an impelling technology in the field of life science.

Hypothesis 3. Impelling technologies have higher level of collaboration, especially in patent assignees' collaboration. A lot of studies have shown that there is a positive correlation between collaboration and better production of science. For instance, Guimerà, et al. (2005) pointed out that collaboration could spur creativity, solving old problems and inspiring fresh thinking. In the field of scientific researches, Whitfield (2008) pointed out that there is a picture of science's increasingly collaborative nature and which determine a team's success. Wuchty, Jones and Uzzi (2007) found that there's something about between-school collaboration that's associated with the production of better science. Kato & Ando (2013) found a positive correlation between their research performance and degree of internationalization.

Hypothesis 4. Impelling technologies have higher level of impacts. Citation-based analysis is the most frequently used method to carry impact analysis. The original use of citation for evaluation is Journal Citation Reports from Thomson Reuters to evaluate journals impact factors. Garfield (1979) pointed out that citation analysis could introduce a useful measure of objectivity into the evaluation process at relatively low financial cost. Numerous approaches have been devised to assess future technological impacts based on patent citation information with the core purpose of identifying the current technologies that will drive technological changes over the coming few years (Lee et al., 2012). There are also some network-based method were used to do technology impact analysis. For example, Ko et al. (2014) presented a combined approach for constructing a technology impact network basing on patent co-classification and identifying the impact and intermediating capability of technology areas from the perspective of a national technology system. This paper uses paper citations to compare the difference of impacts between impelling technologies and non-impelling technologies.

ITFM frame

A few factors from four aspects were introduced to validate the above hypothesis.

Technology life cycle - Evolving of patents and paper were introduced to disclose the evolving features of impelling technologies during the four stages of emerging, growth, maturity and saturation.

International environment - The ITFM model took only policy, plan or program as indicators to reflect the international scientific environment although the related factors are more.

Collaboration - The following network statistics of patent assignees collaboration networks were used to represent the collaboration features of impelling technology.

- Ratio of isolates, which have no collaborators in the assignees collaboration networks G. Counted as n (isolates)/n.
- Ratio of nodes in the largest cluster, counted as n (largest cluster)/n.
- Ratio of clusters compare to nodes, counted as #clusters/n.
- Average degree, let N(i) be the set of assignees collaborating with assignee i. The total number of collaboration assignees with assignee i is the degree of assignee i and is defined as $\eta(i) = |N(i)|$. The average degree of a network G is defined by $\eta(G)=\Sigma_{i \square N}\eta(i)/n$.
- Diameter, which is measured by shortest-path length, has been used to estimate the stage of development through documentation data (Chen, Borner & Fang, 2013, Bettencourt, Kaiser & Kaur, 2009) or patent data (Chen & Fang, 2014). There is a theory that collaboration graph that densify with constant or decreasing diameters. All these studies have showed that collaboration graphs in several scientific and technological fields exhibit initial rapid growth in their diameter, which then tends to stabilize and stay approximately constant at 12~14 (Bettencourt, Kaiser & Kaur, 2009). The assignees collaboration network diameters seem to stabilize at about 12 when a technology come into the stage of maturity (Chen & Fang, 2014).

Note that n is the total number of nodes in the network.

Impact - Two factors of times cited per paper and times cited per patent were used for expressing the technology impacts.

The ITFM frame is listed in Table 1, which is the origin of the following case study.

Table 1. Factors contributing to the ITFM.

Factors		*For validating hypothesis (purpose)*
Technology life cycle	evolving of papers	hypothesis 1
	evolving of patents	
International scientific environment	policy	hypothesis 2
	plan or program	
Collaboration-patent assignees collaboration networks	ratio of isolates	hypothesis 3
	ratio of nodes in the largest cluster	
	ratio of clusters compare to nodes	
	average degree	
	diameter	
Impact	times cited per paper	hypothesis 4
	times cited per patents	

Data and methods

According to the opinions of thirty experts in the field of life science through email consultation, Recombinant DNA (RbDNA) and Monoclonal Antibody (mAb) were selected as impelling technologies to carry out case study. ELISA Diagnosis (ELISA) and Fermentation Technology (FT) were defined as non-impelling technologies to be control group.

Publications in Web of Science^{TM} from 1960s to 2012 (publication year) and US patents in Derwent Innovations Index^{SM} from 1970s to 2012 (basic patent year, defined by DII based on the earliest year of all the publication dates of all members of a patent family) were chosen as quantitative data of case study. Data was acquired from the Web of Science in May 2013. Thomson Data Analyzer (TDA) and Science of Science (Sci^2) Tool (http://cns.iu.indiana.edu) were used to extract the statistic and network information.

Search terms to retrieval papers and patents are listed in Table 2.

Table 2. Search terms used for this study.

	Papers	*Patents*
RbDNA	TS=("DNA recombination" or "recombinant DNA" or "DNA cloning" or "molecular cloning" or "gene cloning")	IPCs: from C12N-015/09 to C12N-015/90
mAb	TS=(("monoclon* antibod*") OR (monoclon* same antibod*))	IP=C12P-021/08
FT	TS=ferment*	IP=(C12C-011/* OR C12G* OR C12P* OR C12J*) AND TS=ferment*
ELISA	TS=elisa, removed the papers in WC class of Spectroscopy, Optics, Physics Condensed Matter, Nuclear Science Technology, Behavioral Sciences, Astronomy Astrophysics and Microscopy.	TS=Elisa

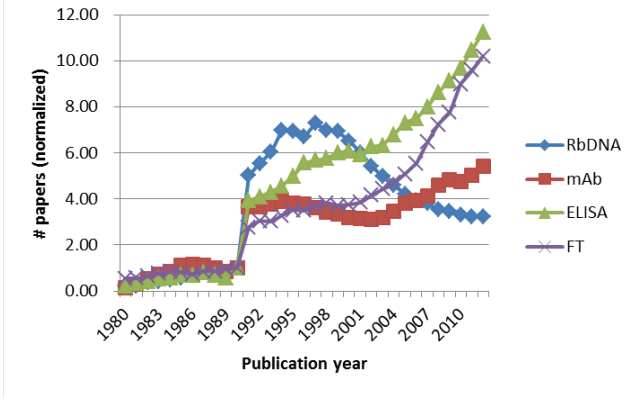
Results and Analysis

Evolving of papers and patents

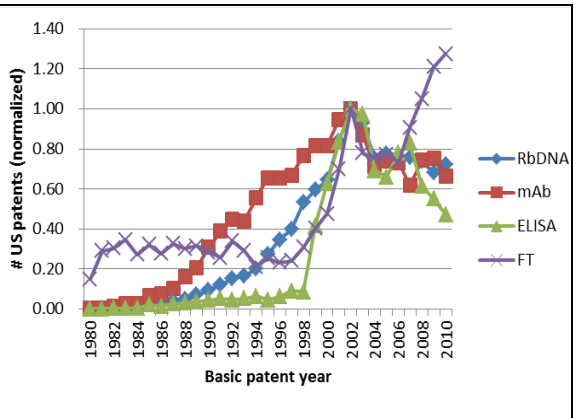
Papers and patents are two external indicators for reflecting the evolving of technologies. The output of papers and patents of the two impelling technologies and two non-impelling technologies were normalized to 1 by their numbers of papers in 1990 and numbers of patents in 2002 separately. The reason of choosing 1990 was that the year 1990 was a jumping-off year, after when the number of papers jumped at least more than three times in 1991. The reason of choosing 2002 was that the year 2002 was a dividing crest, which year had the maximum number of patents, except for FT. Fig. 1 illustrates that the number of papers of both the two impelling technologies stabled at a certain range after three or four years development following the jumping-off from 1990 to 1991. The patents trends show that the number of patents of impelling technologies stabled at a certain level after two years of the patent outputs peak. However, both the papers trends and patent trends of non-impelling technologies had no stable signal no matter which way they go, increase or decrease constantly.

In order to compare the features of impelling technologies at different stages of life cycle, time were sliced into four sections, -1986 (emerging stage), 1987-1993 (growth stage), 1994- (maturity and saturation stages). This division mainly depended on the evolving histories of the two impelling technologies. Although it was not adaptive for on-impelling technologies it

had also been used for distinguishing non-impelling technologies' life cycles with the purpose of comparison.



papers-normalized by the number of papers in 1990



patents-normalized by the number of patents in 2002

Figure 1.Growth of papers and US patents.

International scientific environment

Through watching the histories of the two impelling technologies, we found that Human Genome Project, the first major foray of the biological and medical research communities launched in 1990, boosted the two impelling technologies fast into maturity stage, which could be reflected by the jump of the number of papers. Nevertheless, although the two non-impelling technologies, ELISA and FT, had also been boosted by the Human genome Project, these two technologies had not entered into maturity stage throughout. Actually, beside for the Human Genome Project, there were still more crucial policies had been drawn and put into effect. For example, USA had announced the first Recombinant DNA research Guidelines for normalizing such researches. Even till now, government still made positive policies to maintain the driving functions of impelling technologies. For instance, US Federal Court ruled that synthetic DNA could be patented, which might become a new pushing for the development of RbDNA.

In the aspect of industry, at the stage of growth there were one or a few professional companies born and the number of companies rose sharply at the stage of development and the early maturity stage. For instance, benefited from the development of RbDNA, the first biotechnology company Genentech had been established in 1976. When an impelling technology is mature, the relevant industry would expand rapidly. For example, mAb had brought a rapid growth market of 26 billion USD in 2006 while it was only 4 billion in 2002.

Patent assignees collaboration networks

Figure 2 and Figure 3 illustrate the network features of patent assignees collaboration networks. It is clearly showed in Figure 2c that as time gone on, the ratio of isolates (assignees have no collaborators) decreased year by year and seemed to stabled at a certain level. However, the ratios of isolates of the impelling technologies were much lower all along than that of the non-impelling technologies. The values of the latter were more than twice of the former. The gap was enlarged to more than three times at the stage of development. As a result of the reduction of isolates, the clusters increased and there were many a big cluster became bigger and bigger. It has to be noted that an isolate was also regarded as a cluster. Therefore, a network with high level of collaborative behaviours must has less clusters because of much more isolates and small clusters tend to merge to bigger clusters. Thus the

excellent performance of collaboration leads to generate a super big cluster and less ration of clusters (see Fig. 2a). Figure 2b shows that the biggest cluster of impelling technologies gathered about more than half of the total number of assignees particularly after the stage of development, which was much higher than that of the non-impelling technologies.

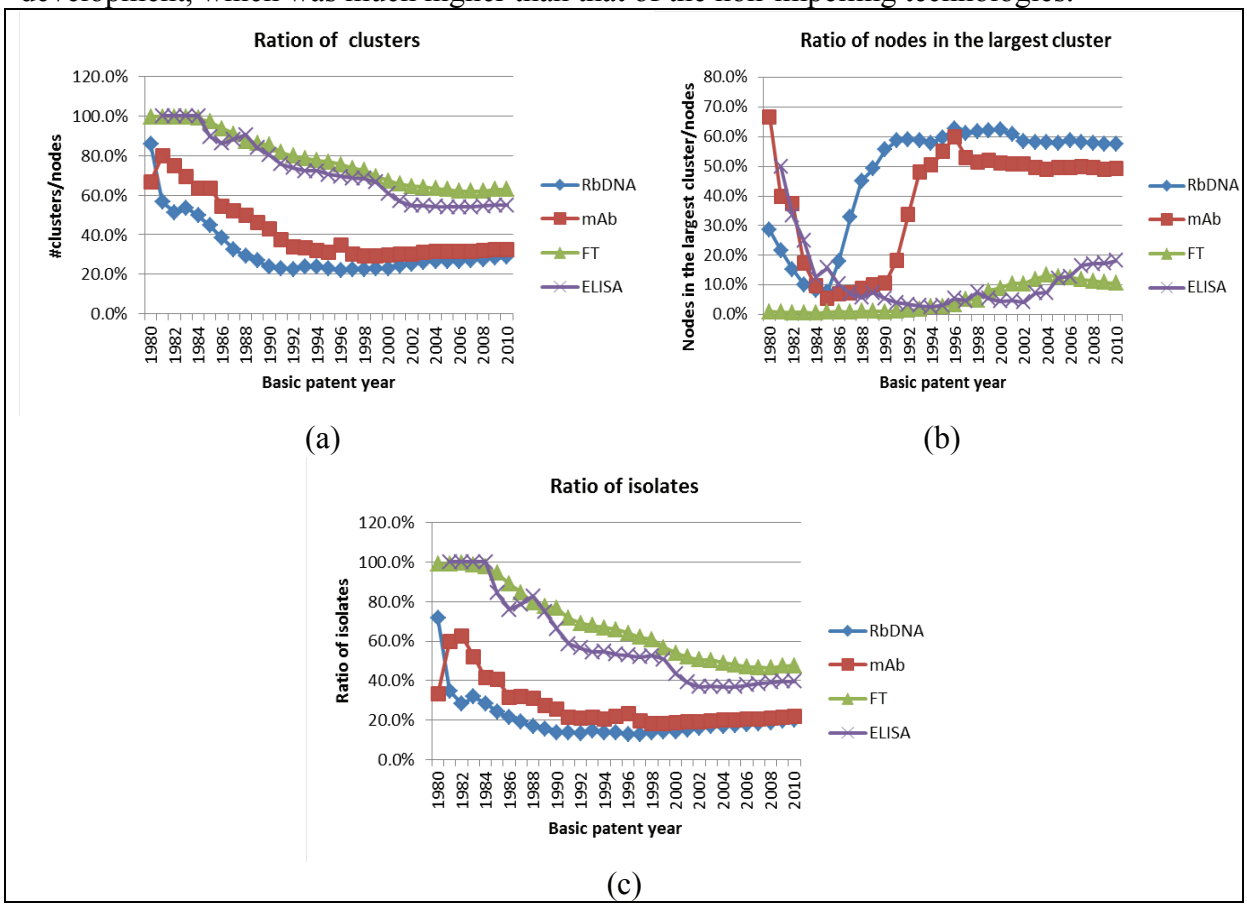


Figure 2. Network features of US patents' assignees' collaboration.

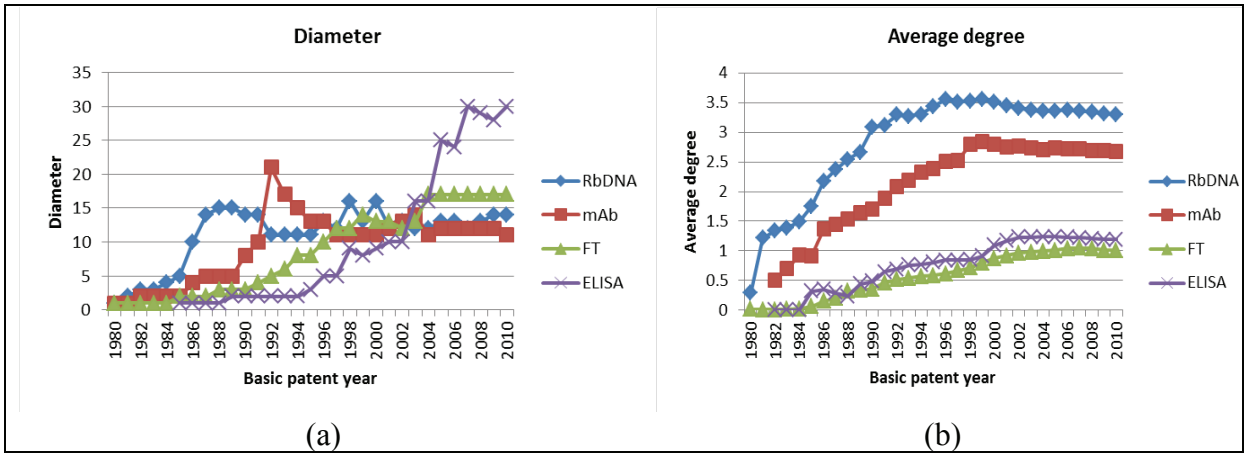

Figure 3. Diameters and average degrees of assignees collaboration network.

Benefited from the good network performance, the impelling technologies had higher average degree all the time. It was about three times higher than that of the non-impelling technologies at the stage of maturity, ten and four times during the period of growth and development respectively.

Impact

The average times cited of papers and patents of the two impelling technologies and two non-impelling technologies were illustrated in Figure 4.

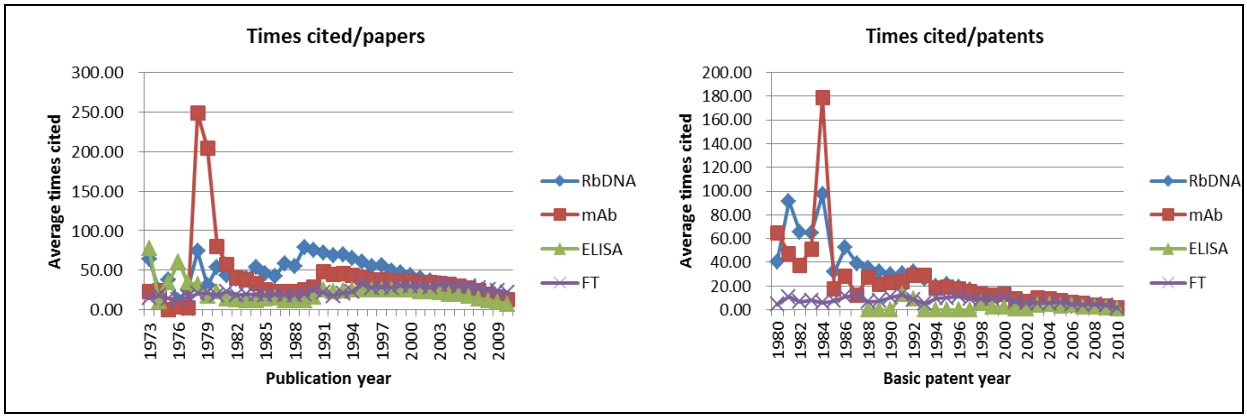

Figure 4. Average times cited of papers and US patents.

The results showed that the average times cited of papers of impelling technologies was two times higher than non-impelling technologies during the whole period of this analysis. The value of impelling technologies was 30 and 50-80 compared to 18 and 20 of non-impelling technologies at the stages of growth (before 1986) and development (1987-1993). For patents, the average times cited of impelling technologies and non-impelling technologies were 66 and 7 in stage of growth, 24 and 9 in stage of development correspondingly. However, the advantages of impelling technologies were eroded as time goes on in the stage of maturity.

Quantitative ITFM

Through the above case study we might conclude some unique features of impelling technologies in the field of life science.

First, impelling technologies had higher rates of evolution from the stage of growth to maturity, which could be illustrated particularly by the papers evolving patterns. When it comes to the technologies of RbDNA and mAb, it took only about one year that both of the two impelling technologies had finished their transform. At the same time, impelling technologies represented distinct feature at the stage of maturity. Nevertheless, the two non-impelling technologies represented no obvious such transformation. It seemed like that both the two non-impelling technologies were still at the stage of growth. However, the fermentation technology had a much longer history than both the two impelling technologies. The reason of it represented such evolutionary feature might just due to the position as a non-impelling technology, which contributes more and more to the society development, but always is a applied technology and will not play more impelling functions.

Second, significant policies or programs boosted the rapid progress of impelling technologies. Although non-impelling technologies had also been pushed by specific policies or plans, the range was lower than that of impelling technologies. When the impelling technologies switched into maturity stage, they usually drove the explosive increase of industry.

Third, impelling technologies had much higher impact than non-impelling technologies, which could be reflected by the times cited per paper/patent. The value of times cited per paper/patent of impelling technologies was two to three times higher than non-impelling technologies. It was highlighted during the process of involving from the stage of development to maturity. In the case of life science, for papers, the value of impelling technologies was 50-80 compared to 20 of non-impelling technologies, for patents, the values were 24 and 9 correspondingly.

Last, collaboration behaviour measured by the collaborations of patent assignees was much more broad and general for impelling technologies. Assignees collaboration networks of impelling technologies had fewer isolates, and there were only about 20% assignees were isolates at the stages of development and maturity. Much more assignees had collaborated with others and become much bigger clusters with a result of the number of clusters decreased. The biggest cluster (principal component) gathered a large number of assignees that took up more than half of the total number of all nodes in the networks at the stage of maturity. As a result, the average degree of impelling technologies reached to 3 which were three times to that of non-impelling technologies at the stage of maturity. The diameters of impelling technologies stabilized at 12 at the stage of maturity. Non-impelling technologies had no such features of stable diameters.

The results indicate that hypothesises listed above were answered by the case study. Based on the results of the comparison of impelling technologies and non-impelling technologies in the field of life science, a quantitative model is induced in table 3. The model can be used for foreseeing any new impelling technologies that have just born or at different stages, especially at the stages of development and maturity.

Table 3 Quantitative ITFM.

	Indicators	***Features***		
		Growth (- 1986)	***Development (1987-1993)***	***maturity (1994-)***
International scientific environment	**Policies, plans &projects**	New incentive, convenient policies enacted	Pushed significantly by major project	Still focus of policies, plans & projects
	Industry	Start-up companies	Number of companies would rise sharply	Industry expand rapidly
Evolving of papers and patents	**Papers evolution**	/	Evolved into maturity stage in few years	Stable (no sign of stable)
	Patents evolution	Steady increase	Steady increase	Stable(no sign of stable)
Collaboration-Features of patent assignees collaboration networks	**Ratio of isolates**	40% (*95%*)	20% (*70%*)	20% (*50%*)
	Nodes in the largest cluster/nodes	20% (*10%*)	35% (*3%*)	55% (*10%*)
	#clusters/#nodes	60% (*97%*)	35% (*80%*)	30% (*65%*)
	Average degree	1 (*0.1*)	2 (*0.5*)	3 (*1*)
	diameters	3 (*1*)	12 (*3*)	Stable at 11-14 (no sign of stable)
Impacts	**average times cited of papers**	30 (*18*)	50～80 (*20*)	Decreased yearly
	average times cited of patents	66 (*7*)	24 (*9*)	No difference between impelling and no-impelling technologies

Notes. The values of non-impelling technologies were listed in brackets.

Discussions

This paper defines impelling technologies and constructs an ITFM model for foreseeing technologies that have potential to become impelling technologies. There is no doubting that this is an attractive topic all the time for many kinds of scientists, policy makers and stakeholders. The theoretical basis of this study is the positive correlation between the four hypothesises and the performance of an impelling technology. Four classes of indicators were introduced into the ITFM model and demonstrated on two impelling technologies and two contrasted non-impelling technologies in the field of life science. Indeed, this work is the first study about impelling technologies foresight and got some valuable results which could be

used for many new technologies foresight, such as synthetic biology. Such application study would be carried out in the near future.

Nevertheless, there are still some shortages of this study. First, the ITFM model can be used only for evaluating existed technologies and not for future technologies that have not born yet. Indeed, this topic is also interesting and important. Second, the values in the ITFM were concluded from the four technologies from life science, which might volatile when used in other fields. Actually, different impelling technologies even in the field of life science might get different values. Therefore, the values in ITFM model are referenced values. The relative performance of impelling technologies is more important when the model is used for evaluating other technologies. Third, impelling technologies foresight is a complex question, which is hard to be identified easily through one or two models or methods. There must be many other indicators that could reflect the unique features of impelling technologies. Therefore, this work is just a beginning of such efforts for foreseeing impelling technologies.

Acknowledgements

We would like to thank many fellows in the field of life science from CAS, who gave a lot of advises in choosing the technologies used for case study. The paper did benefit greatly from detailed comments by an anonymous reviewer. This work is funded by the Documentation and Information Special Project of Chinese Academy of Sciences (2013). This work is funded in part by the National High Technology Research and Development Program of China (863 Program) under grant no. 2014AA021503. Abstract
This paper describes the process by which almost all authors of papers in the Web of Science (WoS) can be characterised by their sex and ethnicity or national background, based on their names. These are compared with two large databases of surnames and given names to determine to which of some 160 different ethnic groups they are most likely to belong. Since 2008 the authors of WoS papers are tagged with their addresses, and many have their given names if they appear on the paper, so the workforce composition of each country can be determined. Conversely, the current location of members of particular ethnic groups can be found. This will show the extent of a country's "brain drain", if any. Key results are shown for one subject area, and *inter alia* it appears that the majority of researchers of Indian origin who are active in lung cancer research are working in the USA. But East Asians (Chinese, Japanese and Koreans) tend to stay in their country of birth.

Conference Topic
Methods and techniques

Introduction
There is continuing research interest in the sex and ethnic composition of research personnel. A brief survey of the literature in 2013-2014 indicates that there is a widespread interest in the problems faced by female researchers (no fewer than 24 countries were involved in such research, and there were 71 papers in the two years, including several exploring the problems in countries outwith North America and western Europe (*e.g.*, Gonenc et al., 2013; Homma, Motohashi, & Ohtsubo, 2013; Bettachy et al., 2013; Isfandyari-Moghaddam & Hasanzadeh, 2013; Garg & Kumar, 2014). However there is much less interest in the situation of ethnic groups, and that only in the USA (Griffin, Bennett & Harris, 2013; Pololi et al., 2013; Campbell et al., 2013; Hassouneh et al., 2014), with one exception (Johansson & Sliwa, 2014; Sliwa & Johansson, 2014), which concerned foreign women in a UK business school. Attention in the USA is focussed almost entirely on under-represented minorities (African-Americans, Hispanics, and in some cases Native Americans), and hardly at all on the problems that may be encountered by researchers of Asian origins, notably Chinese and Indians, who may have to cope with difficult immigration (Teich, 2014), integration and living experiences when they move to the USA. In fact, as we shall see, they are hardly "under-represented minorities" but rather over-represented compared with their presence in the population. (A fuller survey of the relevant prior literature was given in Roe et al., 2014.)
This paper provides a method whereby the researchers in a given scientific subject area can be characterised by their ethnicity or national background and their sex. This is important for science policy, including the monitoring of the changing roles and positions of women in research and the extent to which a country is welcoming to researchers from abroad and helps them to integrate. It builds on the methods described earlier (e.g., Roe et al., 2014) but now allows all the authors on multi-national papers to be classified, and is applicable to all the countries represented in the subject area. Conversely, it can reveal the location of researchers

of any particular ethnicity or national origin. The methods have been applied to the subject area of lung cancer research, and results for this area are given in some detail, but they can equally be applied to any other research area.

Attention was focussed on 24 leading countries, responsible for the large majority of global lung cancer research output, as shown in Table 1 with their digraph ISO codes. However, some results are also given for others, because the database listed all countries contributing to lung cancer research, and researchers with names characteristic of 90 different countries.

Table 1. List of 24 leading countries in lung cancer research, 2004-13.

Methodology

The file of lung cancer papers (articles and reviews) was obtained from the Web of Science (WoS) for the six years, 2008-2013, from the intersection of two "filters". One was for cancer, and was based on journal names and title words. These included the names of many individual cancers, genes known to pre-dispose people to an enhanced (or reduced) risk of cancer, and specialist drugs and other treatments such as radiotherapy. The other was for lung disease, and consisted of a number of specialist respiratory journals, such as *Experimental Lung Research, Jornal Brasileiro de Pneumologia, Lung* and *Respiration*, and two title words *lung* and *trachea**. In addition, all the papers in the journals *Lung Cancer* and *Clinical Lung Cancer* were retained, together with papers with *SCLC* or *NSCLC* in their titles. The file contained details of 22,433 papers.

The analysis of the researchers was based on their names, both surnames and given names. The surnames were compared with our listing of 2.6 million family names which is based on records of the majority of the adult population in the following countries: Australia, Brazil, Denmark, Germany, Ireland, Italy, Netherlands, Norway, South Africa, Spain, Sweden, the UK and the USA as well as surname frequency distributions for Austria, Belgium, France, India and Japan. For some countries in Eastern Europe and the Middle East, the files were supplemented by data on the names of scientists from these countries found in the WoS. We were able to classify names into over 160 different ethnicities, nationalities and regions within countries, but in this study the classification was simplified to include own country and eight main groups:

- own country (OWN) – this also included representatives of countries who have been the main sources of immigrants, such as France and the UK in Canada;
- other European country (EUR: Albania, Balkan, Belgium, Bosnia, Britain, Bulgaria, Croatia, Cyprus, Czech, Denmark, Estonia, Finland, France, Germany, Greece, Hungary, Iceland, Ireland, Italy, Latvia, Lithuania, Malta, Montenegro, Netherlands, Nordic, Norway, Poland, Portugal, Romania, Russia, Serbia, Slovakia, Slovenia, Spain, Sweden, Switzerland);
- Latin America (LAT: including Brazil, Guyana and Mexico);
- Levant and Mediterranean (LEV: Algeria, Egypt, Israel, Lebanon, Libya, Morocco, Saudi Arabia, Tunisia, Turkey, Ukraine);

- Africa (AFR: Afrikaaner, Angola, Cameroon, Congo, Eritrea, Ethiopia, Ghana, Ivory Coast, Kenya, Malawi, Mauritius, Nigeria, Sierra Leone, Somalia, Sudan, Uganda);
- South Asia (SAS: Bangladesh, Burma, India, Pakistan, Sri Lanka);
- China (CHI);
- other Asia (ASI: Afghanistan, Armenia, Azerbaijan, Cambodia, Georgia, Iran, Iraq, Japan, Korea, Laos, Malaysia, Mongolia, Nepal, Philippines, Singapore, Thailand, Vietnam);
- other non-European and Oceanic (OCE: Australia, Caribbean, Fiji, Indonesia, New Zealand).

The methodology is more fully described in a recent paper by Roe et al. (2014).

Given names often (but not always) connote the sex of the person, and we have compiled a list of some 0.7 million such names, including some misspellings and phonetic misrepresentations. This has recently been complemented with the given names of all UK doctors on the Medical Register – over 328,000 individuals, many of whom come from other countries. Some given names connote a different sex in different countries – for example, Andrea is female in the UK but male in Italy. A few countries (in the present study, only Poland) have surnames with gender endings and this can also be used to determine the sex of an author.

In (Roe et al., 2014), attention was confined to papers from a single country, but we were now able to identify the names of the authors from each of the countries in a multi-national paper because the WoS lists them with their addresses in the following format:

> *[Scagliotti, Giorgio V.] Univ Torino, Thorac Oncol Unit, Dept Clin & Biol Sci, S Luigi Hosp, I-10043 Turin, Italy; [Germonpre, Paul] Univ Ziekenhuis Antwerpen, Edegem, Belgium; [Planchard, David] CHU Poitiers, Poitiers, France; [Reck, Martin] Krankenhaus Grosshansdorf, Grosshansdorf, Germany; [Lee, Jin Soo] Natl Canc Ctr Korea, Goyang, South Korea; [Biesma, Bonne] Jeroen Bosch Ziekenhuis, Shertogenbosch, Netherlands; [Szczesna, Aleusandra] Mazowieckie Ctr Leczenia Chorob Pluc & Gruzlicy, Otwock, Poland; [Morgan, Bruno] Leicester Royal Infirm, Dept Radiol, Leicester, Leics, England*

although not all the authors have given names that would allow their sex to be determined.

A special macro was written to enable the names of all authors from each of the countries to be listed in appropriate columns of a spreadsheet for each paper. These were then each classified by national group and sex, where available, so that the contributions of each of the national groups and sexes could be determined. However, the main analysis was performed on the long list of 84,533 different names, each of which was associated with a country and had its frequency of occurrence listed. For each of the 24 selected countries, and for the rest of the world (RoW), the composition of the lung cancer research workforce and the contributions (sums of the numbers of papers) from researchers from each ethnic group (or world region) were determined.

However, we found during our analysis that some East Asian names belonging to researchers working in China, Japan or South Korea, had been misclassified as European as they were ambiguous, such as Jung, Lee and Park. It was obvious from the given names of these researchers if they were Orientals or Europeans. Thus Jung, Andreas working in Germany was clearly German, but Jung, Deuk-Kju working in South Korea was Korean. Likewise, Park, Bernard J. working in the USA was considered to be of European origin, but Park, Byung-Joo in Korea was taken as Korean. These were manually corrected, and some other adjustments to ethnicity were made.

It also became apparent that some names with different given names or initials actually referred to the same person. Thus there were only two Aaronsons in our list of researchers,

one was Neil and the other Stuart A. Both could be classed as male. Another Aaronson, S.A. was clearly the same as Aaronson, Stuart A, and so could be counted as male. We were able to sex quite a lot of researchers without given names in this way.

Results

The data on the national origins and on the sex of the lung cancer researchers in the 24 selected countries, plus the Rest of the World, were obtained from a large file that looked like this:

Table 2. Small excerpt from the file listing the names of all lung cancer researchers.

Name	*Country*	*ISO*	*Count*	*Ethnic*	*Sex*	*Region*
Aakre, J.	USA	US	1	NO	M	EUR
Aakre, Jeremiah	China	CN	1	NO	M	EUR
Aakre, Jeremiah A.	USA	US	4	NO	M	EUR
Aamini, Mahnaz	Iran	IR	1	IR	F	ASI
Aapro, M.	Switzerland	CH	1	FI	X	EUR
Aarab-Terrisse, S.	France	FR	1	MA	X	LEV
Aarndal, Steinar	Norway	NO	2	NO	M	EUR
Aaron, Jesse	USA	US	1	UK	M	EUR
Aarons, Y.	Australia	AU	1	ES	F	EUR
Aarons, Yolanda	Australia	AU	1	ES	F	EUR

The top person in this list evidently worked both in China and the USA, and the first and ninth names were sexed by comparison with the row(s) below.

For the analysis by sex, all 24 countries, plus the RoW, have been included in Table 3. The table shows the percentages of names that could be sexed, and the percentage of such names that were female. The calculation was made both for the number of researchers (this will be an over-estimate, as in Table 2 there are only 7 people, not 10) and for their total contributions.

The high percentage of females in China is clearly anomalous as fewer than half the names could be sexed – this was also the case for Taiwan and Korea. Among European countries, Canada and the USA, on average just over 80% of names could be sexed, and the female percentages are therefore more reliable. Austria, Belgium, Germany and the Netherlands score noticeably low on female participation. On the other hand Poland, a former Communist country where females were strongly encouraged to work (Webster, 2001), ranked highly, and the 10 other eastern European countries (the new "accession Member States" of the European Union) as a group ranked more highly still, with an actual majority of female researchers (51.5%) though their collective contribution was only 46.6%.

Table 3. Analysis of lung cancer researchers in different countries by sex. P = number of people; C = number of contributions (integer count). F = number of females; M = number of males. Countries are ranked by percentage of female researchers.

The five South American countries (Argentina, Brazil, Chile, Colombia and Venezuela) also scored well for female participation with nearly 46% of researchers and 44% of contributions, slightly higher than the values for Brazil alone. The three Mediterranean Latin countries (Italy, Portugal and Spain) also scored well, and Portugal had the highest female participation, with over 61% of female researchers, whose contribution was 58%.

The correlation of the percentage of females in the above table (for the 11 countries for which a comparison could be made) with that obtained from another (unpublished) study on cancer screening where a similar methodology was used is quite high ($r^2 = 0.63$). However lung cancer averaged only 39% compared to 46% for cancer screening. Sweden was an exception, with a higher female percentage in lung cancer (43%) compared with 40% for cancer screening.

For the analysis of ethnicity/national origins of the researchers, we first determined the percentage of researchers with "own country" ethnicity. Table 4 shows, for each country, the national background(s) of the names that were selected and the corresponding percentages of their numbers and contributions.

Table 4. Numbers and percentages of "own country" researchers

The result for Brazil is anomalous, as most of its researchers are descended from Europeans and would have European or Latin American names. (A scientific conference in Caxambu of the Brazilian Biochemical Society, which one of us attended in 1994, was almost entirely populated by Brazilians who appeared to be of European origin.) If these are allowed as "own country" names, then they would represent 90% of Brazilian researchers with a contribution of 91%.

The countries with the greatest fraction of their lung cancer workforce of non-native origin appeared to be the Nordic ones (Denmark, Sweden and Norway), and Canada. The UK also had a high proportion of its lung cancer researchers with non-national ethnic backgrounds (40%) and the same percentage of contributions. On the other hand, Italy had only 10% of non-Italians, and Korea and Japan even fewer foreigners (8% and 5% respectively) though there were rather more in Taiwan (21%) and in China (16%). This feature of Italian research was found in a previous study (Roe et al., 2014).

We now consider the contribution of other European researchers to the lung cancer research of the 14 selected European countries. This is shown in Table 5.

Table 5. Contributions of researchers from other European countries to the lung cancer research of 14 selected European countries. P = people; C = contributions (integer count).

	Other EUR, %				*Other EUR, %*				*Other EUR, %*	
Country	*P*	*C*		*Country*	*P*	*C*		*Country*	*P*	*C*
DK	52.4	53.8		FR	28.7	29.5		ES	17.3	19.9

GR	33.9	32.2		DE	21.5	21.2		IT	6.6	6.0
AT	33.7	37.4		UK	21.3	21.3				

The results are similar to those of Table 4, except that the UK dropped from fifth to tenth place with its proportion of other European nationals among its lung cancer researchers. Its acceptance of non-Europeans was therefore correspondingly greater. There were 7.0% with a South Asian background, three fifths of them Indian, 3.1% Chinese and 4.0% from other Asian countries. These percentages are much higher in Europe except that Sweden had a slightly greater percentage of researchers of Chinese origin. The UK also had 2.2% of lung cancer researchers with North African or Levantine names (third highest in Europe), 0.8% with African names (second to the Netherlands) and 0.7% with names from Latin America (highest in Europe). Altogether, its lung cancer research population with non-European names amounted to 19% of the total.

These percentages can be compared with census data for England and Wales in 2011 (ONS, 2012). There were about 5.3% of "other White" including Irish (corresponding approximately to "other Europeans" in the above table), 2.5% of Indian origin, 4.2% of other Asians, and 0.7% of Chinese. So the Chinese were over-represented among lung cancer researchers by 3.1/0.7 = 4.4, the Indians by 4.2/2.5 = 1.7 and other Asians were slightly under-represented by 4.0/4.2 = 0.95. The other Europeans were also over-represented by 21.3/5.3 = 4.0. Many of the Chinese would have been graduate students and would probably have returned to China or gone elsewhere after obtaining their doctorates or other degrees.

Canada and the USA were even more accepting of non-Europeans, and their percentages of the different groups are shown in Table 6. Almost 40% of US lung cancer researchers were of non-European ethnicity or national background, of whom by far the largest group were Chinese (13.8% of the total), followed by Indians (5.8%) and Koreans (3.5%). Despite the large numbers of Latin Americans now in the population, they represent only 4.3% of American lung cancer researchers, even when people with Brazilian, Portuguese and Spanish names are included. US Census data for 2010 show that "Latinos" accounted for well over one third of those living in the USA but born abroad, compared with the Chinese (5%) and Indians (4%). However, only 5% of them had university degrees, compared with 50% of the Chinese and 74% of the Indians (US Census Bureau, 2012).

Table 6. Percentages of non-European lung cancer researchers in Canada and the USA.

	CHI	*ASI*	*SAS*	*LEV*	*LAT*	*AFR*	*Other*	*Total*
CA	11.0	9.6	5.6	4.2	0.9	0.4	2.7	34.4
US	13.8	9.6	7.7	4.5	1.4	1.0	1.8	39.8

The file also allows us to determine where lung cancer researchers with given ethnicities are now based and how much they are contributing to either their countries of origin or their new host countries. We previously found (Basu, Roe & Lewison, 2012) that the output of cancer research papers by people of Indian origin now living in Canada and the USA was greater than that of Indians remaining in India. In lung cancer research, of the 2,233 researchers with Indian names, over half (1,164 or 52%) are working in the USA and only 637 (28.5%) in India. There are 124 in the UK, 80 in other European countries, 73 in Canada and 155 elsewhere. The situation is very different for the Chinese, Japanese and Koreans, see Table 7.

Table 7. Current locations of lung cancer researchers from China, Japan and Korea (S).

Ethnicity \ Workplace	*China*	*Europe*	*Japan*	*Korea*	*USA*	*Other*	*Total*
CN	11301	220	124	178	2762	2725	17310
JP	18	27	8485	9	341	90	8970
KR	1151	40	51	3688	702	443	6075
CN, %	65.3	1.3	0.7	1.0	16.0	15.7	
JP, %	0.2	0.3	94.6	0.1	3.8	1.0	
KR, %	18.9	0.7	0.8	60.7	11.6	7.3	

Clearly, most of these East Asians remain in their own country, although the Chinese travel abroad the most, and the Japanese the least, and hardly at all to China or Korea. There is also very little movement to Japan by Chinese and Koreans, and some of the 51 Koreans working in Japan may be ones whose families have been there for several generations. In 2005, there were some 901,000 people of Korean ancestry living in Japan (out of a population of 128 million) or 0.7%. The percentage of the lung cancer researchers in Japan with Korean names was 0.6%, which is slightly less.

We can also see where the lung cancer researchers with various "European" names are now - some will have stayed in their own country, some have gone to the United States, and some have gone elsewhere. The two figures below show the situation. The five largest countries (in terms of numbers of named researchers) are on the left chart and the next nine are on the right chart. However, many of those with British, German, Polish and Irish names will have been resident in the USA for several generations rather than being recent immigrants.

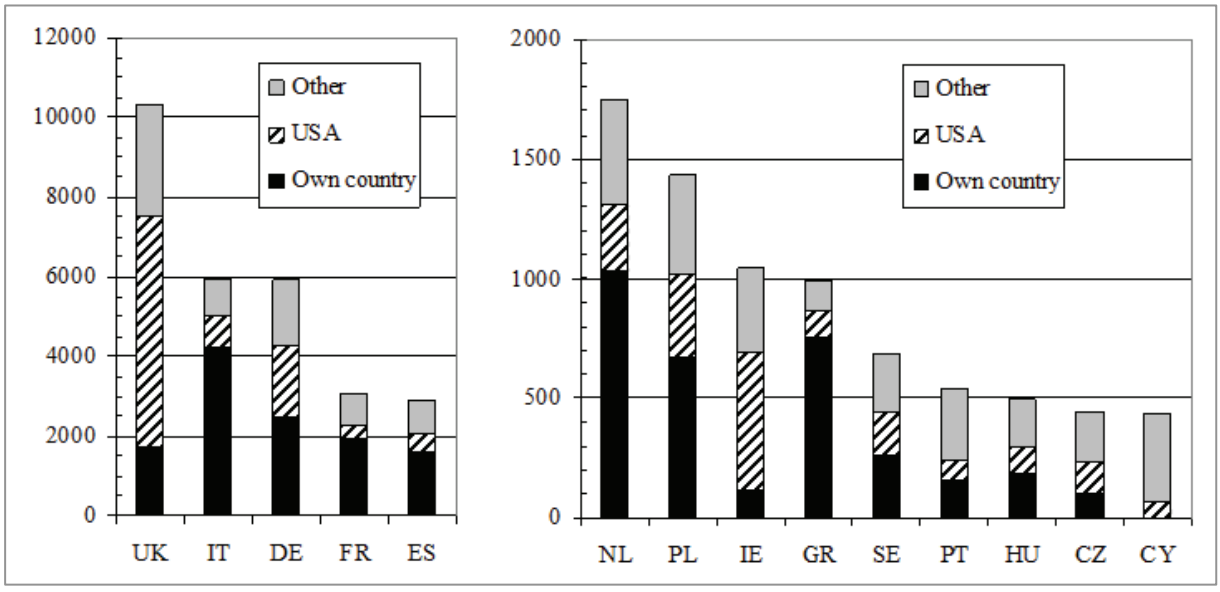

Figure 1. Locations of lung cancer researchers with names characteristic of different European countries - in own country, in the USA, and in other countries.

The file of lung cancer researchers also enables us to investigate whether there is a difference between men and women in the numbers of papers that they write. Figure 2 shows the sex ratio F/(M+F) for groups of authors who publish sufficient papers to put them in a given centile. Thus of the 84,533 authors, the top 1% (n = 845) each wrote at least 17 papers, and the figure shows that just under 26% of those whose sex could be determined were female. By contrast, the 53,143 authors with but a single paper (probably mainly graduate students) were nearly 44% female. This shows clearly that the percentage of females falls off with production, which is probably strongly correlated with seniority. A similar graph could be

produced for individual countries, or ethnic groups, provided that there are enough people in the group or country to make the analysis worth-while.

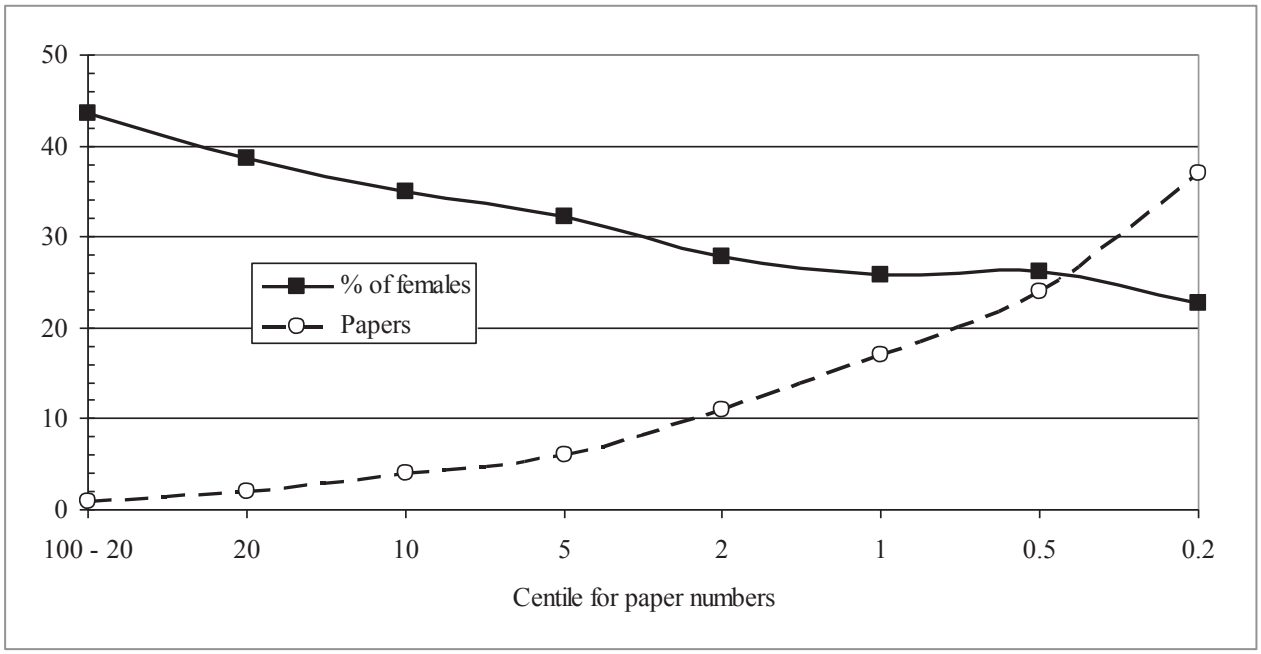

Figure 2. Percentage of female authors whose number of lung cancer papers put them in given centiles of the population of 84,533 authors.

Discussion

This paper greatly extends the methodology used in Roe *et al*., 2014 by its application to all the papers in a subject area, including multi-national ones, and by the provision of a file of all the named researchers, classified by their ethnicity and sex, and the country or countries in which they were working. This allows many research questions to be addressed, and some of them have been in this paper.

However, the methodology still has some limitations, and these are currently being tackled. The first is that, although Aakre, J. can be identified as the same as Aakre, Jeremiah and so classed as male, the file contains two separate entries (actually three in this case because he also published a paper with a Chinese address), which should be amalgamated. The second limitation is that the number of each researcher's papers is given only as an integer count, and for many purposes it would be more useful to have a fractional count, based on the number of different authors of each paper. This is sometimes problematic, as quite a lot of papers list individuals with more than one affiliation. This would not matter if these are all in the same country, as is usual, but increasingly nowadays senior researchers have appointments in more than one country. We would need to fractionate these people's contributions by country in order to make the sum of the individual contributions equal the number of papers (less those with anonymous authors).

A further problem is that, although most names can be classed by country or region within it, some can not be, at present. (The lung cancer database only has 392 names not classified by ethnicity, less than 0.5% of the total.) This is well within the margin of error for most bibliometric studies. However, there is a bigger problem with ambiguous family names where the given names are not on the paper. We have approached this on the basis that most East Asians stay in their own country (see Table 7). However this method would not apply so strongly to Europeans, and as movement and marriage between EU Member States becomes increasingly common, there will be more errors in attribution of researchers to countries.

We have also found that the percentage of names that cannot be sexed is quite high, so that the results for some countries are not at all representative – notably for China. Clearly, we need to acquire more information on the sex associated with particular Chinese, Japanese and Korean names, although some names may not be strictly unisexual. (This occurs also with some European and some British given names, such as Hilary and Robin, where a minority of holders are respectively male and female.) We previously took a ratio of at least 10:1 as indicative of the association of a given name with just one sex, but there may be some errors, though these could be reduced if a researcher has two given names and one can be sexed definitively. This again will need improvements to the software.

Acknowledgments

This study was funded by King's Health Partners and the Global Lung Cancer Coalition as part of their evaluation of lung cancer research world-wide.

Abstract
One of the most important requirements of building applicable models and meaningful indicators for the use of scientometrics at the micro and meso level is the correct identification and disambiguation of authors and institutes. Platforms like ResearcherID or ORCID with author registration providing high reliability but lower coverage now provide appropriate data sets for the development and testing of stochastic models describing the publication activity and citation impact of individual authors. This paper proposes a triangular model incorporating papers, citations and authors analogously to the dichotomous model used at higher levels of aggregation like countries or fields. This model is applied to a set of authors in any field of science identified by their ResearcherID. However, the main advantage of classical citation indicators to study citation impact under conditional productivity turned out to be the main problem in this triangle: the possible heterogeneity of the collaborating authors results in low robustness. A mere technical solution to this problem would be fractional counting at three levels, but the conceptual issue, the different roles of co-authors causing this heterogeneity, will never be solved by any algorithm.

Conference Topics
Methods and techniques; Data Accuracy and disambiguation

Introduction
Spectacular progress has been made in author identification, the disambiguation of names and their institutional assignment on the basis of correct affiliation and cleaned address data extracted from bibliographic databases. In particular, this is one of the most important and basic requirements of building applicable models and meaningful indicators for the use of scientometrics at the micro and meso level. Correct author identification is not only indispensable in studies of academic careers, researchers' mobility, authors' publication and collaboration patterns (Braun et al., 2001) but also in monitoring constitution and performance of research teams (Strotman & Zhao, 2012). The task outlined here is practically twofold: On the one hand, the large-scale disambiguation and assignment of authors forms still one of the big challenges in scientometrics. Although the quality of disambiguation and assignments of authors has considerably improved due to sophisticated algorithms and scientometric techniques, e.g., using "bibliometric fingerprints" (Tang & Walsh, 2010) and similarity patterns (cf. Caron & van Eck, 2014), automated processes proved not sufficient to provide reliable reference standards even if optional interaction of individual authors has been made possible. In this context author identification of the Mathematical Reviews and Elsevier's Scopus databases might just serve as examples. Mathematical Reviews was one of the first databases that applied automated processes (since 1985) for author identification. Challenges are, among others, mobility, topic shifts, career breaks, occasional and infrequent publication activity, e.g., so-called transients (Price & Gürsey, 1976). Incorrect institutional assignment, multiple identities as well as unresolved homonyms are still frequently observed errors. This is contrasted by the possibly higher reliability but lower coverage of identifiers that are based on author registration as, for instance, the ResearcherID of the Web of Science database (Thomson Reuters) and the Open Researcher and Contributor ID (ORCID). The latter IDs are sensitive to human errors and their willingness to regularly update and maintain publication assignment to their IDs. A previous study has pointed to the representativeness bias in favour of more prolific authors (Heeffer et al., 2013).

The second issue is partially related to methodology but also of conceptual nature. The methodological issues arise from the superposition of multiple assignments of publication to subjects, on the one hand, and to co-authors and their particular profiles, on the other hand.
Stochastic models for publication activity and citation impact of authors, however, require partitions, which can only partially approximated by corresponding fractionation procedures (cf. Glänzel et al., 2014 for multiple subject assignment in the context of Characteristic Scores at Scales at different levels of aggregation). A further issue arises from the different stages of the individual careers of authors at the same time; while the same publication year ensures the same age of papers in a given citation window, a pre-set publication year collects papers of scientists who are situated in completely different stages of their careers at the same time. The fact that a PhD student or post-doctoral fellow might collaborate with a senior scientist makes the situation even more complex. Thus the question arises whether the same reference standard derived from the data set should apply to the junior as to the senior co-author. And this leads us directly to the conceptual problem: What is the weight of co-authors and their profiles in determining standards for possible benchmarking exercises? This implies that large-scale statistics calculated on the basis of given publication periods and selected subject fields will not be appropriate as reference standards at the micro level but might indeed mirror the profiles of larger institutions and countries adequately and thus serve as general model at these levels of aggregation.
In this paper a triangular stochastic model analogously to the models used at higher levels of aggregation will be described and opportunities and limitations of such a model will be discussed. In the following we will mainly focus on the following questions.

1. What is the relationship between authors' productivity and their citation impact?
2. How can the relationship between the authors' citation impact and the impact of their publications be described?
3. What is the possible effect of co-authorship on these patterns?
4. Can any reference standard for evaluative studies be derived from the model and the empirical data?

This short introduction already adumbrates the possibilities but also the limitations of scientometric models that are created on the basis of the identification and assignment of individual authors. We optionally attempted to use Thomson Reuters' *Distinct Author Identification System* (DAIS), which is based on clustering author names, institution names, and citing and cited author relationships (Thomson Reuters, 2012). As all automated processes, this results in a broader coverage, but suffers from false positives. We have found nearly 30 authors with more than 300 papers each in 2011 according to the DAIS and the most productive author had 1272 WoS indexed papers. However, a simple manual check of names and profiles of authors associated with the same DAIS code revealed different persons with the same family name and first initial but partially different given names and different research profiles. In order to reduce uncertainty we decided therefore to use Thomson Reuters' ResearcherID in conjunction with journal articles published in the same year hazarding the consequences of representativeness bias. From the viewpoint of the model and the analysis this restriction is, however, immaterial. In this context we would like to stress again that the possible biases in representativeness of author selection is insignificant from the viewpoint of the creation and applicability of the model. More important in this context is the reliability of identification of the authors and their affiliations. Nevertheless, we will first have a look at representativeness of author selection on the basis of Thomson Reuters' ResearcherID (RID). This first part of the analysis forms a straight continuation of a previous study on productivity of registered authors by Heeffer et al. (2013).

Data sources and data processing

All papers indexed as articles, proceedings papers, reviews and letters in the 2011 volume of Thomson Reuters Science Citation Index Expanded (SCIE) have been selected. The reason for this choice of a single year publication window, which results from structural properties of author representation and productivity reflected by annual document indexation in bibliographic databases, is as follows. We have already mentioned at the outset that citation processes of scientific papers published in the same year have the following properties: Within a given citation window, all documents in the set have the same age at any particular time and the citation process is not *homogeneous*, that is, citation frequencies at the initial period differ from those at later stages. Paradigmatically this phenomenon has been characterised as a combination of phases of maturing and decline in citation processes (Glänzel & Schoepflin, 1995; Moed et al., 1998). As a consequence, enlarging the citation window will not simply result in a multiplication of citations by a factor proportional to the length of the window. The situation is completely different when a population with heterogeneous age structure is underlying the process and authors are constantly entering and leaving the system. While the citation process of a fixed document set can be described, for instance, by a simple birth process (e.g., Glänzel & Schoepflin, 1994), the publication distribution of an author set, which is subject to changes and interacts with the "environment", requires a different model taking also the effect of immigration and emigration into account. Such model has been proposed by Schubert and Glänzel (1984). This is the situation we find in any publication period in a bibliographic database: Newcomers are entering the author population, terminators are leaving the system and continuants are members of the population for a longer time including the complete period under study (cf. Price & Gürsey, 1976). As a consequence, publication activity in a longer time period can be simulated by multiplying productivity by a proportionality factor according to the length of the period. Therefore it is initially sufficient to select a shorter period of, e.g., one year as the basis of the analysis.

The reason why we have chosen the year 2011 was that in this particular year the share of papers with registered RID was the largest. We expected, of course, that this share will increase and that more authors will be registered in more recent years but the fact that this share decreases beyond 2011 is probably caused by the attitude of authors to update registration and register newly indexed papers not always immediately and regularly but rather intermittently. The choice of 2011 was also convenient because it allows the observation of citations in an appropriate time span. In addition to this publication year we could therefore choose the three-year citation window 2011-2013.

Methods and results

Theoretical considerations

As already mentioned in the previous section, the inclusion of productivity patterns in citation statistics permits insight into a complex system with the provision of a whole set of benchmarks and reference values. From the mathematical viewpoint, we deal with two basic variables that can stochastically be considered random variables, ζ expressing publication activity and ξ standing for citation rates. Yet the two variables are not assumed to be independent and it is commonly known that more prolific authors tend to be more cited as well. Therefore $P(\xi=i|\zeta=j)$ does not necessarily equal $P(\xi=i)$ for all $i, j \geq 0$ and the conditional expectation $E(\xi|\zeta=j)$, being a function of ζ and taking its values with probability $P(\zeta=j)$ is not necessarily constant. In our case, the following measurable variables occur: The publication activity of a (randomly chosen) author in the mirror of the SCIE database in 2011, the citation impact of a (randomly chosen) paper indexed in the 2011 volume of the SCIE and the citation impact of an author with one or more papers in 2011 with the intermediate conditional

measure of citation impact, provided the author has a given number of publications $j \geq 0$ in 2011.

The following mathematical description, which is indeed necessary to avoid confusions, will, however, be restricted to the absolute necessary. The first question formulated in the introduction relates to the relationship between authors' productivity and their citation impact. This can be formulated as follows. Since citation impact is always measured through the citation rates of individual publications, an author's citation impact can theoretically be obtained as

$$P(\xi=i) = \Sigma_j P(\xi=i|\zeta=j)\cdot P(\zeta=j) \text{ for all } i \geq 0,$$

with the corresponding expectation

$$E(\xi) = \Sigma_j E(\xi|\zeta=j)\cdot P(\zeta=j).$$

Index j is assumed to be positive because the trivial case $P(\xi=i|\zeta=0) = 1$, if $i = 0$ and $P(\xi=i|\zeta=0) = 0$, otherwise, can be excluded (no citations without publications). The corresponding statistics are then denoted as $f_i|j$ and $x|j$. Both statistics (conditional empirical distribution and mean value) refer to the citation impact of authors. Furthermore, the corresponding conditional mean citation rate of an author's *papers* can be obtained by dividing $x|j$ by the number of papers j, that is, $(x|j)/j$ with $j > 0$ is an estimator of the expected citation rate of the individual papers of an author with j papers in the given publication year.

In order to tackle the second problem, we have to introduce a third variable, which will complete the triangular model. Using the notation η for the citation impact of a single paper by an individual author, we obtain a more complex formula than above for the conditional probabilities taking all possible combinatorial combinations concerning number of publications and their citations into account but the relationship of their expectations simply reduced to $E(\xi) = E(\eta)\cdot E(\zeta)$. Under the simple assumption that the likelihood not to be cited is the same for all papers of the author, i.e., $q = P(\eta=0)$ for all $j > 0$, we can approximate the probability of author uncitedness and citedness as $P(\xi=0) = \Sigma_j q^j \cdot P(\zeta=j) = P(\eta=0)^j$ and $P(\xi>0) = 1–P(\xi=0)$, respectively. The reason for the relative simplicity of this expression is that uncitedness of an author in a given period implies that none of his/her papers is cited. The extreme cases $P(\xi=0) = 0$ and $P(\xi=0) = 1$ are obviously equivalent with $q = 0$ and $q = 1$, respectively. We will denote the empirical value of q by g_0. Using the mean values x, z and y as estimators of expected citation rate of an author, the expected publication activity of an author and the expected impact of the author's papers, respectively, we obtain the simple relationship $x = y\cdot z$. From the elementary considerations we can conclude that at least basic statistics can be readily expressed with the aid of two variables.

Finally, it might be worth mentioning in this context that the above random variables and the corresponding statistics also form the groundwork for modelling Hirsch-type indices, notably their cumulative versions such as the successive h-index (e.g., Schubert, 2007).

The sample

The sample of RID authors does – as already observed by Heeffer et al. (2013) – not form a *random sample* of the complete author population in the database as RID authors are less frequent at the low end (particularly among single-paper authors), and are more productive at the high end of the productivity distribution.

Switzerland	23582	1.29	1.73	3.3%	1.38	2.16	5.0%	34.6%
Taiwan	25550	0.92	0.93	1.1%	1.19	1.55	2.9%	17.0%
Thailand	5819	1.08	0.89	1.0%	1.32	1.48	2.6%	16.9%
Turkey	22571	1.02	0.63	0.8%	1.39	1.34	2.7%	12.8%
UK	91438	1.16	1.46	2.4%	1.28	1.90	3.9%	31.6%
USA	333610	1.09	1.40	2.2%	1.25	1.95	3.9%	20.0%
World total	1229248	1.00	1.00	1.2%	1.13	1.42	2.2%	21.1%

Nevertheless, from the viewpoint of the objectives of this study, this bias is primarily insignificant. In total we have 1,229,248 documents among which 259,341, that is, 21.1% had

at least one registered (RID) author. This share considerably varies among countries. The share ranges between about 10% in Africa, Arabic countries and India till about 50% and even more in Brazil, Singapore and Portugal.

Table 1 displays statistics of countries with at least 5,000 publications in 2011. In particular, the variable RCR represents the relation of observed citation impact and the corresponding journal-based expectation, NMCR stands for corresponding relation between observation and discipline-based expectation and %HC is the share of highly cited papers, that is, of papers that have received at least seven times as many citations as the standard of their discipline (see Glänzel et al., 2009 for exact definitions). The last variable %RID, finally, expresses the share of papers with (at least one) author with registered RID. The comparison of relative citation rates and the share of highly cited papers provides empirical evidence that papers by registered authors exhibit distinctly higher citation impact than the corresponding national standards. We would also like to mention that only very few exceptions have been found in smaller countries not displayed here, e.g., Jordan and Latvia, where the share of highly cited papers and the RCR values did not reach their national standards created by all authors.

Representativeness of publications by authors with RID in individual subject fields is in line with our intuitive expectations: The share of papers by RID authors is the lowest in Mathematics (13.0%), clinical and experimental medicine (14.2% for general & internal medicine and 14.2% for non-internal specialties) and engineering (18.7%). This is contrasted by the corresponding shares in physics, chemistry and biosciences (29.8%, 28.5% and 25.0%, respectively).

Productivity and impact of RID authors

The bias in publication-activity statistics of registered authors has already been stressed (cf. Figure 3 in Heeffer et al, 2013). In particular, RID authors are less frequent at the low end, and more productive at the high end of the productivity scale. Figure 1 shows the distribution of papers over RID authors in 2011. The underlying data are based on the short period of only one year so that the share of single-paper authors is consequently large. Nevertheless, the productivity distribution has the expected long tail: 87 authors have (co-)authored more than 50 papers each. We just mention in passing that the maximum count amounted to 296. This almost incredibly large annual publication output of publishing almost one paper a day is, however, formally correct. The author with an affiliation at the University Sains in Malaysia and a second, more recent one at the King Saud University in Saudi Arabia is active in crystallography. In this context we have to notice that the number of his co-authors per paper is rather low, so that even fractionation would not essentially decrease this author's publication count. This example also illustrates that conceptual issues might have more weight than the number or seniority of co-authors. Before we discuss field-specific aspects of authorship statistics, we still have a look at general citation patterns.

In Figure 2, the citation distribution over authors is compared with the corresponding distribution by papers. In addition to the two series of bars expressing the frequency of citations by RID authors and their papers, respectively, a solid line displays the citation distribution of all papers indexed in the SCIE database to illustrate the bias of the sample. The more moderate skewness and greater expectation of the distribution of citations over authors are plausible and in line with the theoretical rudiments described in the previous subsection since usually we have $z > 1$ and $g_0 \in (0, 1)$.

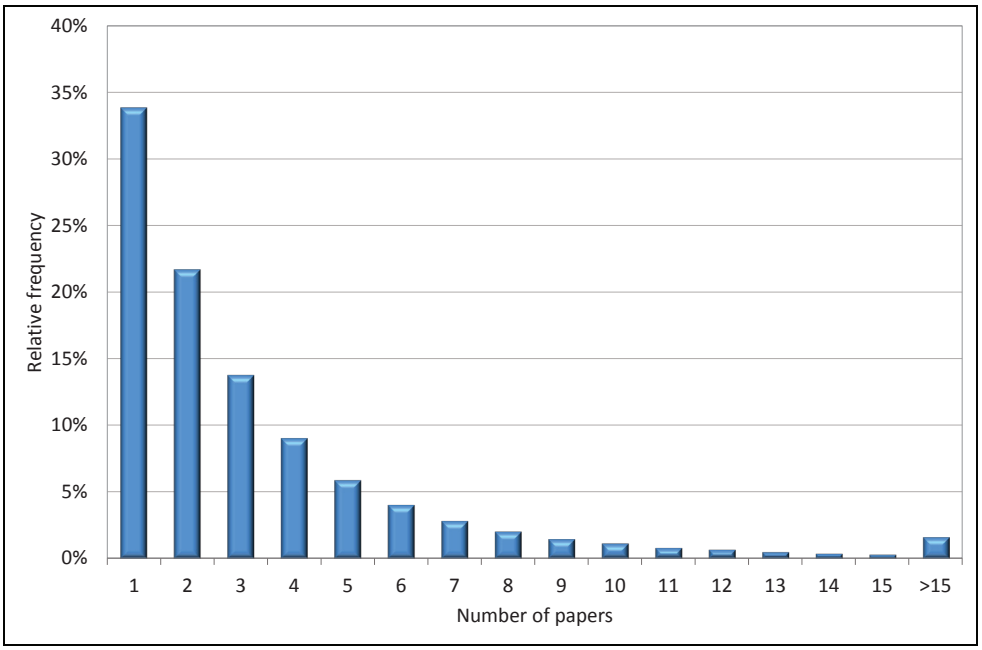

Figure 1. Relative frequency of publication activity of RID authors in 2011. [Data sourced from Thomson Reuters Web of Science Core Collection].

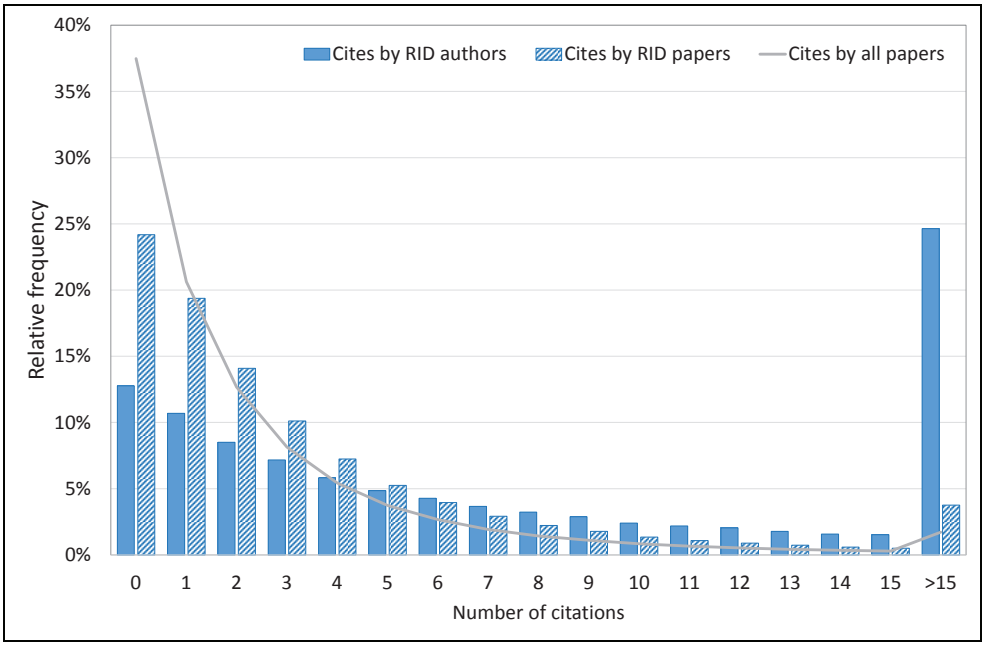

Figure 2. Empirical citation distribution related to RID authors in 2011 in a 3-year citation window. [Data sourced from Thomson Reuters Web of Science Core Collection].

A simple regression analysis aims at studying the relationship of productivity and citation impact of authors, on the one hand, and his/her publications, on the other hand. Conditional mean citation rates in the citation window 2011–2013 received by papers published in 2011 by registered authors have been plotted against their productivity (see Figure 3). Productivity higher than 32 papers has been omitted because of low frequency and considerably fluctuations beyond this level. A power-law model for author citations reflects a very strong correlation, whereas the regression for article citations by authors proved to be linear with somewhat weaker correlation.

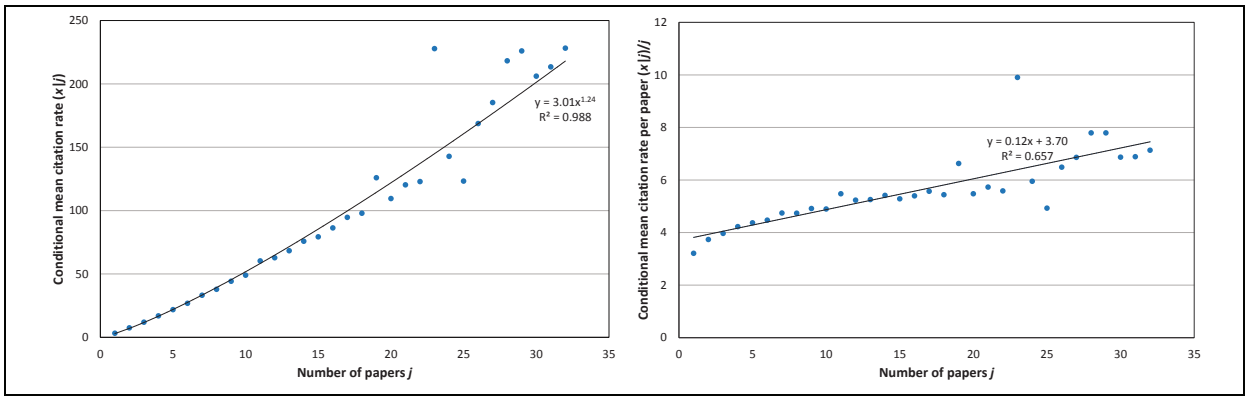

Figure 3. Plot of conditional citation impact of RID authors (left-hand side) and RID papers (right-hand side) based on a 3-year citation window vs. productivity in 2011 [Data sourced from Thomson Reuters Web of Science Core Collection].

While a positive effect of productivity on the expected citation impact of authors was, of course, expected (an increase of papers cannot result in less citations), the positive correlation between number of papers and the mean citation rate of *those* papers is as such not necessarily an inherent property of the model and as we described in the first subsection, the three variables ξ, ζ and η are not assumed to be independent. This indeed substantiates that the publication output of more productive authors exhibit also higher mean citation rates of their output. We have to emphasise that this holds at least for registered authors.

Table 2. Indicators of productivity and citation impact of RID authors and their papers by major science fields. [Data sourced from Thomson Reuters Web of Science Core Collection].

Field	*y*	*z*	*x*	f_0	g_0

In order to conclude the analysis, we have calculated the mean values of the basic statistics *x*, *y* and *z* as well as the shares of cited authors and papers f_0 and g_0 by subject fields (see previous subsection for description). Table 2 shows these indicators for the 12 major fields in the sciences according to the Leuven–Budapest classification scheme (see Glänzel & Schubert, 2003). As explained in the theoretical part $x = y \cdot z$, $x \geq y$ and $f_0 \leq g_0$ is to be observed. Also subject-specific peculiarities are expected. The *y* and g_0 values concerning the citation impact of papers are by and large in line with the expectations: high impact and low

share of uncited papers in the biomedical sciences and the opposite situation in engineering and mathematics. Nevertheless, the very high impact of chemistry (with low uncitedness) was somewhat surprising and somewhat deviates from the general citation patterns of the fields. Chemistry seems also to be somewhat overrepresented in terms of author registration; 33.5% of all RID authors are active in this field. This is followed by physics with 27.4% and biosciences with 20.8%. All other fields have shares of registered authors below 20% with neuroscience and mathematics having the lowest ones (7.6 % and 4.4%, respectively). In this context we have to mention that the distribution of shares of RID authors over fields is rather strongly correlated with the corresponding distributions of their papers ($r = 0.928$). Hence the question arises whether statistics as presented in Table 2 could be used as reference standards for publication activity and citation impact of authors at the national or institutional level. It has already be stressed in the introduction that an application at the individual level is not recommended because of the heterogeneous age and profile structure of the underlying reference data. Other details regarding this question will be tackled in the following subsection.

Limitations

After the methodological groundwork has been laid for capturing and describing the relationship between productivity and citation impact of authors and their papers, we have also to look at considerable limitations of possible applications of the indicators derived from this model. The low variation of average productivity over subject fields gives already a first hint of possible issues. As already observed by Heeffer et al. (2013) on the basis of the three-year publication period 2009–2011 and RID authors from eight selected countries, the distribution of average productivity was rather flat and ranged – except for physics – roughly between 2 and 3 papers by RID author. Only the average activity in physics with 5 papers per author was distinctly higher. The accustomed and specific inequality of citation impact of papers in different subject areas is almost missing in the productivity statistics what surprises since it is known that scientists in mathematics and engineering are usually less productive – at least as reflected by journal literature – than their colleagues in most fields of the natural and above all in the life sciences. The reason for the observed phenomenon is quite complex but readily explicable. In order to discuss this in detail we have first to refer to the corresponding statistics on citation rates of given paper sets. Provided that the publication year or period as well as the citation window is properly defined and chosen and the subject classification is appropriate, multiple subject assignment of individual papers is then the only severe issue to cope with. Various fractional counting and weighting models have been developed to overcome this problem and to build suitable reference standards for benchmark analysis. Even for more complex statistics than simple shares and means, fractionation by subject can still yield extremely robust statistics as the methods of characteristic scores and scales has shown for various citation windows and aggregation levels (cf. Glänzel, 2007; Glänzel et al., 2014). The question of co-authorship, in general, and how the individual co-authors' actual contribution to a paper should be credited, in particular, is at least in the context of paper-based citation indicators a secondary issue and not primarily related to the definition of citation indicators. The situation becomes completely different, whenever author productivity is directly included in indicator building as, for instance, in our "triangle model" based on the author-paper-citation relationship. The different (academic) age and the different profiles of authors have already been mentioned as possible sources of bias or even distortion, notably in the context of creating benchmarks for individual-author statistics. The most serious issues are related to co-authorship and cannot be simply solved by fractionation by co-authors and/or subjects. Collaboration of senior with junior co-authors, that is, of authors with strong publication record and less active authors, independently of their actual contribution to

the paper in question and their function in preparing it, might have quite strong effect on the resulting indicators at the author level but also at higher level of aggregations. Here we would also like to point to two further issues, firstly the fact that a prolific author in one subject might only play a marginal part as researcher in a different subject in which he/she is collaborating with a possibly less prolific author, who, however, takes the part of the senior co-author of the paper(s) in this topic. Secondly, when it comes to measuring citation impact, an uncited author might be a co-author of a frequently cited author but the joint publications are not cited. This also implies that a mere author–citation analysis in conjunction with productivity studies does not yet suffice; an additional paper–citation analysis is needed for an adequate interpretation. And it becomes clear that a simple fractionation algorithm will not be able to solve these problems. A superposition of fractional counting at three levels (co-author credit, assignment by author profile and subject of publications) is required to solve at least the technical part of this problem: the large overlap by multiple assignments (authors, papers, subjects) could, of course, be resolved and indicators could then be additive over these actors and units at the price of very low robustness. Finally, the most important conceptual issue described in this subjection, the different roles of authors in different environments, will never be solved by using any algorithm.

Concluding discussion

Elementary statistics including relative frequencies and (conditional) mean values have been used to illustrate a simple model of the author-paper-citation relationship. Both opportunities and limitations have been sketched. The use of a joint model for studies of author productivity and impact at higher levels of aggregation is a topical issue in scientometrics: Hitherto the celebrated but also disputed h-index (Hirsch, 2005), originally proposed for the assessment of research performance at the micro level, was the only one that has combined these two aspects, and afterwards been extended for the use at higher aggregation level in the context of institutional and journal evaluation as well.

For illustration purposes, we have selected authors with ResearcherID and active in 2011 in order to exclude errors in author identification as far as possible. Of course, we have to mention that homonyms and synonyms still occur in RIDs too (cf. Heeffer et al., 2013) but the weight of errors is reasonably small. The main advantage of this model is the possibility of studying citation impact under the condition of the author's productivity, and the identification of high performance in terms of both productivity and impact. However, the same precision as experienced with "classical" citation indicators defined on paper sets could not be reached. The main problem is of conceptual nature: Authors and their papers might hold a different position in various environments created by co-authorship of subject-related issues. This has already induced Hirsch to revise his index in terms of co-authorship (Hirsch, 2010). His new indicator also substantiated that complex constellations cannot be described by separately fractionated parts of the model.

The conclusions drawn from this study are two-fold: On the one hand, author-identification systems need to extended in a reliable way to reach a nearly complete coverage of the author population in the database so that indicators based on author IDs can be considered representative enough to be used as reference standards. The limited discriminative power of author-based indicators and the heterogeneity of the underlying author population, on the other hand, prevents the use of the indicators for the analysis of individual research performance as well as in the context of fine-grained benchmark studies at higher levels of aggregations.

Finally, we would like to emphasise again the necessity and general use of the model introduced in this study, which is formally independent of any author-identification system. The model makes is possible to formalise and describe the relationship between authors, their

publications and the citations those publications receive. The neglect of the structural properties and peculiarities of this "triangle relationship" might result in misinterpretation or even miscalculation of statistics and indicators at this level. The use of author identification in this context is an important means of demonstrating the measurement of this relationship for at least a considerable share of active authors.

Abstract
Advances concerning publication-level classification system have been demonstrated striking results by dealing properly with emergent, complex and interdisciplinary research areas, such as nanotechnology and nanocellulose. However, less attention has been paid to propose a delineation procedure using specific subjects and understand how it could provide interesting regards about it. This study aimed at proposing a delineation procedure to retrieve relevant research areas addressed to nanocellulose using the research areas clustered by the CWTS Web of Science Publication-level Classification System. The procedure involved an iterative process, which includes developing and cleaning set of core publication regarding the subject and analysis of which cluster they might be associated. Nanocellulose was selected as the subject of study. A discussion about each step of the procedure was also provided. The proposed delineation procedure enabled to retrieve relevant publications from research areas involving nanocellulose. Twelve research topics were identified, mapped and associated with current research challenges on nanocellulose.

Conference Topic
Methods and techniques

Introduction
In recent years, bibliometrics has been used often to monitor and quantitatively assess scientific fields within the context of science policy and research management (Moed, Glänzel, & Schmoch, 2004; Okubo, 1997; Raan, 2014). Partly, it is a consequence of the increased use of Internet since the early 1990s and the development of information technologies. Together, they made a huge volume of scientific databases available. Meanwhile, scientific studies have become more complex and interdisciplinary, involving the exchange of knowledge between scientists from different disciplines. Nanotechnology-focused research is a good example. Bibliometric indicators and tools are useful instruments to study and gain insight in science and, in particular, complex fields or research areas, c.f., van Raan (2004). Therefore, many studies on nanotechnology relied on bibliometric approaches (Hullmann & Meyer, 2003; Igami, 2008; Kostoff, Koytcheff, & Lau, 2009; Milanez, Faria, Amaral, Leiva, & Gregolin, 2014; Mogoutov & Kahane, 2007; Wang, Notten, & Surpatean, 2012). The problems often are: how to delineate a field or research area, how to retrieve the relevant data, and which publications to include and which not.

In this sense, classification systems have been used as an indispensable tool to study the structure and dynamics of scientific fields (Boyack, Klavans, & Börner, 2005; Glanzel & Schubert, 2003; Leydesdorff, Carley, & Rafols, 2013; Waltman & van Eck, 2012). They can simplify literature search and retrieving procedures (Glanzel & Schubert, 2003; Waltman & van Eck, 2012). According to Glanzel and Schubert (2003), classification of science into a disciplinary structure can be as old as science and, currently, most of them are based on journal assignment, such as the Web of Science and Scopus systems. The drawback of these

journal-based classification systems is the fact they do not deal properly with multidisciplinary journals or interdisciplinary research (Waltman, van Eck, & Noyons, 2010).

The development of publication-level classification systems has been a current subject of research (Boyack et al., 2011; Waltman & van Eck, 2012). Boyack et al. (2011) clustered a corpus of 2.15 million biomedical publications from Medline database (2004-2008) which generated coherent and concentrated cluster solution of text-based similarity approaches based on keywords extracted from titles and abstracts. They found their approach more precise than the Medical Subject Headings. Waltman and van Eck (2012) proposed a methodology to clustering a large-scale set of scientific publication indexed on Thomson Reuters' Web of Science database. Each publication was assigned to a single research area, which was organized in a three-level hierarchical structure. Their methodology took into account direct citation to cluster the publication. They labelled each research area with discriminative keywords extracted from titles and abstracts. Such publication-level classification systems may be used to gain insights on research areas involved in specific subjects.

In the present study, we intended to map relevant research areas associated with nanocellulose, which is a sustainable nanomaterial that has a great potential for innovation (Isogai, 2013; Mariano, Kissi, & Dufresne, 2014; Milanez, Amaral, Faria, & Gregolin, 2013; Moon, Martini, Nairn, Simonsen, & Youngblood, 2011). Nanocellulose has been a research area for many countries, including the major producers of cellulose worldwide, such as the USA, Canada, Finland, Sweden and Brazil (Milanez et al., 2013). Different disciplines are involved with nanocellulose research since its properties and behaviour have allowed applications as reinforcement agent in composite materials, packing material, optically transparent paper for electronic devices, texturizing agent in cosmetics and food, bio-artificial implants and bandages (Isogai, 2013; Klemm et al., 2011; Mariano et al., 2014; Moon et al., 2011; Siqueira, Bras, & Dufresne, 2010).

Nanocellulose is a generic term referring to cellulose nanofibrils on the one hand and cellulose nanocrystals on the other (Dufresne, 2013; Klemm et al., 2011; Moon et al., 2011; Siqueira et al., 2010; TAPPI, 2011). Cellulose nanocrystals are basically shorter and rod-like crystalline cellulose, whereas cellulose nanofibrils are long chains of alternate amorphous and crystalline cellulose. Consequently, they differ on their mechanical and functional properties (Eichhorn et al., 2010; Mariano et al., 2014; Moon et al., 2011). Both types of nanocellulose can be obtained from renewable sources, including natural fibres, plants, pulp and forest and agricultural residues. Moreover, cellulose nanocrystals can be biosynthesized by bacteria, resulting in the also called bacterial cellulose (Klemm et al., 2011; Milanez et al., 2013; Moon et al., 2011).

Checking the research topics associated with nanocelluloses will provide insights into current technical challenges concerning this nanomaterial, such as increasing the scale of production minimizing costs, characterization of sources and mechanical properties. Surface modifications to reduce moisture adsorption and improve the adhesion between the nanomaterial and the polymeric matrix, thermal degradation, and biocompatibility with living tissues has also been target of research (Gardner, Opo, Oporto, Mills, & Samir, 2008; Isogai, 2013; Klemm et al., 2011; Mariano et al., 2014; Milanez et al., 2013; Moon et al., 2011; Siqueira et al., 2010).

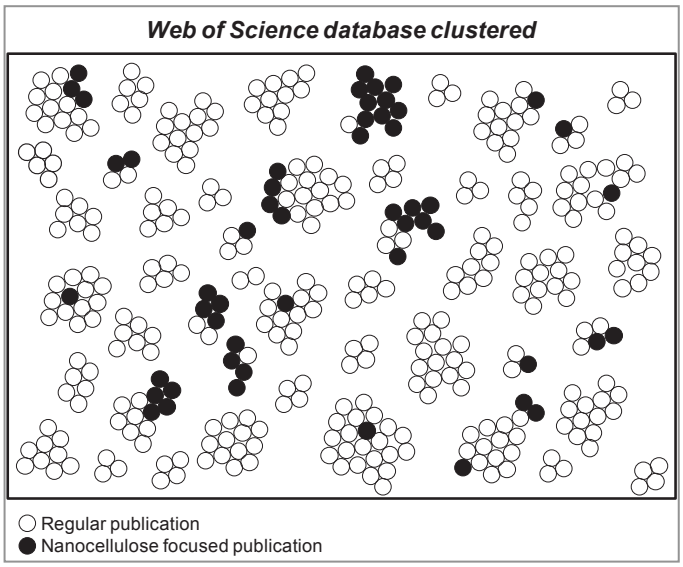
This study aims at proposing a delineation procedure to retrieve relevant research areas addressed to a specific topic. Nanocellulose was selected as a case, but it may be used for other subjects, of course. The approach involves research areas identified in the CWTS Web of Science Publication-level Classification System, a 2014 update of the version introduced by Waltman & van Eck (2012). This paper is structured as follows. In the next section, we describe the overall delineating procedure and its general issues. Next, we discuss details

concerning specific parts and tasks. We present and discuss results in Section 3 and finally in Section 4 we draw our conclusions.

Methodology

Overall delineation procedure

To delineate the field, i.e., to collect a relevant set of publications to represent it, we will select clusters from the CWTS publication level classification system. By this method we will identify papers that will not easily be picked up by keyword or journal based search strategies. Figure 1 presents a schematic representation of the distribution of the clustered Web of Science publications according to CWTS Publication-level classification system (Waltman & van Eck, 2012). Predefined nanocellulose publications are indicated as black circles and the first step is retrieving all research area that contains at least one of them.



Source: authors.

Figure 1. Schematic representation of Web of Science publications clustered according to the CWTS Publication-level Classification System. The black nodes represent the publications focused on nanocellulose.

Figure 2 depicts the proposed procedure as an iterative process which can be described in four main steps:

1. *Determine an initial set of publication concerning the theme of interest.* In this first step, a set of publication which well represents the theme of interest (nanocellulose) is retrieved via the online Web of Science database, using a straightforward search strategy. This set of publication is a starting set and will be refined as well as expanded through the next steps;
2. *Prior retrieval of nanocellulose research areas*. The second step involves locating the research areas (publication clusters) with at least one publication from the initial set of nanocellulose. The bottom level of the classification scheme was used in this study (Waltman & van Eck, 2012);
3. *Analysis of retrieved research area and cleaning of the initial set*. The content of each research area was analysed pragmatically. A cleaning task was developed by selecting terms to eliminate part of the initial set of nanocellulose publication. This step provided a final set of nanocellulose publication clusters and enhanced the precision of research area assigned to nanocellulose;

4. *Final retrieval and selection of relevant nanocellulose research areas*. After cleaning the initial set of nanocellulose publication, the research areas (publication clusters) were retrieved again. Finally, as the number of topics retrieved was high, a selection that relies on the 80/20 rule was conducted reaching the final research areas associated with nanocelulose.

Figure 2. Iterative process of the overall procedure proposed.

Determine an initial set of publication on nanocellulose

A search expression was developed considering several terms and synonyms recommended by experts and found in nanocellulose literature (Klemm et al., 2011; Milanez et al., 2013; Siqueira et al., 2010; Siró & Plackett, 2010), as can be seen from Table 1. The search expression encompassed different words that refer to cellulose nanocrystals, cellulose nanofibrils, and bacterial cellulose as well as other generic forms, such as nanocellulose, cellulose nanoparticles, and cellulose nanofiller. The search was conducted in March 31th 2014 in the online Web of Science database (topic search). Only articles that attended the CWTS Web of Science publication-level classification system criteria[1] were used, though.

Prior retrieval of nanocellulose research areas

Research areas that contained at least one publication from the nanocelulose set were retrieved from the CWTS Web of Science Publication-level database. In total, 533 research

[1] The classification system takes into account only *article*, *letter* and *review* published from 2000 to 2013 and indexed in the Science Citation Index Expanded and the Social Science Citation Index. Moreover, to be part of one research area, a publication must be related, either directly or indirectly, to at least 49 other publications in terms of citation (Waltman & van Eck, 2012).

topics were found. These clusters showed large differences in terms of volume (number of publications included). The largest cluster contains 2,751 publications whereas the smallest one covers only 50 publications. Almost 80% of these clusters contained less than three publications from the initial set.

Interestingly, we found that two research areas (clusters) included 56.3% of the initial nanocellulose set of publications. Moreover, in these two clusters, more than 80% overlapped with the initial set. Their descriptive labels also pointed towards nanocellulose research. Therefore, they were considered as nuclei of research in nanocellulose. Other clusters in which the representation of the initial set was much lower, were considered peripheral research areas and their relevance to nanocellulose research was evaluated (see next section).

Analysis of retrieved research area and cleaning of the initial set

An analysis of the content of publications in the peripheral research areas was conducted. We wanted to check whether these articles focused on the nanomaterial as an object of research. If not they were considered noise. Because an evaluation of all research area retrieved would be too labour intensive, we made a selection. The checking task was performed only on those clusters that matched one of the following criteria:

- Research topics that contained at least 20 publications from initial dataset;
- Research topics of which at least 5% overlapped (percentage proportion) with the initial set.

A total of 20 (peripheral) clusters were evaluated. The analysis regarded only articles from the initial dataset. The task involved reading each title to decide whether the article was a study focused upon nanocellulose or not. When the title was not clear, the abstract was also consulted.

Once the checking process was completed, specific terms were identified to clean the initial set of nanocelulose publications. Only research topics with high percentage of "noise publication" were used[2]. Noun-phrases were obtained with support of VOSviewer corpus map analysis applied to titles and abstracts from publications belonging to these clusters. Table 2 present the terms used to clean the nanocellulose-focused publications retrieved using the search expression from Table 1. They were applied on the title, abstract, author's keyword and keyword plus search field. The effect of this cleaning task on the nuclei clusters and the peripheral clusters we used will be discussed in the results.

Final retrieving and selection of relevant research areas

The final set of nanocellulose publication comprised 2,600 nanocellulose publications (named now as core-nanocellulose) and they were assigned to 428 research areas, which still would be a highly number of cluster to be evaluated. Furthermore, 81.0% of these clusters included only one or two publications from the core-nanocellulose publication, which questions their actual relevance to the advances on nanocelulose studies. Therefore, a selecting step was introduced.

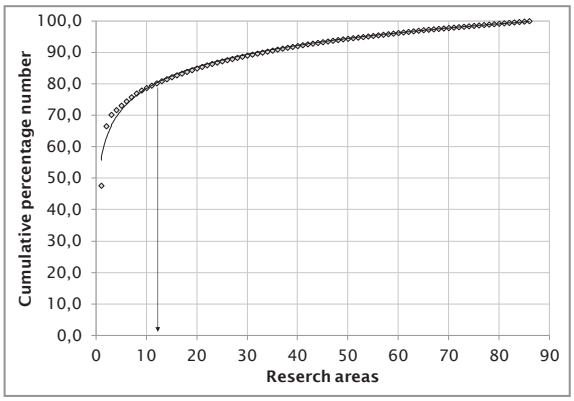
We introduce here the *Pareto Principle* (or 80/20 rule). This principle states that "roughly 80% of the effects come from 20% of the causes" (Juran & Godfrey, 1998) and is found in

[2] The presence of "noise publications" is usual in bibliometric analysis because there is no exhaustive search.

bibliometric and library studies (Gupta, 1989; Kao, 2009; Stephens, Hubbard, Pickett, & Kimball, 2013). We hypothesize that 80% of the core set will be assigned to 20% of the areas. To reach these relevant research areas, the steps below were carried out:

1. The research areas were listed in descending order of the total number of publications from the core-nanocellulose;
2. Research topics with one or two publications from the core-nanocellulose were excluded[3]. This yields 85 research areas remaining;
3. The representativeness of each research area was calculated by the number of publication of the core-nanocellulose of that cluster divided by 2,200 (which is the total of publication found in the 85 remaining research areas);
4. The cumulative percentage number of publications from the core-nanocellulose was obtained summing the values from the step before, as can be seen from Figure 3. The number of research to be assessed was those where the cumulative percentage number of publication reach approximately 80%.

We found that twelve research areas covered the required 80%, which means 14.1% of the total of 85 research topics. We do not claim that our selecting procedure was perfect, but a quick analysis of the chosen research topics showed themes currently found in nanocellulose literature.



Source: CWTS Web of Science Publication-level database.

Figure 3. Cumulative percentage number to research areas with six or more publications from the core-nanocellulose.

Independency test

An independency test was conducted to evaluate the effectiveness of the procedure proposed. The test involved retrieving the number of publication from the top five authors before and after cleaning and selecting the relevant research areas. The percentage decreases of their overall number of publication and from their main cluster were verified.

Results and discussion

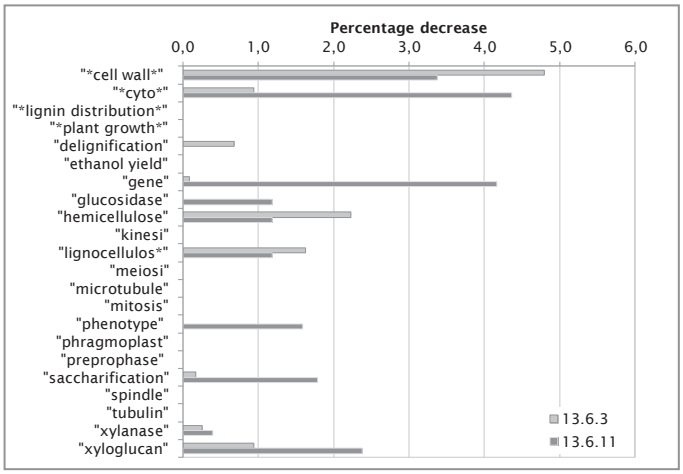
In this section we discuss the effect of cleaning up the core set of publications by using 'cleaning terms', i.e., terms to increase the accuracy of our initial set. Moreover, we present a basic structure of the field on the basis of the delineation we developed.

Effect of cleaning the initial set of nanocellulose publications

Half of the 22 terms we used to clean the nanocellulose search strategy did not affect the coverage of core-nanocellulose publications in the nuclei research areas, as depicted in Figure

[3] According to Waltman and van Eck (2012), the lowest research area contains 50 publications, consequently, clusters with less than 1% of proportion were not accounted for.

4. To the other half, none term could reduce the coverage in more than 5%. The terms that influenced research area 13.6.4 the most were "*cell wall*" and "hemicelluloses" while "*cyto*", "gene" and "*cell wall*" were the ones that decreased the most core-nanocellulose coverage in cluster 13.6.11. Overall, research topic 13.6.11 had its core-nanocellulose publication reduced in 17.5% while the decrease to cluster 13.6.3 was 10.2%. Nonetheless, both clusters still concentrated publication from the core-nanocellulose after the cleaning tasks (the proportion was 74.0% to research area 13.6.3 and 72.1% to 13.6.11). Therefore, they still had the status of nuclei research areas.



Source: CWTS Web of Science Publication-level database.

Figure 4. Effect of cleaning terms on the number of publication from nuclei research areas.

As to the 20 peripheral research topics whose nanocellulose set of publication were evaluated, no direct correlation was observed between the proportional relevance of each clusters and the percentage of noise, according to Figure 5. Four research topics had a high percentage (>70%) of 'noisy' publications mainly focusing on biological issues of plants, ethanol production, and enzymes aspects, not having the nanomaterial as a final object of research. Since these four were used to select the cleaning terms, the cleaning affected them highly. Two of them were even eliminated. Furthermore, other peripheral clusters had their nanocellulose publication coverage diminished, as shown on Figure 6.

Figure 6. Effect of cleaning terms on the number of publication from selected peripheral research areas.

Effect of cleaning procedure on top five authors (independency test)

A second test verified the effect of the cleaning process on the coverage of key-authors (top 5). The decrease in the number of publication is presented in Table 3. All authors concentrated their publications on nuclei research topics, mainly on 13.6.3. Only author E focuses primarily on research area 13.6.11. Although the result shows that the overall number of publication diminished in more than 10%, their position as the top authors did not changed but for author E, who went down to the seventh position. It should be noted, however, that research area 13.6.11 was affected more by the cleaning procedure than 13.6.3.

Table 3. Effect of on main authors publications.

Author	*Number of publication*		*Decrease (%)*	
	*Before**	*After**	*Overall*	*Nuclei*
A	87	78	-10,3	-6,33
B	51	40	-21,6	-14,9
C	50	43	-14	0
D	50	39	-22	-18,2
E	48	29	-39,6	-26,5

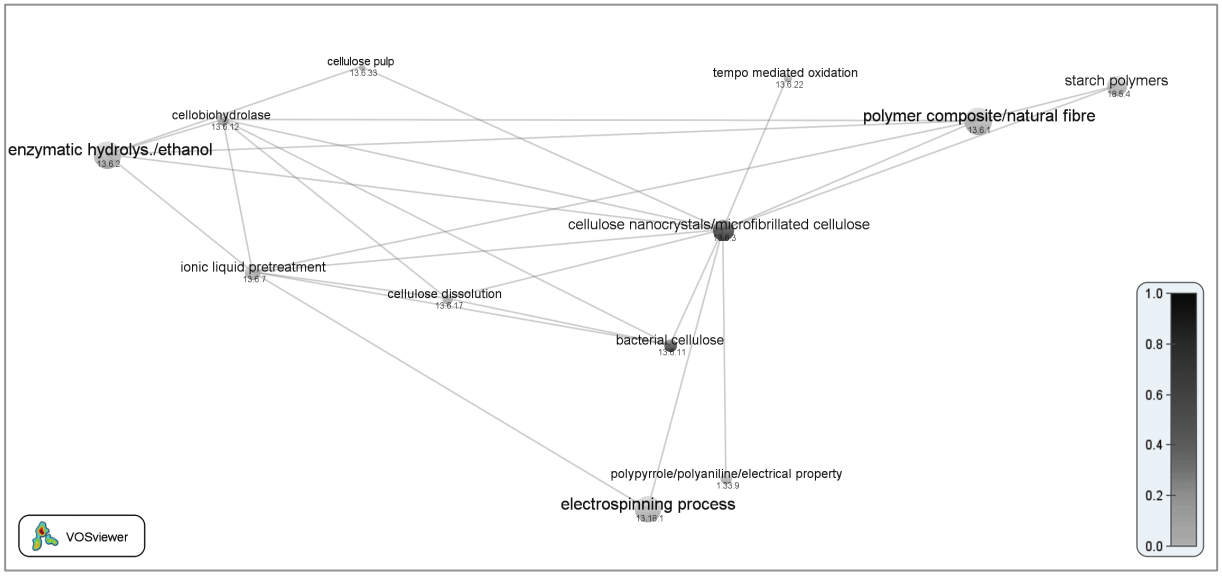
Map of the Nanocellulose research topics

The delineating approach was able to retrieve two nuclei research areas, one associated with cellulose nanocrystals and nanofibrils and other to bacterial cellulose. The peripheral research topics regards biodegradable polysaccharides (starch polymers), polymer composites based on natural fibres, and intrinsically conducting polymers. Other peripheral research areas included enzymatic hydrolyses and ethanol production, cellobiohydrolyse, cellulose pulp and cellulose dissolution, and ionic liquid pre-treatment. Electrospinning process and tempo mediated oxidation, which is an treatment that uses the chemical compound (2,2,6,6-Tetramethylpiperidin-1-yl)oxy (TEMPO), were also part of the final selection. These themes appears frequently in nanocellulose-focused studies (Azizi Samir, Alloin, & Dufresne, 2005; Charreau, Foresti, & Vazquez, 2013; Chirayil, Mathew, & Thomas, 2014; Dai et al., 2014; Domingues, Gomes, & Reis, 2014; Durán, Lemes, & Seabra, 2012; Eichhorn et al., 2010; Isogai, 2013; Klemm et al., 2011; Moon et al., 2011; Orts et al., 2005; Pääkkö et al., 2007; Siqueira et al., 2010; Siró & Plackett, 2010)

Figure 6 presents a map with these research topics (nodes). The map positions the topics on the basis of their citation relations. The closer two topics, the more frequent the citation traffic between them. The node labels match the main content of the clusters. Moreover, all selected clusters had their set of nanocellulose publication evaluated in the cleaning task.

The nuclei research areas are darker and positioned in the centre of the map. Research area 13.6.3 (cellulose nanocrystals/microfibrillated cellulose) has citation connections to all clusters. On the other hand, research topic 13.6.11 is connected only with four other clusters, which might indicate its lower relevance than the other nucleus research area. At the top right of the map are located two research areas addressed to starch polymers and polymer composites based on natural fibres. These research topics regard the development of sustainable materials (Durán et al., 2012; Moon et al., 2011; Siqueira et al., 2010; Isogai, 2013).

Research area concerning enzymatic hydrolysis is highly close to the research topic cellobiohydrolase, i.e., enzymes that perform the process of hydrolyse, and ionic liquid pre-treatment, which also relies on enzymatic approaches. However, they were located further than the nuclei clusters. Indeed, one of them was considered as highly noisy (13.6.2), but we should take into account that nanocellulose obtainment has been also studied as a secondary product of bio-ethanol production (Beecher, 2007; Zhu, Sabo, & Luo, 2011). Moreover, enzymatic pre-treatment has been researched to improve nanocellulose defibrillation (Pääkköet al. 2007; Moon et al., 2011; Klemm et al., 2011; Siqueira et al., 2010; Isogai, 2013).



Source: CWTS Web of Science Publication-level database.

Figure 6. Selected research area according to the procedure proposed.

At the bottom of the map, electrospinning process and conductive polymers were positioned closely, but there is no citation connection between them. Electrospinning is a technique used to produce micro- and nano-sized polymer-based fibres, and nanocellulose has been studied to improve the mechanical property of the final fibre (Dai et al., 2014). Nanocellulose electrical and magnetic properties have also been explored to be used with conductive polymers (Moon et al., 2011; Klemm et al., 2011). The other three research areas (cellulose pulp, cellulose dissolution and tempo mediated oxidation) are the smallest ones, and probably the publications that belong to them might be associated with other clusters on new updates performed using the classification system (Waltman & van Eck, 2012). Tempo mediated

oxidation is a current technique to perform pre-treatment of nanocellulose (Klemm et al., 2011; Isogai, 2013).

Conclusion

The proposed delineation procedure enabled us to retrieve relevant publications from research areas involving nanocellulose. Twelve research topics were identified, mapped and associated with current research challenges on nanocellulose. Two of them were highlighted as nuclei since they contain most part of the initial set of publications. The effect of the cleaning step on nuclei and peripheral clusters provided valuable feedback and demonstrated its importance to establishing relevant clusters afterwards. The independency test showed that the cleaning procedure could have been too rigorous and further research should be carried out to understand how it affected core authors' publication.

Delineating scientific fields is a complex task as boundaries are not frequently well established since scientific studies have become more complex and interdisciplinary. More and more exchange of knowledge between scientists from different disciplines is involved. Our approach retrieves and delineates the real nuclei and the peripheral research areas concerning nanocellulose studies. This clear separation provides suggestions for further research, putting the nuclei research in context. One of the ideas involves the knowledge flow from peripheral research topics to the nuclei areas. We intend to map how they provide the necessary knowledge to face nanocellulose current challenges and how country and scientific institutions are contributing to this evolution.

Abstract
This paper proposes an Ontology-Based Data Management (OBDM) approach to a multi-dimensional research assessment. It is shown that an OBDM approach is able to take into account the recent trends in quantitative studies of Science, Technology and Innovation, including computerization of bibliometrics, multidimensionality of research assessment, altmetrics, and, more generally, the generation of new indicators with higher granularity and cross-referencing specificities according to increasingly demanding policy needs. The main features of *Sapientia* are presented, the Ontology of Multi-dimensional Research Assessment, developed within a project funded by the University of Rome La Sapienza. Illustrative examples are given of its usefulness for the specification of well known as well as recently developed indicators of research assessment.

Conference Topics
Methods and techniques; Indicators; Science policy and research assessment

Introduction: An Ontology-Based-Data-Management Approach to Multi-Dimensional Research Assessment

The quantitative analysis of Science and Technology is becoming a "big data" science, with an increasing level of "computerization", in which large and heterogeneous datasets on various aspects of Science, Technology and Innovation (STI) are combined. Within this framework, optimistic views, supporting "the end of theory" in favour of data-driven science (Kitchin, 2014), have been opposed to more critical positions in favour of theory-driven scientific discoveries (Frické, 2014) while a more balanced view emerged from a critical analysis of the current existing literature (Ekbia et al., 2015), leading the information systems community to further deeply analyse the critical challenges posed by the big data development (Agarwal, 2014). It has been rightly highlighted that "Data are not simply addenda or second-order artifacts; rather, they are the heart of much of the narrative literature, the protean stuff that allows for inference, interpretation, theory building, innovation, and invention" (Cronin, 2013, p. 435). Moreover, the need for accountability of STI activities to sustain their funding in the current difficult economic and financial situation is increasingly asking for rigorous empirical evidence to support informed policy making. Indeed, the needs to overcome the logic of rankings and the new trends in indicators development, including granularity and cross-referencing, can be explored and exploited in open data platforms with a clear description of the main concepts of the domain (Daraio & Bonaccorsi, 2015). The multidimensionality of research assessment and scholarly impact (Moed & Halevi, 2015), and the recent altmetrics movements (Cronin & Sugimoto, 2014), are questioning the traditional approach in indicators development.

Research assessment, indeed, is becoming increasingly complex due to its multi-dimensionality nature. A Report published in 2010 by the Expert Group on the Assessment of University-Based Research, installed by the European Commission proposed "a consolidated multidimensional methodological approach addressing the various user needs, interests and purposes, and identifying data and indicator requirements" (AUBR, 2010, p. 10). A key notion holds that "indicators designed to meet a particular objective or inform one target group may not be adequate for other purposes or target groups". Diverse institutional missions, and different policy environments and objectives require different assessment processes and indicators. In addition, the range of people and organizations requiring information about university-based research is growing. Each group has specific but also overlapping requirements (AUBR, 2010, p. 51).

Table 1. Main types of research outputs.

Printed outputs (texts)	**Non-printed outputs (non-text)**	**Main type of impact**
Scientific journal paper; book chapter; scholarly monograph	Research data file; video of experiment; software	Scientific-scholarly
Patent; commissioned research report;	New product or process; material; device; design; image; spin off	Economic or technological
Professional guidelines; newspaper article; communication submitted to social media, including blogs, tweets.	Interview; event; art performance; exhibit; artwork; scientific-scholarly advise;	Social or cultural

A research assessment has to take into account a range of different types of research output and impact. As regards output forms, one important distinction is between text-based and non-text based output forms. The main types are presented in Table 1. This table is not fully comprehensive. The specifications of the Panel Criteria in the Research Excellence Framework in the UK (REF, 2012, page 51 a.f.) provide more detailed lists of possible output forms arranged by major research discipline. Table 1 includes forms that are becoming increasingly important such as research data files, and communications submitted to social media and scholarly blogs. A framework for the assessment of these forms is being developed in the field of altmetrics (e.g., Taylor, 2013). The last column indicates the main types of impact a particular output may have. A distinction is made between scientific-scholarly impact, and wider impact outside the domain of science and scholarship, denoted as "societal", a concept that embraces technological, economic, social and cultural impact. A comprehensive overview of the types of impact, and the most frequently used impact indicators is presented in Table 2. The reader is referred to AUBR (2010 and Moed & Halevi (2015) for a further discussion of this table.

It is also important to include the inputs in the analysis; they should be jointly analysed with the outputs to assess the overall impact of the process (see e.g. Daraio et al., 2014, for a conditional multidimensional approach to rank higher education institutions). To meet all these new trends and policy needs a shift in the paradigm of the data integration for research assessment is needed. In this paper we advocate an OBDM approach to research assessment. This new approach radically changes the traditional paradigm of construction of STI indicators and offers a flexible and powerful tool for designing new indicators and develop rigorous policy making. The confidence in this new approach comes from three directions: (i) recent efforts from policy makers to support the creation of new datasets on S&T; (ii) bottom up standardization initiatives; (iii) development of almetrics and web-based indicators. To start with, in the last few years, several initiatives at European level have been based on an intense production and use of new data.

Table 2. Types of Research Impact and Indicators.

Type of impact	Short Description; Typical examples	Indicators (examples)
Scientific-scholarly or academic		
Knowledge growth	Contribution to scientific-scholarly progress: creation of new scientific knowledge	Indicators based on publications and citations in peer-reviewed journals and books
Research networks	Integration in (inter)national scientific-scholarly networks and research teams	(inter)national collaborations including co-authorships; participation in emerging topics
Publication outlets	Effectiveness of publication strategies; visibility and quality of used publication outlets	Journal impact factors and other journal metrics; diversity of used outlets;
Societal		
Social	Stimulating new approaches to social issues; informing public debate and improve policy-making; informing practitioners and improving professional practices; providing external users with useful knowledge; Improving people's health and quality of life; Improvements in environment and lifestyle;	▪ Citations in medical guidelines or policy documents to research articles ▪ Funding received from end-users ▪ End-user esteem (e.g., appointments in (inter)national organizations, advisory committees) ▪ Juried selection of artworks for exhibitions ▪ Mentions of research work in social media
Technological	Creation of new technologies (products and services) or enhancement of existing ones based on scientific research	Citations in patents to the scientific literature (journal articles)
Economic	Improved productivity; adding to economic growth and wealth creation; enhancing the skills base; increased innovation capability and global competitiveness; uptake of recycling techniques;	▪ Revenues created from the commercialization of research generated intellectual property (IP) ▪ Number patents, licenses, spin-offs ▪ Number of PhD and equivalent research doctorates ▪ Employability of PhD graduates
Cultural	Supporting greater understanding of where we have come from, and who and what we are; bringing new ideas and new modes of experience to the nation.	▪ Media (e.g. TV) performances ▪ Essays on scientific achievements in newspapers and weeklies ▪ Mentions of research work in social media

Legend to Table 2: Partly based on AUBR (2010) and Moed & Halevi (2015)

In the field of data on universities, the pioneering efforts of Aquameth (Daraio et al., 2011; Bonaccorsi & Daraio, 2007) and subsequently of Eumida (Bonaccorsi, 2014) have been transformed in an institutional initiative called ETER (European Tertiary Education Register), which will make publicly available microdata on universities in 2015. In the same field, the mapping of diversity of European institutions (Huisman, Meek & Wood, 2007; van Vught, 2009) led to the experimental project U-Map, after which there has been an institutional effort towards a multidimensional ranking exercise, called U-Multiranking (van Vught & Westerheijden, 2010). In the field of Public Research Organisations, there has been an effort to build up a comprehensive list of institutions and to survey their activities within the European Research Area (ERA) context. The results of the large ERA surveys, run in 2013 and 2014, will be made available in 2015. These efforts from Europe have a major counterpart on the other side of the Atlantic, where the STAR Metrics initiative (see https://www.starmetrics.nih.gov/) has promoted a federal and research institution collaboration to create a repository of data and tools that is producing extremely interesting results. All these efforts, however, are based on the construction of new datasets, or the integration of existing datasets into new ones. They do not solve the issue of comparability

and standardization of information and of inter-operability, updating and scalability of databases. It is interesting to observe that, in parallel to these efforts put in place by public institutions and policy makers, there have also been massive bottom up efforts aimed at standardizing the elementary pieces of information. Moreover, these efforts have been based on the construction of partial ontologies. Consider the following.

- ORCID (http://orcid.org/) is a non-profit organization, supported by research organizations, agencies, providers of publication management systems, and publishers, aiming at giving all researchers a unique identifier (ORCID_id number) and keeping it persistent over time. Established at the end of 2009, but operational since end 2012, it has almost reached one million researchers worldwide. Most of the increase has been achieved in a very short time frame: from 100,000 in March 2013 to almost 970,000 as of October 2014 (with 35% from European, Middle East and Asian countries);
- CERIF is a Europe-based initiative aiming at standardizing the operations of funding agencies, with the help of a full-scale ontology of almost all research products (http://www.eurocris.org);
- CASRAI (www.casrai.org) is a Canada-US initiative for the standardization of data on research institutions and funders (also supported by a committee of Science Europe; http://www.scienceeurope.org/scientific-committees/Life-sciences/life-sciences-committee);
- ISNI (www.isni.org) provides lists and metadata on higher education, research, funding and many other types of organizations, while Ringgold (www.ringgold.com) does the same in the world of publishers and intermediaries.

These initiatives are strongly supported by international scientific associations (see for example CODATA http://www.codata.org and the VIVO network of scientists: http://www.vivoweb.org/).

Finally, the rapid growth of alternative metrics and web-based metrics has also created a large space for the production of data from publicly available and other sources (Cronin & Sugimoto, 2014). Summing up, there are powerful trends that point to the need to change the overall philosophy of the production of S&T indicators. Instead of an environment in which indicators are produced in close circles, by constructing ad hoc databases, with no built-in interoperability, updating and scalability features, we have to move towards an environment in which elementary pieces of information are fully standardized, micro-data consistent with standardized definitions are (mostly) publicly available, and indicators are constructed following the policy demands on the basis of stable platforms constantly integrated and updated, instead of starting from scratch each time a new indicator is needed.

Main advantages of an OBDM approach compared to conventional data-base integration approaches

While the amount of data stored in current information systems and the processes making use of such data continuously grow, turning these data into information, and governing both data and processes are still tremendously challenging tasks for Information Technology. The problem is complicated due to the proliferation of data sources and services both within a single organization, and in cooperating environments. The following factors explain why such a proliferation constitutes a major problem with respect to the goal of carrying out effective data governance tasks:

- Although the initial design of a collection of data sources and services might be adequate, corrective maintenance actions tend to re-shape them into a form that often diverges from the original conceptual structure.
- It is common practice to change a data source (e.g., a database) so as to adapt it both to specific application-dependent needs, and to new requirements. The result is that

data sources often become data structures coupled to a specific application (or, a class of applications), rather than application-independent databases.
- The data stored in different sources and the processes operating over them tend to be redundant, and mutually inconsistent, mainly because of the lack of central, coherent and unified coordination of data management tasks.

The result is that information systems of medium and large organizations are typically structured according to a "sylos"-based architecture, constituted by several, independent, and distributed data sources, each one serving a specific application. This poses great difficulties with respect to the goal of accessing data in a unified and coherent way. Analogously, processes relevant to the organizations are often hidden in software applications, and a formal, up-to-date description of what they do on the data and how they are related with other processes is often missing. The introduction of service-oriented architectures is not a solution to this problem per se, because the fact that data and processes are packed into services is not sufficient for making the meaning of data and processes explicit. Indeed, services become other artifacts to document and maintain, adding complexity to the governance problem. Analogously, data warehousing techniques and the separation they advocate between the management of data for the operation level, and data for the decision level, do not provide solutions to this challenge. On the contrary, they also add complexity to the system, by replicating data in different layers of the system, and introducing synchronization processes across layers. All the above observations show that a unified access to data and an effective governance of processes and services are extremely difficult goals to achieve in modern information systems. Yet, both are crucial objectives for getting useful information out of the information system, as well as for taking decisions based on them. This explains why organizations spend a great deal of time and money for the understanding, the governance, the curation, and the integration of data stored in different sources, and of the processes/services that operate on them, and why this problem is often cited as a key and costly Information Technology challenge faced by medium and large organizations today (Bernstein & Haas, 2008).

We argue that ontology-based data management (OBDM, Lenzerini, 2011) is a promising direction for addressing the above challenges. The key idea of OBDM is to resort to a three-level architecture, constituted by the ontology, the sources, and the mapping between the two. The ontology is a conceptual, formal description of the domain of interest to a given organization (or, a community of users), expressed in terms of relevant concepts, attributes of concepts, relationships between concepts, and logical assertions characterizing the domain knowledge. The data sources are the repositories accessible by the organization where data concerning the domain are stored. In the general case, such repositories are numerous, heterogeneous, each one managed and maintained independently from the others. The mapping is a precise specification of the correspondence between the data contained in the data sources and the elements of the ontology.

The main purpose of an OBDM system is to allow information consumers to query the data using the elements in the ontology as predicates. In this sense, OBDM can be seen as a form of information integration, where the usual global schema is replaced by the conceptual model of the application domain, formulated as an ontology expressed in a logic-based language. With this approach, the integrated view that the system provides to information consumers is not merely a data structure accommodating the various data at the sources, but a semantically rich description of the relevant concepts in the domain of interest, as well as the relationships between such concepts. The distinction between the ontology and the data sources reflects the separation between the conceptual level, the one presented to the client, and the logical/physical level of the information system, the one stored in the sources, with the

mapping acting as the reconciling structure between the two levels. This separation brings several potential advantages:

- The ontology layer in the architecture is the obvious mean for pursuing a declarative approach to information integration, and, more generally, to data governance. By making the representation of the domain explicit, we gain re-usability of the acquired knowledge, which is not achieved when the global schema is simply a unified description of the underlying data sources.
- The mapping layer explicitly specifies the relationships between the domain concepts on the one hand and the data sources on the other hand. Such a mapping is not only used for the operation of the information system, but also for documentation purposes. The importance of this aspect clearly emerges when looking at large organisations where the information about data is widespread into separate pieces of documentation that are often difficult to access and rarely conforming to common standards. The ontology and the corresponding mappings to the data sources provide a common ground for the documentation of all the data in the organisation, with obvious advantages for the governance and the management of the information system.
- A third advantage has to do with the extensibility of the system. One criticism that is often raised to data integration is that it requires merging and integrating the source data in advance, and this merging process can be very costly. However, the ontology-based approach we advocate does not impose to fully integrate the data sources at once. Rather, after building even a rough skeleton of the domain model, one can incrementally add new data sources or new elements therein, when they become available, or when needed, thus amortising the cost of integration. Therefore, the overall design can be regarded as the incremental process of understanding and representing the domain, the available data sources, and the relationships between them. The goal is to support the evolution of both the ontology and the mappings in such a way that the system continues to operate while evolving, along the lines of "pay-as-you-go" data integration pursed in the research on data-spaces (Sarma et al., 2008).

The notions of ODBM were introduced in (Calvanese et al. 2007; Poggi et al. 2008), and originated from several disciplines, in particular, Information Integration, Knowledge Representation and Reasoning, and Incomplete and Deductive Databases. The central notion of OBDM is therefore the ontology, and reasoning over the ontology is at the basis of all the tasks that an OBDM system has to carry out. In particular, the axioms of the ontology allow one to derive new facts from the source data, and these inferred facts greatly influence the set of answers that the system should compute during query processing. In the last decades, research on ontology languages and ontology inferencing has been very active in the area of Knowledge Representation and Reasoning. Description Logics (DLs, Baader et al., 2007) are widely recognized as appropriate logics for expressing ontologies, and are at the basis of the W3C standard ontology language OWL. These logics permit the specification of a domain by providing the definition of classes and by structuring the knowledge about the classes using a rich set of logical operators. They are decidable fragments of mathematical logic, resulting from extensive investigations on the trade-off between expressive power of Knowledge Representation languages, and computational complexity of reasoning tasks. Indeed, the constructs appearing in the DLs used in OBDI are carefully chosen taking into account such a trade-off (Calvanese et al., 2007).

As indicated above, the axioms in the ontology can be seen as semantic rules that are used to complete the knowledge given by the raw facts determined by the data in the sources. In this sense, the source data of an OBDI system can be seen as an incomplete database, and query answering can be seen as the process of computing the answers logically deriving from the

combination of such incomplete knowledge and the ontology axioms. Therefore, at least conceptually, there is a connection between OBDM and the two areas of incomplete information (Imielinski & Lipski, 1984) and deductive databases (Ceri et al., 1990).

Sapientia at a glance

The main objective of *Sapientia* is to model all the activities relevant for the evaluation of research and for assessing its impact. For impact, in a broad sense, we mean any effect, change or benefit, to the economy, society, culture, public policy or services, health, the environment or quality of life, beyond academia.

Table 3. Modules of the Sapientia Ontology.

N.	Module Name	Module Description
1	Overview	presents the terminological inventory needed to define the ontology domain: what is to be known to assess research activities and their impact on human knowledge and the economic system
2	Agent	models the individuals involved in the world of research, carrying out knowledge-related activities
3	Activity	models the main knowledge related activities matching them with public and relevant commitments of the agents involved in the domain (each module from 4 to 11 is devoted to a kind of knowledge-related activity - the module name corresponds to the appropriate specialization of the concept *Activity*)
4	*Research activity*	models, among the knowledge-related activities, those that allow the scientific community to advance the state of the art of knowledge
5	*Educational_activity*	models, among the knowledge-related activities, those that allow people to improve their knowledge
6	*Conferring degrees activity*	models, among the knowledge-related activities, those that grant degrees allowing people to widely qualify themselves
7	*Publishing activity*	models, among the knowledge-related activities, those that allow people to know the results of research activities
8	*Preservation activity*	models, among knowledge-related activities, those that permit the preservation of the value of things (related to research activities)
9	*Funding activity*	models, among the knowledge-related activities, those that assign and distribute the funds needed to carry out research, educational and service activities
10	*Inspecting activity*	models, among the knowledge-related activities, those that control and assess research, educational and service activities
11	*Producing activity*	models, among the knowledge-related activities, those that produce economic, society and cultural value
12	Space	models the space and its roles
13	Taxonomy	models the relevant taxonomies that classify the elements of the domain
14	Time	models the depth of time of the domain (this module is spread through the others)

Hence, *Sapientia* covers what is to be known about assess research activities and their impact on human knowledge and the economic system. For this purpose the ontology embraces:

- the inter-relationships between research activities (Modules Research_activity, Publishing_activity);

• the relationships between research activities and people's personal knowledge (Modules Teaching_activity, Conferring_degrees_activity, Publishing_activity, Producing_activity);
• the relationships between research activities and other missions of individuals and institutions (Modules Inspect_activity, Producing_activity);
• the relationship between research activities and the knowledge locally available to the companies in the economic system, enabling their innovative behavior (Module Producing_activity).

The *Sapientia* ontology includes also the activities that are needed for fostering these relationships (Modules Preservation_activity, Inspecting_activity and Funding_activities). The 14 modules that compose *Sapientia* are listed in Table 3.

Modelling choices

We pursued a modelling approach based on processes, which were conceived as collections of activities. A process is composed by inputs and outputs. Individuals and activities are the main pillars of the ontology.

We consider the building of descriptive, interpretative, and policy models of our domain as a distinct step with respect to the building of the domain ontology. However, the ontology will intermediate the use of data in the modelling step, and should be rich enough to allow the analyst the freedom to define any model she considers useful to pursue her analytic goal.

Obviously, the actual availability of relevant data will constrain both the mapping of data sources on the ontology, and the actual computation of model variables and indicators of the conceptual model. However, the analyst should not refrain from proposing the models that she considers the best suited for her purposes, and to express, using the ontology, the quality requirements, the logical, and the functional specification for her ideal model variables and indicators. This approach has many merits, and in particular:

- it allows the use of a common and stable ontology as a platform for different models;
- it addresses the efforts to enrich data sources, and verify their quality;
- it makes transparent and traceable the process of approximation of variables and models when the available data are less than ideal;
- it makes use of every source at the best level of aggregation, usually the atomic one.

More generally, this approach is consistent with the effort of avoiding "the harm caused by the blind symbolism that generally characterizes a hasty mathematization" put forward by Georgescu Roegen in his seminal work on production models and on methods in economic science (Georgescu-Roegen, 1970, 1971, 1979). In fact, one can verify the logical consistency of the ontology and compute answers to unambiguous logical queries.

Moreover, the proposed ontology allows us to follow the Georgescu-Roegen approach also in the use of the concept of process. We can analyze the knowledge production activities, at an atomic level, considering their *time* dimension and such *funds* as the cumulated results of previous research activities, both those available in relevant publications, and those embodied in the authors' competences and potential, the infrastructure assets, and the time devoted by the group of authors to current research projects. Similarly, we can analyze the output of teaching activities, considering the joint effect of *funds* such as the competence of teachers, the skills and the initial education of students, and educational infrastructures and resources. Thirdly, service activities of research and teaching institutions provide infrastructural and knowledge assets that act as a *fund* in the assessment of the impact of those institutions on the innovation of the economic system. The perimeter of our domain should allow us to consider the different channels of transmission of that impact: mobility of researchers, career of alumni, applied research contracts, joint use of infrastructures, and so on. In this context,

different theories and models of the system of knowledge production could be developed and tested (Etzkowitz & Leydesdorff, 2000).

Table 4. Indicators considered for the test of the completeness of Sapientia.

#	Indicator (I)	*Sapientia's Modules*												
		2	3	4	5	6	7	8	9	10	11	12	13	14
I1	Number of published articles	A					F					F,D1	D1	D2
I2	Number of citations	A					F					F,D1	D1	D2
I3	Citations per article	A					F					F,D1	D1	D2
I4	Normalized citation rate	A					F					F,D1	D1	D2
I5	Highly cited publications	A					F					D1	D1	D2
I6	Journal Impact Factor	A					F						F	D2
I7	Subject Normalized Impact Factor	A					F						F	D2
I8	Scimago Journal Ranking Impact Factor	A					F						F	D2
I9	H-index	F					F					A	F	D2
I10	E-index	F					F					A	F	D2
I11	Number of patents	A									F	F,D1	D1	D2
I12	Full text article download count	A					F					F,D1	D1	D2
I13	Mentions in social media	A					F					F,D1	D1	D2
I14	Research output per academic staff	A					F					F,D1	D1	D2

I37	Research Infrastructures and facilities	A					F	F				D1	D1	D2
I38	Research ethics						F					A,F	F,D1	D2

Testing the Ontology: analysis of the competency questions

One way to check if the ontology contains all the relevant information and/or details to represent the domain of interest, currently used in knowledge representation, is based on the specification of competency questions (Gruninger & Fox 1995). These questions correspond to check whether the ontology contains enough information to answer these types of questions or whether the answers require a particular level of detail or representation of a particular module of the ontology that needs to be further developed. The analysis of the competency questions of *Sapientia* has been carried out on the indicators contained in the paper by Moed and Halevi (2015), integrated with the additional indicators reported in the AUBR (2010) document. In addition, other key references of the ontological commitments have been Moed, Glanzel and Schmock (2004), Moed (2005) and Cronin and Sugimoto (2014), together with the knowledge background of the team of the project.

Table 4 contains the list of indicators considered for the verification of the competency questions. Associated to each indicator are reported the following pieces of information:

- Facts (F) are the content of the data, the relevant information about atomic events relevant for the construction of the indicator;
- Aggregation level (A) is the minimal aggregation level: the concept which classifies the objects included in the indicator;
- Dimensions of the analysis (D), are descriptive properties which are relevant to access higher level of aggregation. They are evaluated by the dimension of taxonomy (D1) and that of time (D2).

Table 5 summarizes the number of facts (F), aggregations (A) and dimensions (D) by module, as reported in Table 4, to check the comprehensiveness of *Sapientia* with respect to the indicators listed therein. Put it in another way, we checked whether our ontology was able to include all the relevant conceptual information requested by the specification of the listed indicators in Table 4. The answer to this question is indeed positive.

Table 5. Some statistics on the "usage" of the Ontology modules.

	2	3	4	5	6	7	8	9	10	11	12	13	14
F	7	1	2	1	2	20	1	7	3	6	13	5	2
A	34	0	1	0	0	0	0	0	0	0	2	1	0
D	2	0	0	0	0	0	0	0	0	0	31	31	38

By inspecting Table 5 it clearly appears that only a few modules are used for the specification of the indicators reported in Table 4. This means that our ontology covers a much broader conceptual domain with respect to the one underlying (even if not formally specified) by the indicators reported in Table 4. The most frequently used module is the Publishing module (7), followed by Space (12) and Funding (9). We note that the modules 12 (Space), 13 (Taxonomy) and 14 (Time) are used in the majority of the cases to further characterize the dimensions of the considered indicators.

A new way to conceive and specify STI indicators

By adopting an OBDM perspective a new approach to designing indicators can be implemented. This new approach aligns very well with the recent trends described in the introduction.

The traditional approach to indicators' design is based on informal definitions expressed in a natural language (English, typically). An indicator is defined as a relationship between variables, e.g. a ratio between number of publications per academic staff, chosen among a predefined set of data collected and aggregated ad hoc, by a private or a public entity, according to the user needs, and hence not re-usable for future assessment and use.

The OBDM approach we pursue in this paper permits a *more advanced specification* of an indicator according to the following dimensions:

- the *ontological dimension*. It represents the domain (portion) of the reality to be measured by the indicator (obviously, in the scope of this paper, all indicators will share the *Sapientia* ontology as their ontological part);
- the *logical dimension*. It denotes the question that has to be asked to the ontological portion in order to retrieve all the information (data) needed for calculating the indicator value. In this case the data are extracted from the sources through the mapping considering the logical specification of the query;
- the *functional dimension*. It indicates the mathematical expression that has to be applied on the result of the logical extraction of data carried out in the previous point in order to calculate the indicator value;
- the *qualitative dimension*. It specifies the questions that have to be asked to the ontological part in order to generate the list of problems affecting the meaningfulness of the calculated indicator. An indicator will be considered meaningful if the list of its problems is empty.

In addition to the advantages of the OBDM recalled in previous sections above, the main specific benefits of this approach for designing indicators are the following:

1. It offers a space to *freely* explore the *generation of new indicators,* not previously specified by users, thanks to the *multiple inheritance* in the hierarchy of the concepts (a concept can be subsumed in several concepts).
2. For standard indicators specified by the users it can be seen immediately what is *missing* or which *problems* exist to calculate them;
3. It provides more alternatives and diagnostic ways to check the *robustness* of indicators with respect to opportunistic behaviour and the general goals of the assessment;
4. The formal specification of the indicators is made *independently* of the data. In this way, when applied to heterogeneous data sources, OBDM offers the opportunity to compute "comparable" indicator values at different level of aggregation. Moreover, it offers a reference system to *check the comparability* level among the heterogeneous sources of data and to identify where to invest in order to overcome the remaining existing comparability problems.
5. This approach permits an *unambiguous* way to define and compute the indicators. The indicator is calculated always in the same way.

Conclusions and further developments

In this paper we advocated the use of an OBDM approach to research assessment. We explained the reasons why a paradigm shift in research assessment is needed and outlined the main advantages of an OBDM approach over traditional databases integration approaches. We described the main objectives and structure of *Sapientia* the Ontology of Multi-dimensional Research Assessment. Finally, we illustrate the new indicator design methodology implicitly provided by an OBDM approach.

Sapientia 1.0 has been closed on the 22nd December 2014 and consisted of around 350 symbols (including concepts, relations and attributes). The full documentation of the Ontology is under way together with the mapping with several sources of data. Due to the works on the documentation and the mapping with the data in progress, as well as the limited number of pages available, we concentrated our presentation on the methodological aspects related to the development of the Sapientia.

We believe in fact that it will open a new stream of studies to further explore and exploit the OBDM approach for STI indicator designers and policy makers.

Abstract

Before 2012, it was hard to come to a comprehensive evaluation of academic journals in China. For this reason the international influence of journals published in China hadn't been paid enough attention, leading to a bias in the Chinese research assessment system. Since 2012, China National Knowledge Infrastructure (CNKI) invested and carried out the project of the development of the "Annual Report for International Citations of Chinese Academic Journals ". In the same year, CNKI made a comprehensive study on the international citations of more than 6000 journals in China, and found that some journals had a certain international influence. In order to make a comprehensive assessment of the international influence of those journals, CNKI has developed a comprehensive indicator, named the CI index (clout index), combining the effect of both the impact factor and the citation counts. This article describes the purpose, methods and results of part of this project, providing a fresh idea for a comprehensive evaluation of the influence of Chinese academic journals.

Conference Topic

Methods and techniques

Background

In the era of big data and we-media as shown by Bowman & Willis (2003), direct publication and free access are all around, leading to the question: "how can academic journals survive"? It is known that journals, in particular journals sharing a scientific community compete in one market, but journals will survive as long as they have a function for a specific academic community. The main problem that Chinese journals, especially academic journals, are faced with, is the competition with huge international publishing companies. It has been a common knowledge that it is hard for the domestic journals to compete with those international academic journals.

According to Thomson Reuters' SCI data, as shown in Fig. 1, Chinese scholars published 114,130 papers in international journals in 2008. This number has greatly increased to 232.000 in 2013, which is a doubling of that in 2008. While Fig. 2 shows a comparison of the papers Chinese scholars published in the journals covered by the SCI with the papers Chinese scholars published in domestic academic journals in 2013. It can be seen in Fig. 2 that 1.035 million papers have been published in 3569 domestic academic journals in 2013. Compared to the 1,035,142 domestic papers, 206,598 academic papers were published in journals covered by the SCI. This means that one sixth of the Chinese academic papers had flowed overseas. There is also a rapid increase in quantity for the papers in the field of social sciences. The number of Chinese SSCI papers had increased from 4,430 in 2008 to 9,722 in 2013, which means a doubling over five years.

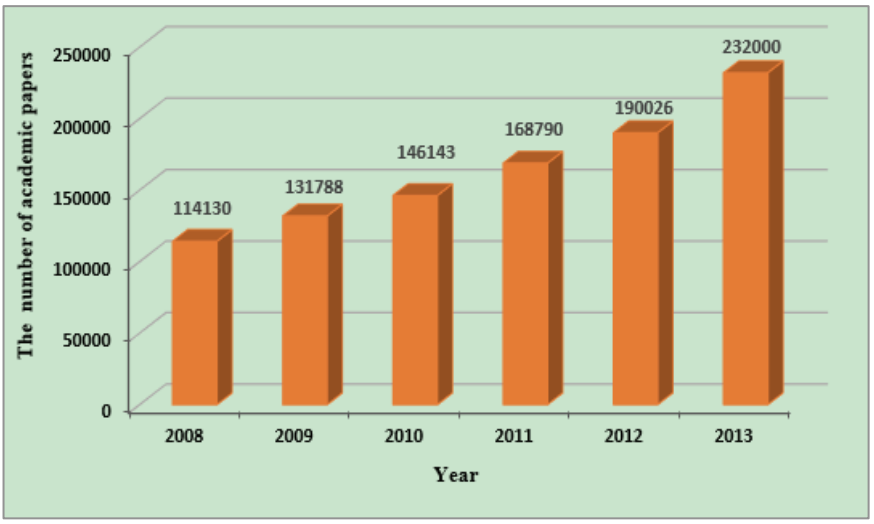

Figure 1. Evolution of the number of academic papers Chinese scholars published in international journals covered by the SCI during 2008-2013.

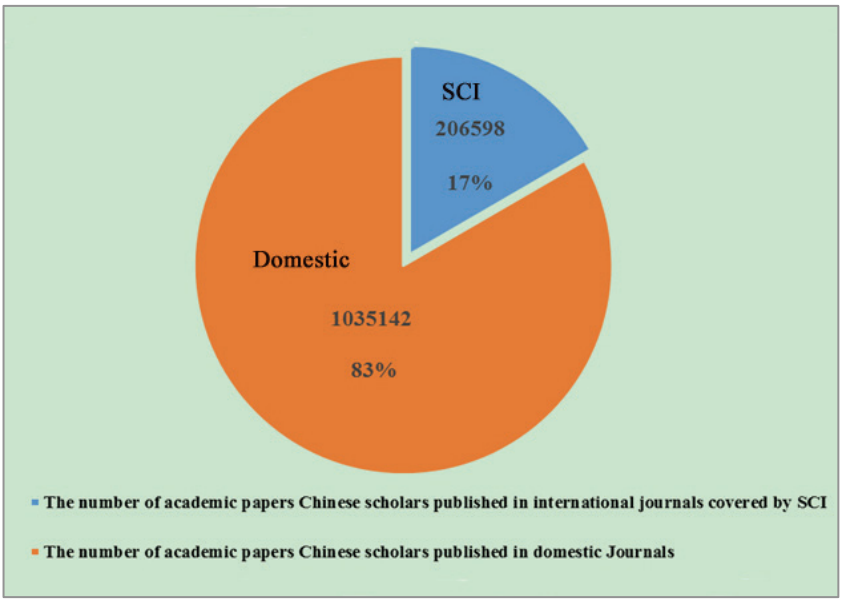

Figure 2. A comparison between Chinese papers published in journals covered by the SCI with papers published by Chinese scholars in domestic academic journals in 2013.

It is seen that so many China's qualified academic papers have flowed overseas and published in international journals, especially SCI journals. While the impact of China's academic journals on international audience was rarely revealed before. We think that, in the information era, with an increasing quantity of journals, the full importance of academic journals should be revealed through an objective evaluation based on a large amount of data. Journal management departments often use an "index set" of journal characteristics. This index set is used for the quantitative assessment of journal's quality. It has become a social consensus that "Scientific decision-making needs the support based on the big data". China's publishing management system, in particular, urgently needs a comprehensive, objective and impartial data set for the allocation of journal publishing resources.

Most scholars agree that publishing academic papers in the journals of a high academic standing is a means of academic communication and the success of a scholar in this can be used as a factor in evaluation exercises. The problem is where to draw the line between journals of high standing and journals of lower standing. In the past, data regarding

international journals were not taken into account for various evaluations of domestic journals. Therefore, it was hard for the domestic journals to compete with those international academic journals.

It is common that the reputation of Chinese scientific journals in the international community is measured by journal Impact factor (IF). Ren (1999) proposed the challenge for Chinese scientific journals using this indicator for the evaluation of Chinese journals. Based on the fact that a journal's international impact had not been adequately considered in the past, research management department such as that of CNKI could only take the SCI as evaluation standard. The Science Citation Index (SCI) initiated by Eugene Garfield is a unique retrieval and evaluation tool (Garfield, 1955). Yet it is known that it is not adequate for the local evaluations of less developed non-English speaking countries, or for the retrieval of these countries' publications (Ren & Rousseau, 2002). Since English is the most widely used language in science, journal publishers prefer to publishing in English to attract a larger reader base, resulting in more visibility, increased citations and higher IF, as shown in the study by Ren & Rousseau (2004). According to the above discussion, it is necessary for us to take an international perspective and a domestic view to evaluate the influence of China's academic journals, i.e. consider both domestic and international journals' citing citations to Chinese academic journals, in order to conduct scientific and reasonable evaluations of Chinese academic journals. For the citations by domestic journals, CNKI has developed "Annual Report for Chinese Academic Journal Impact Factors" since 2009. In this study, we focus on the citations by international journals, introducing the research purpose, methods and results of the "Annual Report for International Citations of Chinese Academic Journals".

Purpose

In this study, we conduct a quantitative assessment of academic journals published in Mainland China, either in Chinese or in English, in order to make an evaluation of their quality. Moreover, we analyze their world-wide influence by mining their cited records of citations by international journals. In the following we first give our understanding of an academic journal of high quality.

A journal of high quality provides products and services meeting or exceeding its readers' expectations. As such the quality of an academic journal is a comprehensive reflection of its publication level as manifested through the importance of its articles for the advancement of science. Following national and international norms, timeliness of publication and a large reader base also contribute to a journal's quality.

Influence of an academic journal refers to the ability of the journal to arouse its readers' attention and thinking, obtain their recognition and even alter their thoughts, opinions and behavior. A high-level journal influences academic development, by the ideas, concepts, theories, methods, findings, inventions and facts it introduces to the scientific community. Besides these objective aspects, a high-level journal has also an emotional influence, associated with its brand name, on its reader community.

Influence is not only a reflection of quality, but also a function of time. High quality papers, including editorials, show their influence gradually over time. Dissemination of journals can be judged scientifically and objectively by the frequency of being cited in domestic and foreign academic literature.

Method

Index system

Some scholars have suggested that data including downloading and online comments should be considered. These ideas are related to the altmetrics, or social influmetrics, movement

(Rousseau & Ye, 2013). Even the new Nature Index includes altmetric data (refer to the website: www.natureindex.com). However, downloading is a complex issue. It ranges from results of web crawling to students' learning, or providing intelligence services, and does not only include use for academic research. Moreover, based on current data analysis technology, it is still a challenge to judge if online comments are scientific or rigorous. In contrast, citation is a reflection of academic norms. Each author is required to respect the intellectual property rights of the literature he or she cites. Otherwise his/her behavior might be considered as misconduct. Therefore, statistical analysis of citations is considered as a relatively reliable and quantifiable technique.

Citation and publication statistics may include the following items:

(1) Statistics related to received citations such as the total cites in a year. Citations may include mutual journal citations and a history of received citations over a period of several years.

(2) Quantity of published literature such as the amount of published papers (further subdivided into types such as 'normal' articles, reviews, editorials, etc.), proportion of funded papers and proportion of articles with foreign collaboration.

(3) "Calculated indicators for evaluation: Indicators related with cited frequency such as immediacy index, the 2-year impact factor, 3-, 4-, or 5-year impact factor, etc. Indicator related with mutual citations: mutual citation index. Indicators related to the life cycle of literature: citing half-life, cited half-life, etc."

(4) The composition of the editorial board and the prestige of the editor-in-chief.

Selection of statistical sources for the international citations report

Statistical sources for the international citation report must be journals selected according to the standard for the evaluation of the international influence. Besides the journals from American and European countries, representative journals from other countries should also be included. The list of source journals should be based on suggestions from domestic and foreign experts. It is known that SCI database includes the most representative journals from the American and European countries and, as such, may be acceptable for reflecting the international influence of Chinese academic journals. Hence, at least for the current year, we still use the SCI database as the statistical source to evaluate academic journals. This means that we consider 8,621 academic journals covered in this database.

The case for humanities and social science fields is more complicated. It is not enough to merely use the 6,429 journals of SSCI and the A&HCI to evaluate the humanities and social sciences journals. For a more comprehensive statistic of the international influence of China's humanities and social sciences journals, we add well-known databases as a supplement, including those of leading international publishing groups such as Elsevier, Springer, Wiley, and Emerald. In this way, 1483 source journals (non-WOS humanities or social science journals) are included, which are good supplements for the source journals. According to experts' recommendations, we have also supplied 441 journals in minor languages, which pay attention to Chinese issues. These journals have not been included in the worldwide major databases, but they are indispensable for the research of local social science experts (Ossenblok, Engels & Sivertsen, 2012).

Data standards

In order to ensure the accuracy of the statistical data, we have established data processing standards, procedures, as well as quality requirements. Accordingly, we normalized and standardized the raw data and set up a series of databases as follows:

(1) The document database of norms for titles of more than 7,000 Chinese and English journals in China.
(2) The bibliographic database of China's academic journals, a collection of about 8,000 domestic academic journals and more than 42 million publications, used for citation links.
(3) Set up "the Statistical Standards of the Published Paper Amount". According the norm, make the statistics on the amount of published papers, as well as the cited papers published in the recent six years.

The development process

(1) Collection of data: including data retrieval in the WOS database, and the processing of data from supplementary journals.
(2) Standardized data processing: automatic processing of data such as citation links, and fuzzy title matching. If necessary these techniques were augmented by manual inspection to improve efficiency and accuracy.
(3) Detection: verification of data integrity and accuracy checks to ensure that the data meets the quality standards, plus an annual appraisal of a group of experts.
(4) Trial calculation, validation, and sample verification: indicator calculation must be double checked by several persons, and those journals with large inter-annual variations in one or more indices are the target of special attention.

Results

According to the method mentioned above, we developed the "International citation annual report" providing evaluation data of Chinese academic journals, first released in 2012. In December 2014, the 2014 Annual Report (Xiao & Du, 2014) was published and the evaluation data for more than 6000 academic journals were provided. These results were released in the "Database of Statistical Analysis of Individual Journal's Impact" available on the website of the CNKI (www.cnki.net).

Selection of highlights

Definition of a new international impact index: the clout index, denoted as CI

Several indicators like the journal impact factor and total cites are commonly used for the evaluation of a journal. Before continuing we first provide a short review of those indicators. The idea of a journal IF was first propagated by Eugene Garfield in the journal Science in 1955 (Garfield, 1955, 2006). Currently, the journal IF is generally regarded as representing the quality of academic journals in terms of citations received by its published articles. It is usually assumed that journals with a high IF carry meaningful, prominent, and quality research (Saxena, 2013). However, this single parameter is clearly not sufficient (Vanclay, 2012, Glaenzel, 2009). First of all, according to its definition, the IF reflects the performance of a journal in the most recent two years. The cited half-life for an academic journal is about 4 to 12 years, while the period of the most recent two years is merely the peak time for citation (and even that depends on the field), accounting for about 20% of the total citation amount, as shown in Fig.3. Second, the journal IF is independent of factors like the history and scale of journals and may reflect the popularity of published topics (Rousseau et al., 2013). Besides, journal IF depends on the research field: high journal IF is likely achieved for journals covering large areas of basic research with a rapidly expanding but short lived literature that use many references per article (Seglen, 1997). Using the IF as the single measure would lead to artificial constraints on the quantity of published work as well as the tendency to publish a large number of papers in line with the current popular trends without solving any

fundamental problem. Journals that act like this would lose their basic function as real academic communication platforms.

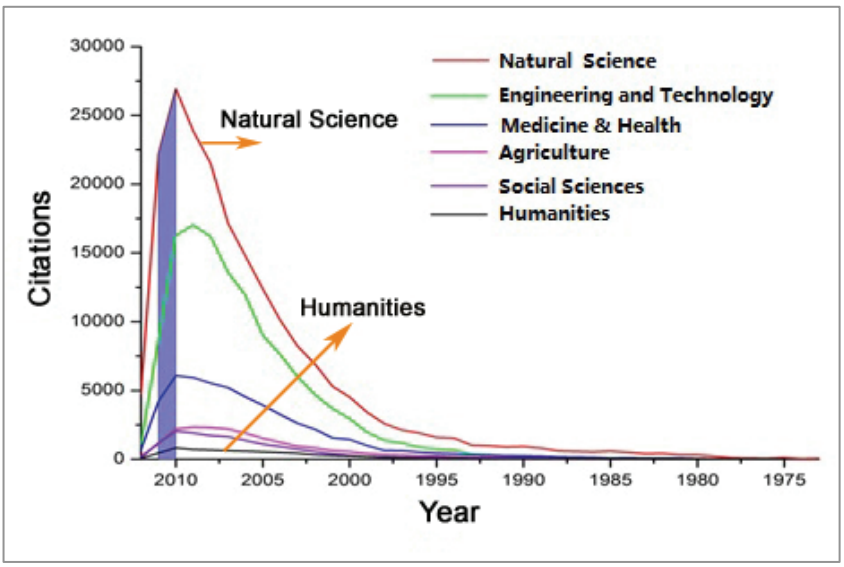

Figure 3. Cited half-life for different subject categories.

Total cites is directly related to journals' publishing history and scale. As shown in Fig. 3, we should also mention that total cites, which include the other 80% of citations that are excluded from the calculation of the IF, reflect the total impact power. However, it is also unreasonable to only consider total cites as the single evaluation factor. It might encourage researchers to aggressively increase their publishing quantity at the expense of academic quality.

Here, we should mention the topic of self citations. Whenever citations are used as indicators to evaluate scientific research, self-citations are often considered controversial. Many scholars have studied self-citation and some suggest that self-citations should be removed from citation counts, at least at micro and meso levels (e.g. analyses of persons, research groups, departments, and institutions) (Aksnes, 2003, Thijs & Glaenzel, 2005). Today the indicator of self-citations has been widely used in the evaluation of scientific journals.

We all know that IF and citations are field dependent, and therefore, indicators which compare expections to observed values are also interesting, see the work of Glaenzel, Schubert and Braun to MOCR (The Mean Observed Citation Rate) and MECR (The Mean Excepted Citation Rate) (Braun et al., 1985, Schubert et al., 1989). While Bonitz et al. (1997) stuied the Matthew effect of countries and Matthew citation journals, and presented the established characteristic of the so-called Matthew Effect for countries: field-dependency, time-stability and order of magnitude. Boyack & Klavans (2014) made the analysis on non-source publications in a different context, including non-source items in a large-scale map of science. These studies have inspired our work on exploring a comprehensive indicator for the evaluation of non-WOS-source domestic academic journals.

Thus, we have developed a comprehensive indicator, named as the Clout Index (CI), which takes both the IF and total cites into account. To be precise, we replace the WOS IF and total citations with the non-self-cited IF and total non-self-cited citations in the calculation of the CI values, taking into account that most of Chinese journals are not covered by the WOS.

First, we normalize the non-self-cited IF and total non-self-cited cites by a linear normalization method (the same for the two indices) shown in Equation (1), where V represents the parameter that has to be normalized, while N represents the normalized value. In this way the two values are in the range [0, 1].

$$N_i = \frac{V_i - V_{\min}}{V_{\max} - V_{\min}} \quad (1)$$

For the next step, we apply Eq. 2 to calculate the CI value:

$$CI = \sqrt{2} - C = \sqrt{2} - \sqrt{(1-x)^2 + (1-y)^2} \quad (2)$$

Fig. 4 shows a schematic distribution of CI values calculated by Eq.2. The points scattered in Fig. 4 represent the CI values of the selected journals. It should be noted that, in Eq. 2 and in Fig. 4, *x* and *y* stand for the normalized non-self-cited IF and total non-self-cited cites, respectively. From Fig.4, it can been seen that the origin coincides with non-self-cited IF = 0 and total non-self-cited cites = 0, while the point (1, 1) represents that the journal has reached the maximum value in both the non-self-cited IF and total non-self-cited cites. If we take the point (1, 1) as the center and CI value as radius to draw circles, then points on the same circle have the same CI value. The points located in the bottom-left area have lower CI values while the ones in the up-right area have higher values.

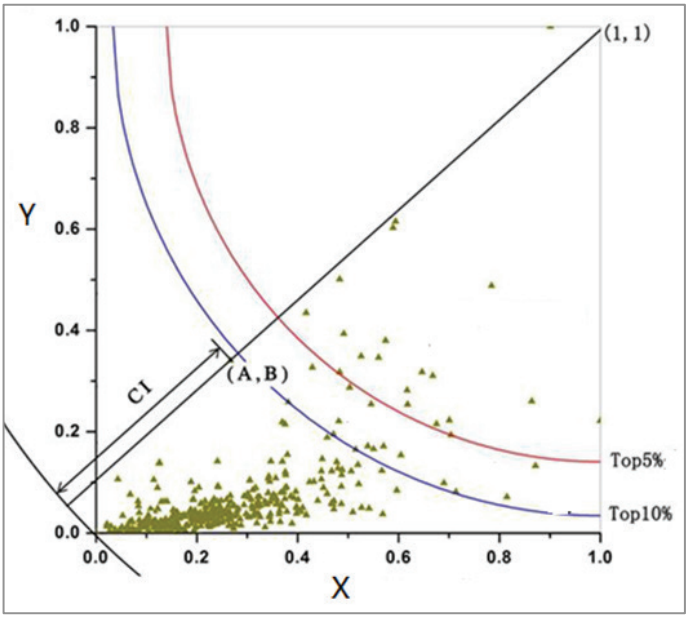

Figure 4. Schematic view of the Clout Index (CI) and selection of top journals in China.

In Figure 4, we drew two curves with the point (1,1) as their center, and CI(1) and CI(2) as radius, respectively. Here, CI(1) and CI(2), represent the critical CI values of selected Top 5% and Top 10% journals, respectively. We consider journals with CI values above the Top 5% as "The Highest International Impact Academic Journals of China", while CI values between CI(1) and CI(2) as "The Excellent International Impact Academic Journals of China". Here, China's academic journals published either in English or in Chinese are both considered.

At this point, we would like to explain why we choose a vector sum method for the calculation of the CI value instead of using a simple linear sum. Figure 5 shows a comparison of the linear sum and the vector sum method. The scatterplot itself in Figure 5 is the same as in Figure 4. First, we consider that IF and cites have the same weight as evaluation indicators. If we take the linear sum method, i.e. CI=*x*+*y*, we obtain oblique straight lines with different lengths to show equal CI values. Here, *x* and *y* have the same definition as those for Figure 5. Compared to the result obtained from the linear sum method, the CI value is smaller by the vector sum method, when the points closed to x or y axes. In this system, journals with higher single index, either IF or cites are easily excluded. Thus, our algorithm gives a better way to match the evaluation principle: "not only quality but also quantity matters".

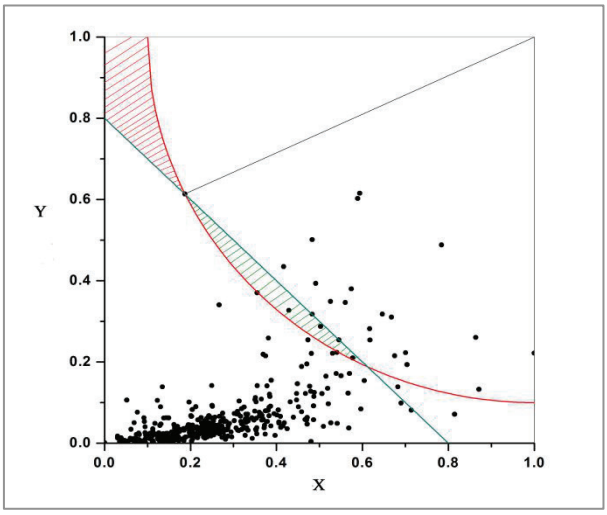

Figure 5. A comparison of the linear sum and the vector sum method.

In our system, we consider that journals with both higher IF and higher cites are journals of high-quality. Those journals commonly have higher influences in their scientific field. Fig. 6 shows the schematic view of the scatterplot of the CI value for both the SCI journals as well as Chinese domestic journals. We use double logarithmic coord. system in Fig. 6, where our developed vector sum method is applied to calculated the CI values for SCI journals and China's domestic journals. Both of the statistical sources are WOS database. The green triangles represent the CI values for the international SCI journals, while the black ones show the domestic journals covered by SCI. Those related to the Top 5% journals are shown in red, while for Top 5-10% journals in dark blue. Lower CI values for other domestic journal are shown in orange. It is clear that the majority of international journals covered by the SCI is situated in the area with both higher IF and higher citations. Situations are similar for the Top 5% and Top 5-10% domestic journals. Thus justifies that our vector sum method is a good method for the evaluation of the journals, and the CI index can be considered as an effective and reasonable indicator for the quantitative assessment of journal impact.

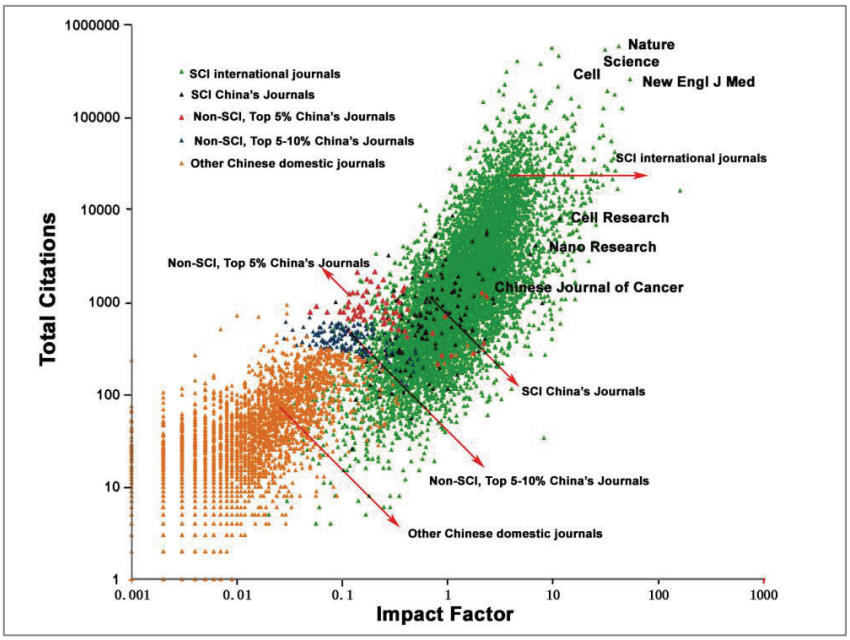

Figure 6. A schematic view of the scatterplot of the CI values for both the SCI journals and China's domestic journals.

Problems in the selection of top journals

Division of subjects

There is, among domestic journals in various disciplines, a large imbalance in the level of international influence and the extent of "going global". If top journals were selected per discipline, excellent journals in highly visible disciplines may be excluded, while journals with less international influence in disadvantaged disciplines may come into the list. This is not the way we want to highlight the most influential journals. As time goes by, we expect that the international influence of various disciplines will be improved and developed in a balanced way. At that time we will be able to perform sub-discipline rankings.

Comprehensive consideration of domestic and international influence

In the evaluation of international influence we should consider domestic and international influences as two sides of the same coin. However, first, a separate evaluation is more helpful for understanding the situation of the journals in both domestic and international market. Secondly, there is no recognized method showing how to merge these two reports, however, see Jin & Rousseau's study for an earlier merging attempts (Jin et al., 1999, Jin & Rousseau, 2004). The main difficulty lies in the point that there are different opinions on the issue of whether "a domestic citation is equal to an international citation." Considering the fact that "the annual report of the impact factors of China's academic journals" has been well developed for years, in this article, we mainly discuss the research method of the annual report of the international citations.

The selection process and resulting top list

To highlight the most influential journals, this year we continue selecting "The Highest International Impact Academic Journals of China" and "The Excellent International Impact Academic Journals of China". By ranking the journals of STM (Science/ Technology/ Medicine) and AH&SS (Humanities and Social Sciences) according to the CI values, we selected the Top 5% and the Top 5-10% journals; then sent the selection method, data of indicators and the primary list to more than 70 experts for peer review.

Some journals were removed from the list for their bad reputation evaluated by peer reviewers, while other ones were supplemented in sequence. This was done in such a way as to make sure that the total number of selected journals stayed the same. Finally we determined 176 STM journals and 61 AH&SS journals as "The Highest International Impact Academic Journals of China", and 174 STM journals and 60 AH&SS journals as "The Excellent International Impact Academic Journals of China" Among these 471 Top 5-10% journals, 458 are core journals selected by various domestic institutions, and most of the other 13 are journals in English or newly created ones.

Summary and outlook

(1) An international report has been issued for three successive years and approved by government departments in charge of journals, editorial department of journals and academic circles. This encourages us to keep this work going.

(2) With the accumulation of data, many meaningful conclusions can be drawn from the analysis of inter-annual variations in data.

(3) There is certainly room to improve the evaluation methods, including the selection criteria of the international source journals, possible improvement of the determination of the CI indicator and the integration of domestic and international lists.

(4) The main points of this article have been written in a manuscript submitted to Acta Editologica in Chinese language (Wu et al., 2014).

Acknowledgments

This study is sponsored by the National Social Science Project of "Evaluation and development strategy of the international influence of Chinese academic journals in English" (No.14BTQ055). The authors would like to express the deepest appreciation to Prof. Ronald Rousseau for his very careful corrections and valuable comments on this manuscript. We are very grateful to Prof. Jerold Mathews in Iowa State University for his careful corrections and good suggestions. And we thank Dr. Bo Liu in CNKI for his valuable discussion on the manuscript.

Is the Year of First Publication a Good Proxy of Scholars' Academic Age?

Abstract
Individual scholars are the central unit of the research system and are increasingly the focus of bibliometric studies. An important aspect in the study of individual scholars is their academic age, which allows for the comparison of scholars that have been academically active in a similar period of time. Based on a sample of Quebec researchers for whom their year of birth, PhD year as well as the year of their first publication are known, we study the relationships among these ages with the aim of determining how their year of first publication can be used to estimate their 'real' age. Moderate correlations have been found among the ages, and the first publication year has a higher correlation with the PhD year than with the birth year. However, an important dispersion of scholars across the different ages is observed; thus, the year of first publication can only be taken as proxy of the real age of scholars. Alternatively, the consideration of cohorts of around 5 years seems to be a reasonable approach. Further research will focus on the exploration of other bibliometric indicators in order to refine the preliminary developments discussed here.

Conference Topic
Methods and techniques

Introduction
In individual-level bibliometric studies, the socio-demographic characteristics of scholars are of central importance to understand and better frame the results obtained (Costas & Bordons, 2011; Gingras, Larivière, Macaluso, & Robitaille, 2008; Mauleón & Bordons, 2006). Among these socio-demographic characteristics we can mention gender (Larivière, Ni, Gingras, Cronin, & Sugimoto, 2013; Mauleón & Bordons, 2006), mobility (Canibano, Otamendy, & Solis, 2011; Franzoni, Scellato, & Stephan, 2012), and nationality (Moed & Halevi, 2014), among others. The development of large-scale author-name disambiguation algorithms (Caron & Van Eck, 2014) as well as the increasing quantity of papers' metadata indexed (e.g. author names and surnames, affiliations, e-mail data, etc.) have allowed the study of the socio-demographic characteristics of scholars at a larger scale. For example, the analysis of the first author names of authors (Larivière et al., 2013) allowed the macro analysis of gender disparities worldwide. The large-scale analysis of the relationship between author names, affiliations and countries collected from scientific publications has open the possibility of studying academic mobility at the world level (Moed, Aisati, & Plume, 2013), as well as the nationality (Costas & Noyons, 2013), migrations (Moed & Halevi, 2014) or even the ethnic origin (Freeman, 2014) of scholars.

A critical element for individual-level bibliometrics is the age of the researchers (Costas & Bordons, 2011; Larivière, Archambault, & Gingras, 2008; Levin & Stephan, 1989), especially from the point of view of its relationship with productivity (Falagas, Ierodiakonou, & Alexiou, 2008; Levin & Stephan, 1989). Age is also a common point of debate in science policy, as it aims to compare scholars of the same 'academic age' (Bornmann & Leydesdorff,

2014). However, one of the main reasons that hinders the development of bibliometric studies at the individual level is the lack of systematic data on the age of scholars, as this information is not systematically collected in bibliographic databases. A commonly used proxy for the study of the age of scholars has been the so-called 'scientific (or academic) age', often defined as the publication year of the first paper of a scholar (Radicchi & Castellano, 2013).[1] The use of this age is very convenient, as it is possible to directly extract it from bibliometric data. However, so far there has not been any analysis on the relationship between this proxy and the real age of scholars. This paper is intended to fill this gap and shed some light on the relationship between the 'bibliometric' age of scholars that can be calculated based on bibliographic information and the 'real' age(s) of individual scholars, namely their birth age and their PhD age. In other words, we aim to infer the birth year and PhD year of scholars based on models that are exclusively based on bibliometric indicators[2] (e.g. first publication year, position of signature, co-authors, etc.). Thus, the main research question can be operationalized as follows: *could the year of first publication (YFP) of a scholar (as recorded in the Web of Science) be considered as a relevant proxy of the birth and/or PhD ages of scholars?*

Methodology

In order to answer the research questions it is necessary to have a dataset of scholars for whom their real ages are certainly known as well as the publication years of their scientific publications. Thus, as our golden set, in this study we have considered one of the (possibly) largest datasets of individual scholars for whom real individual characteristics are known (this dataset has been used in some other studies, e.g. Gingras et al., 2008; Larivière et al., 2011). This dataset is composed by 13,626 university professors from Quebec who have published at least one article during the 1980-2012 period. For every scholar in the dataset, the following individual elements have been codified:

- Year of birth [*Birth year*]
- Year of PhD (year when the scholar has obtained her (first) PhD) [*PhD year*].
- Publication year of their first publication in the Web of Science (WoS) [*YFP*]
- [*Birth year to YFP*], which is calculated as [*YFP*]-[*Birth year*]
- [*PhD year to YFP*] which is calculated as [*YFP*]-[*PhD year*]
- Domain (nine disciplinary fields of activity of the scholar, which is based on the 2000 revision of the U.S. Classification of Instructional Programs (CIP)[3] developed by the U.S. Department of Education's National Center for Education Statistics (NCES).

Complementary, we have also calculated the total number of publications of the scholars in the period 1980-2012 [*P*].

A technical limitation of the dataset is that the WoS publication data starts in 1980, thus meaning that for very old individuals it is not possible to know with certainty if the first publication recorded in the WoS during the period 1980-2012 truly corresponds with their actual first publication. To reduce the effect of this issue, we decided to focus only on those individuals that have a birth year later than 1959 (i.e. we don't expect that many scholars would have a publication before their 20's) and a PhD year also later than 1980 (same criteria

[1] Although this term has also been proposed for the time since the PhD has been awarded (Bar-Ilan, 2014). Some other studies have also focused on the starting year of publication of individuals as proxies of age (Fronczak, Fronczak & Holyst, 2006).

[2] Due to space restrictions, in this paper we focus only on the first publication year as a proxy, and leave for a further version of this paper the consideration of other bibliometric variables.

[3] The Classification of Instructional Programs (CIP) is developed by the U.S. Department of Education's National Center for Education Statistics (NCES). More details can be found at: http://nces.ed.gov/pubs2002/cip2000/

as before). As a result of this filtering we ended up with 3,596 scholars that are the final dataset of our analysis.

Main results

This section presents the main results of the analysis. In Appendix 1 the descriptive scores are presented. Results show that there are differences in individual productivity by domain, which is of course not a surprise. For instance scholars from the Basic Medical Sciences and Health sciences exhibit the highest number of WoS papers, while Humanities the lowest. Similarly, the median birth year of the whole sample is 1965, although there are small differences by domain, with Basic Medical Sciences with the oldest individuals (median=1964) and Social Sciences the youngest (median=1967). The median PhD year of the whole sample is 1998, with the Basic Medical Sciences as the oldest median (1994) and domains such as Business & Management, Education, Non-health professionals getting their PhD on median in 1998.

Regarding the time between the birth of the scholars and the time of their first publication, scholars from Basic Medical Sciences, Engineering, Health Sciences and Science are on median the fastest (32 years) while scholars from Business & Management, Education or Humanities are slower (35 years). From the PhD to the first publication, the fastest are the scholars in Health Sciences (1 year) and the slowest the Humanities (4 years). It is important to keep in mind that here we also have cases with negative values, which means that researchers publish publications before their PhD date; a finding coherent with Larivière (2012).

Relationship between the different ages

In Appendix 2 we present the main correlations between the different ages of the scholars. In Figure 1 a summary of the correlations is presented. In general, there is a reasonably good correlation between birth year and PhD year, and the two real ages of the scholars have moderate correlations with YFP, although the PhD year has a generally better correlation with YFP than the Birth Year. These results suggest that it is reasonable to consider the YFP as a proxy of the scientific age of the researchers.

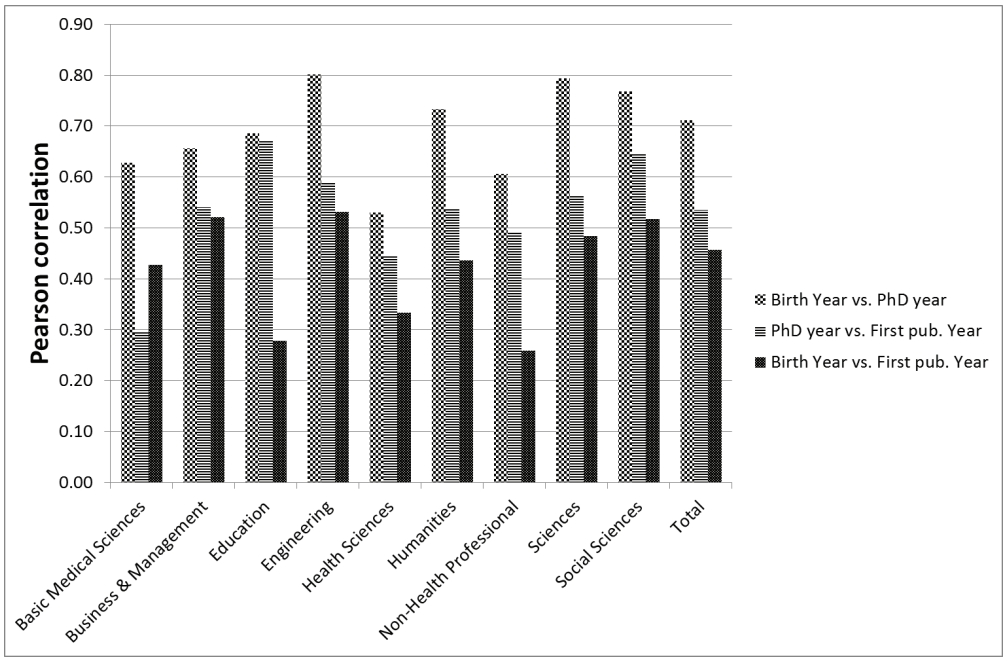

Figure 1. Pearson correlation values of the different ages – by disciplines and all disciplines combined.

YFP as a proxy of the age of researchers

Considering the moderate correlations between the YFP and the real ages of the researchers, we explore the dispersion of the scholars by the different ages. In Figure 2 box plots of each of the three variables (YFP, Birth year and PhD year) grouped by the combination of the same variables are presented. Thus it is possible to understand how scholars distribute across the different ages.

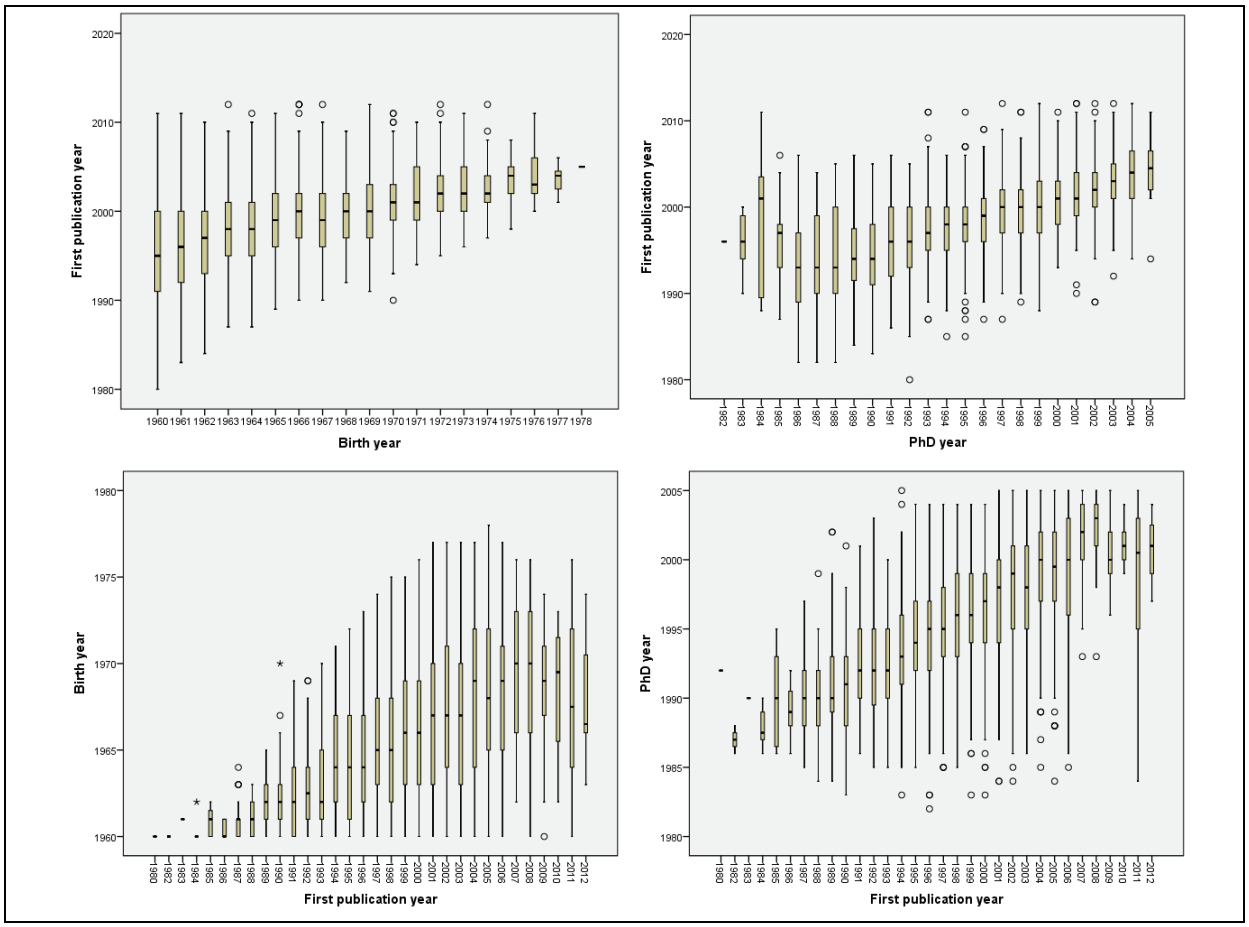

Figure 2. Box plot distribution of scholars across the different ages (all scholars together).

The two graphs on top of Figure 2 present boxplots of YFP observations grouped by each distinct birth year and PhD year. In the case of the birth year, it is possible to see how the earlier the year of birth the larger the variation of the YFP, thus indicating how researchers of all ages start their publication activities at different points in their lives, although the majority (i.e. the 'box' in the graph) tends to concentrate in a range of 5 to 10 years. The YFP median also tends to increase as the birth year increases. In the case of the PhD year we see also a quite disperse distribution of the first publication year of the scholars, although (with the exception of some irregularities among the scholars with the earliest PhD years) we notice a stepper increase in the median value of the YFP as the PhD year increases.

The graphs on the bottom of Figure 2 show the distribution of the two real ages (birth and PhD years) as a function of the YFP. Here we can also see an important dispersion of scholars across the two ages. However, in order to summarize the results of these two graphs, in Figure 3 we present the interquartile ranges (i.e. range of the number of years that include the 50% of all the observations), thus allowing to identify where most of the scholars are located in the distribution as a function of their first publication year.

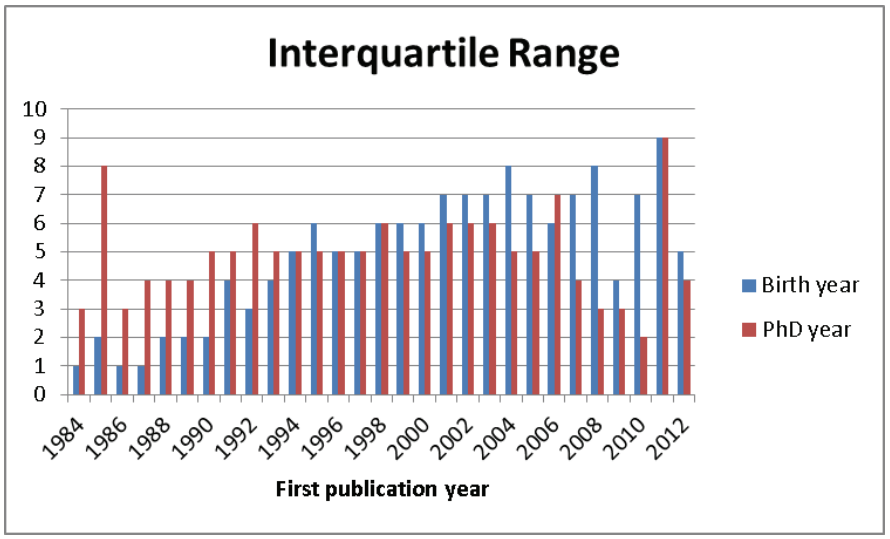

Figure 3. Interquartile range (in number of years) for Birth year and PhD year as a function of YFP.

Figure 3 shows that the interquartile range in all cases is smaller than 10 years for any of the two ages considered. Actually the average for all the YFP years considered is 4.9 years for both ages (with a median of 5). Thus, a possible interpretation of this result is that if we would only count with the YFP of the scholars, with a range of around 5-10 years we would be able to capture the real age of about 50% of all the scholars who started to publish that year.

Exploring a predictive model for the age of scholars based on bibliometric indicators

In this section a more predictive approach is presented. We are interested in estimating the birth and PhD years of a generic researcher by using the YFP indicator in our data sample. Numerous approaches can be taken, from the selection of different models and independent variables that could influence the two ages. In the present study we choose the simple linear regression model, with the average birth year and the average PhD year as dependent variables and the YFP as the independent variable. We will therefore infer on the average birth and PhD year of a scholar, and Figures 4 and 5 provide the linear regression fit of the two models, along with confidence and prediction intervals.

Using linear regression analysis the average ages (birth year and PhD year) of the whole list of scholars are fitted, including a 95% confidence interval as well as a 95% prediction interval. Although both intervals account for the uncertainty of the regression parameter estimates, there is an important distinction between the two intervals. The confidence interval is supposed to cover the true average birth year (of all the scholars in the statistical population) with high probability in 95% of the cases. The prediction interval provides limits on a future sampled observation that is an average of a given number of scholars from the set of all the scholars in the world. The prediction intervals refer then to actual observations in the data, and hence account also for the variation in the data, whereas the confidence intervals refer to the population's (of all scholars) average birth year. The prediction intervals are always larger than the confidence intervals.

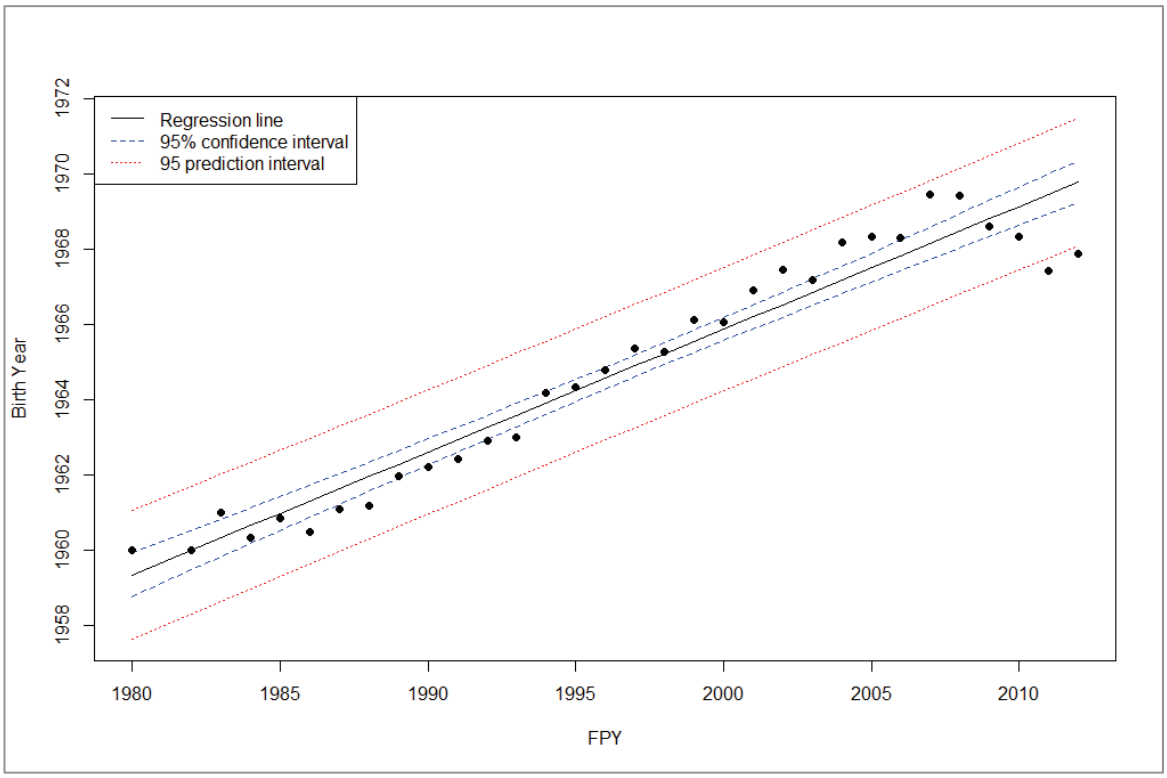

Figure 4. Average birth year by YFP, fitting a regression line and 95% confidence and prediction intervals.

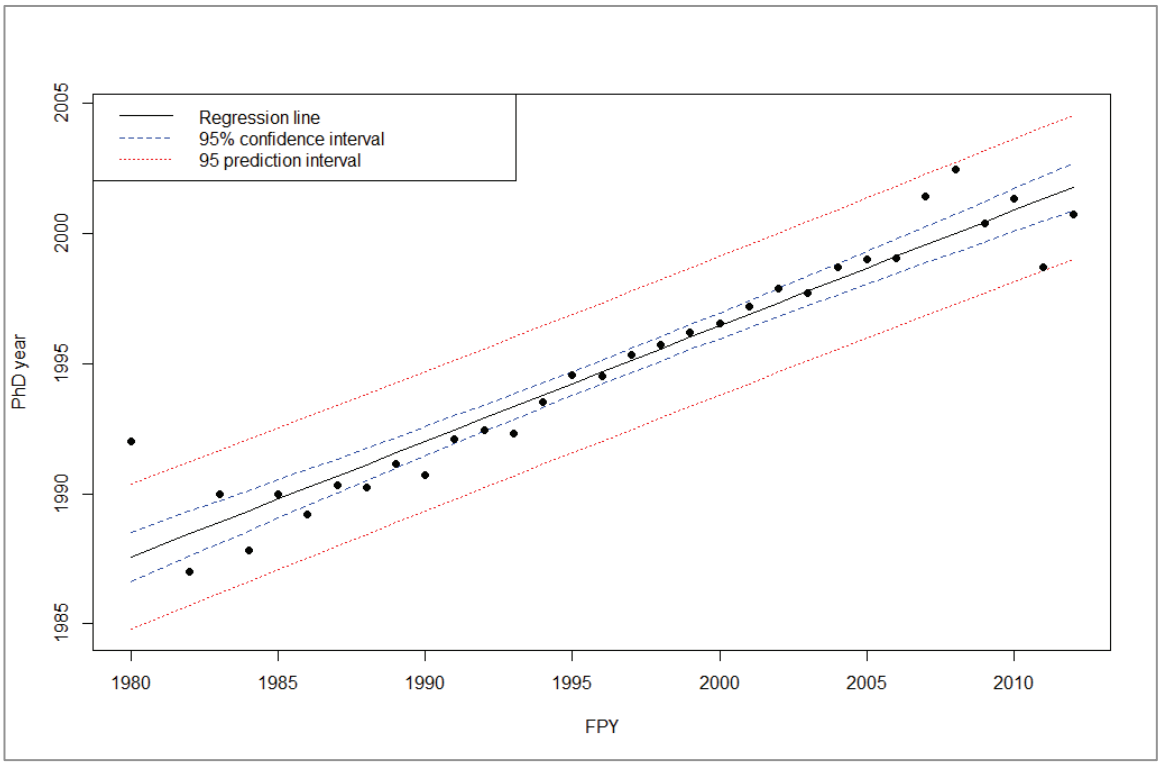

Figure 5. Average PhD year by YFP, fitting a regression line and 95% confidence and prediction intervals.

The main difference with bottom graphs in Figure 2 is that here the target is to estimate the average age of scholars from a given YFP. For example, in Figure 4 we can see how for scholars with a YFP=1995 their average birth year would be 1963, and the prediction interval ranges between 1961 and 1965. A similar pattern is observed in Figure 5 for PhD year (i.e.

with YFP=1995 the average PhD year would range around a period of five years). This suggests that we would be able to estimate the average ages of the scholars with a given YFP within an interval of 5 years. Of course, it is important to keep in mind that this analysis is based on the average values for all scholars, which is different from the individual prediction of individual scholars; however the relatively short prediction intervals (around 5 years) supports the importance of the YFP as relevant proxy for the ages of individual scholars.

Discussion and conclusions

Age is one of the most important socio-demographic determinants of researchers' activities, funding, output and impact. However, the lack of systematically recorded information on the age (real or academic) of researchers makes the need of developing reliable and valid proxies a priority. So far, the age of the first publication of individual scholars has been frequently considered as a proxy of the real age of scholars; however its validity has never been tested. Based on a sample of Quebec researchers for whom their actual birth year, PhD year as well as the year of their first publication are known, a study on the relationships among these ages has been performed.

The three ages correlate moderately well, birth year and PhD year have a good relationship, and YFP has moderate correlations with the other two ages, particularly with the PhD year. It is also possible to detect an important dispersion of scholars across the different ages, indicating that new authors (and new researchers) basically can come from a wide range of years. This means that, in spite of the moderate correlation between the YFP and the other ages, the YFP can only be considered as a proxy for researchers' age, as it does mix researchers with different birth and PhD years. The consideration of cohorts of years seems to be a more reasonable alternative. Thus, it is possible to argue that considering authors who started to publish in a given year, the majority of these scholars would have ages (birth and PhD) within a range of 5 to 10 years.

It is important also to highlight some of the limitations of this study. In the first place, we are working with a dataset of scholars from only one location (Quebec in Canada), so we need to keep in mind the limitations of the representativeness of our sample for the whole world. Thus, issues related with the changes and internal evolution of PhD programs could partly influence the results and hinder their generalization. Secondly, WoS is the only database considered for the determination of the YFP, however scholars can publish outputs not covered by this database, which is likely the case in Quebec, whose local literature in the social sciences and humanities is highly relevant (Larivière & Macaluso, 2011). Thirdly, in this study we haven't explored differences across fields, but arguably there are differences in the relationship between the ages and the first publication year of the scholars as disciplinary differences in individual productivity have been also discussed (Ruiz-Castillo & Costas, 2014).

All in all, considering the limitations previously exposed, our results are still policy-relevant and support the idea that the first publication year(s) of individual scholars can work as a reasonable proxy as their age, particularly when considering cohorts of researchers. For the final version of the paper other approaches will be also considered, including the analysis of the positions of the scholars in the papers (as these positions are related with the age of scholars (Costas & Bordons, 2011), other bibliometric indicators (e.g. the total number of publications of a scholar and total number of citations, which are age dependent) as well as the different disciplines of scholars. Finally, the consideration of other datasets from other countries and/or disciplines is an important development in order to globally validate the different tests and models obtained and to establish a more generalizable approach for the estimation of ages based on bibliometric data. A potential recommendation derived from this study is the relevance of incorporating information about the age, PhD year, gender and other

demographic characteristics in modern Research Information Systems (RIS). This would allow for more accurate studies of the demographics and changes in the trends of scientific productivity of individual scholars.

Corpus Specific Stop Words to Improve the Textual Analysis in Scientometrics

Vicenç Parisi Baradad[1] and Alexis-Michel Mugabushaka

[1]*Vicenc.PARISI-BARADAD@ec.europa.eu*
European Research Council Executive Agency, COV 24/161, B-1049 Brussels (Belgium)

Abstract
With the availability of vast collection of research articles on internet, textual analysis is an increasingly important technique in scientometric analysis. While the context in which it is used and the specific algorithms implemented may vary, typically any textual analysis exercise involves intensive pre-processing of input text which includes removing topically uninteresting terms (stop words). In this paper we argue that corpus specific stop words, which take into account the specificities of a collection of texts, improve textual analysis in scientometrics. We describe two relatively simple techniques to generate corpus-specific stop words; stop words lists following a Poisson distribution and keyword adjacency stop words lists. In a case study to extract keywords from scientific abstracts of research project funded by the European Research Council in the domain of Life sciences, we show that a combination of those techniques gives better recall values than standard stop words or any of the two techniques alone. The method we propose can be implemented to obtain stop words lists in an automatic way by using author provided keywords for a set of abstracts. The stop words lists generated can be updated easily by adding new texts to the training corpus.

Conference Topic
Methods and techniques

Introduction
Textual analysis -also referred to as "lexical analysis"," text mining", "co-word analysis" or "linguistic network"- has a long tradition in scientometric analysis. Earlier references can be found in the pioneering work of Eugene Garfield and others (see Garfield, 1967) studying the potential of citation analysis in information retrieval as compared to methods based on terms frequencies. Callon et al. (1983, 1986) introduced the concept of co-word analysis in science and technology studies. This technique was further developed and popularized in scientometrics by the work of Leydesdorff (1989) and researchers at the Center for Science and Technology Studies (CWTS) at the Leiden University (Noyons & van Raan, 1998).

With the availability of vast collections of research articles and better and faster computer tools, which help text analysis, the technique has firmly established itself in scientometric analysis. Nowadays it is used in various contexts: to study the thematic proximity in a collection of documents; to map scientific papers based on concept maps; to detect dynamics and trends of research based, for example, on centrality of concepts or to characterise a particular research community, by identifying relationships between the terms it uses.

While textual analytical techniques differ in degree of complexities and approaches they take, virtually all of them require relatively intensive pre-processing of the input texts. Typically, the following steps are involved in the pre-processing: (1) tokenization, (2) converting to lower case, (3) stemming and (4) removing stop words. For this last step, researchers typically use standard stop words lists obtained from texts in many different domains.

In this paper we argue that using corpus specific stop words might help the textual analysis. The paper is divided in four parts. The next section reviews briefly existing work on stop words and describes in detail two, relatively simple methods, to extract corpus specific stop words. In the subsequent, third, section we present a case study to illustrate the benefits of corpus specific stop words over more general stop words. The concluding remarks discuss limitations and point to future directions.

Related Work

When researchers in scientometrics started using textual analysis, they were standing in long tradition of information retrieval research. Early studies of word frequencies in a text or collection of documents appeared in the last century, when George K. Zip formulated an empirical law that relates terms frequencies (tf) to rank in a frequency ordered word list (Zip, 1932). This frequency characterisation was used later by Hans Luhn to obtain statistical information of words in texts and to compute a relative measure of the significance of individual words and phrases (Luhn, 1958). Using this measure Luhn hypothesized that the most discriminant words are those appearing in the middle of the frequency rank. Salton went a step further by incorporating the document frequency (df) as a measure of the discriminatory capacity of the words (Salton & Young, 1973). They suggested that words can appear in a document collection either in a random manner or concentrated in a few exemplars and they proposed the product of the term frequency times the inverse document frequency (tf • idf) as a measure of the degree of significance: the words appearing in many documents (df high) or with a low presence (tf low) are considered stop words. Based on these frequency descriptions Christopher Fox elaborated in the 90's a list containing stop words (Fox, 1990) extracted from the Brown Corpus of English literature. Although these stop words can be considered the standard or classical list and they have been frequently used, we note two limitations: first they are quite outdated and second they may be too general to take into account the specificities of a collection of texts. They may not be suitable to filter out words belonging to specific research fields or words of recent apparition. As Makrehchi & Kamel (2008) suggest, specific stop words differ from one domain to another.

Several methodologies have been proposed recently to create new stop words lists, customized to particular corpus. Among them, two proposals attracted our attention due to their relative simplicity.

On one hand, an unsupervised method to compute stop words lists arises from the study of the statistical distribution of words, by Church, K. and Gale, W. (1995) and their hypothesis that common stop words follow a Poisson distribution. This has been used to create a stop word list for particular Polish texts (Jungiewicz & Lopuszyński, 2014). We call this approach the *Poisson stoplist.*

Under this hypothesis one assumes that the document frequency of words (df) in a corpus can be estimated (dfe) from their term frequency (tf) and the total number of documents (N) by using the probability theory:

$$\frac{dfe}{N} = 1 - P(0),$$

where $P(0)$ is the probability of not appearing the word. Assuming a Poisson distribution for stop words, the probability of k instances of a word is given by:

$$P(k, \mu) = \frac{e^{-\mu} * \mu^k}{k!},$$

where μ is the average number of instances per document:

$$\mu = \frac{tf}{N}$$

The relation dfe/df is supposed to be close to 1 for randomly distributed terms (stop words) and shows an increase for highly cluttered terms (keywords); although this depends on the corpus, as Jungiewicz and Lopuszyński found when computing their stop word lists for legal texts from the public procurement domain. They realised that their most common stop words had a high variability in their distribution and replaced the Poisson assumption with a negative binomial distribution, which allows a larger variance.

On the other hand, S. Rose et al. (2010) proposed an unsupervised, domain and language independent method to extract keywords from individual texts called RAKE (Rapid Automatic Keyword Extraction) and a supervised method to elaborate stop word lists based on the intuition that words adjacent to keywords tend to be stop words.
RAKE uses stop words to parse the text and extract candidate key phrases (consisting in one or more words). The key phrases are then scored by computing word co-ocurrences and using a metric that favours words belonging to long key phrases. The top T candidates are chosen as keywords (key phrases).
The method proposed by S. Rose to extract stop words from a corpus resorts on accumulating for each word its 'adjacency frequency' (af) and 'keyword frequency' (kf), together with the term frequency (tf) and document frequency (df). Then, given a selection threshold n, the most frequent words with af > kf are chosen as stop words. This method is called by the author *keyword adjacency stoplist* (because it includes primarily words that are adjacent to and not within keywords: Rose et al. 2010, p. 14). We refer to this method as *RAKE stoplist* in this paper.

Case Study: stop list for a collection of abstracts of funded projects

To study the suitability of the above described methodologies and create our own stop words list we applied them to a corpus from abstracts of projects, funded by the European Research Council, in the Life Sciences domain. This corpus consists of 1579 projects covering diverse research areas. The table 1, shows the number of project abstracts by each research area (which corresponds to the scientific panel in which the project was evaluated).

Table 1. Overview of the corpus of abstracts used in the case study

Scientific areas	abstracts	%
Molecular and structural biology and biochemistry	176	11.1
Genetics, genomics, bioinformatics and systems biology	178	11.1
Cellular and developmental biology	164	10.4
Physiology, pathophysiology and endocrinology	176	11.15
Neurosciences and neural disorders	217	13.7
Immunity and infection	168	10.6
Diagnostic tools, therapies and public health	209	13.2
Evolutionary, population and environmental biology	168	10.6
Applied life sciences and biotechnology	115	7.3

Creating stop words

We randomly chose 80% of the abstracts as a training set and the other 20% as a test set.

Following the algorithms outlined in Rose et al. 2010, we wrote a program in Python to create a table (which we call Frequency table) with all the words (12621 in total) of the training set that contains the words, term frequencies (tf), document frequencies (df), keyword frequencies (kf) and adjacent frequencies (af).
This table was used to create both the *Poisson stoplist* and the *RAKE stoplist*. For the later, we set various thresholds to obtain the top n words with the highest term frequency.

Evaluating the stopwords

To evaluate if the corpus-specific stop words improve textual analysis, we use them in extracting keywords. We compare the keywords extracted using those stop words with

author-provided keywords. The idea is that, depending on the stop words used, the keywords extracted will match more or less the ones provided by the authors and the higher the share of matched keywords the better the stop words list.

It should be noted that author-provided keywords do not necessary contain words which also appears in the abstracts. In our corpus, out of 7845 keywords given by the authors only 3494 (44.5 %) where encountered in the abstracts. This means that the precision and F-measure need to be taken into account with care and thus we have not used them for the evaluation of the quality of the stop words list, resorting only to the recall measure, computed as the relation between the total number of correct extracted keywords and the total number of keywords given by the authors, that appear in the abstracts.

We compared the keywords provided by authors with the keywords extracted using the following lists of stop words

1. Standard *Fox stop words list*
2. Stop words list created using the Poisson distribution hypothesis (*Poisson stoplist*)
3. Stop words list computed using keyword adjacency (*RAKE stoplist*)
4. Stop words lists computed using combinations of *Fox,Poisson* and *RAKE*

For keywords extraction we used a Python implementation of the RAKE algorithm (https://github.com/aneesha/RAKE)

1. *Fox stoplist*

This list serves as a baseline for our work and the computation of the recall of the keywords extracted using RAKE algorithm does not need to tune any parameter. The recall obtained is 56.42%.

2. *Poisson stoplist*

To extract the stop words using this approach we need first to set the threshold for the relation dfe/df. To do that we computed the mean and standard deviation of the dfe/df for all the *Fox* stop words that appear in the training set. Figure 1 shows the plot of these values, where the mean (dfe/df) + std(dfe/df) is 1.55. There are only 14 Fox stop words excluded from the list and apart from the words (*ordering, right and small*) their term frequency is very low. We have used this threshold to obtain the stop words from our training data appearing in at least 10 documents (df>10) and we have obtained a list of 2008 words that gives a recall of 58.25% in our test set, which is better than the *Fox stoplist*.

3. *RAKE stoplist*

To use the RAKE approach we extracted all the words from the training set with af>kf and created an ordered table, sorted in descending order of word occurrence (tf). This table consisted in a list of 2045 candidate stop words. To choose the top best frequency rank we tested subsets of these lists and computed their recall values. The result obtained using all the words in the list was 45.42 % of recall and the results improved by removing words from the list, having a peak at a 53.31% of recall, when using the first 185 words of the rank.

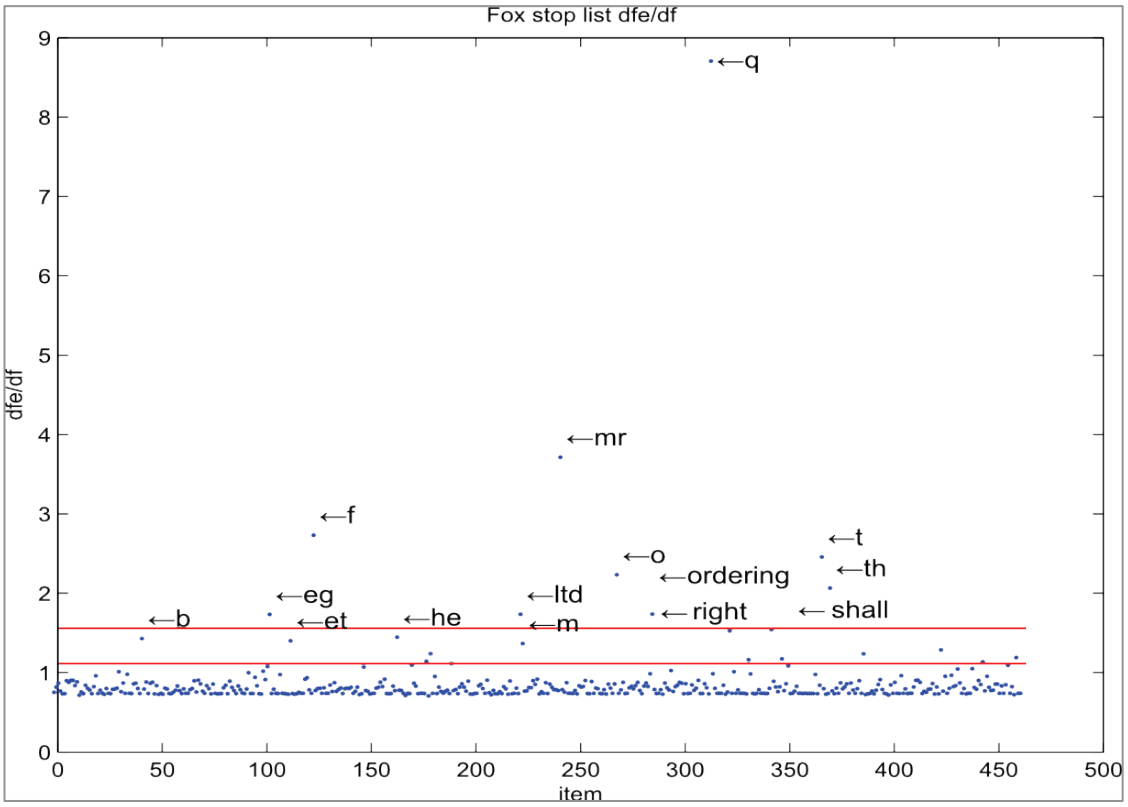

Figure 1. Fox stoplist dfe/df values found in the training corpus. Just a few words are above the standard deviation limit, and they are rarely found (tf very low).

4. *Combinations Poisson and RAKE*

Since the *RAKE stoplist* gave us worse results than the *Fox stoplist*, we tried to combine them with the Poisson approach (*RAKE-Poisson*) and we extracted the words with df>10,af>kf and dfe/df<1.55. This improved the previous results, giving a recall of 62.34%. Note that the condition dfe/df> r can also be seen as an adaptive threshold on tf, since, under the Poisson distribution, it can also be expressed as:

$$tf > N * \ln\left(\left(\frac{df}{N}\right)r - 1\right),$$

and instead of choosing a minimum common tf for all the words, we adapt the tf to each word's df. In Figure 2 we have plotted the df of the RAKE stop words (tf>0) , together with the Fox stop words found in the *RAKE stoplist*. Also we plotted the dfe/1.55 curve which shows the limit above which the words belong to *RAKE-Poisson stoplist*.

After inspecting the frequencies of the RAKE-Poisson stop words we found words expected to appear in Life Sciences texts and we questioned ourselves if their removal from the stoplist would improve the recall results. To check it we removed them by hand and the recall increased to 64.56 %. A more detailed inspection of the stoplist frequencies allowed us to see that just a few words (6 in total) belong to the life sciences domain (genetic, disease, protein, molecular, gene, cell), all them with kf>60 had a 1.1<dfe/df <1.55. In all them the af/kf relation was less than 5 (af/kf<5). This data gave us the intuition that we needed to decrease the dfe/df threshold and also to be more strict on the af/kf condition, so we tested a stoplist consisting in the RAKE intersection with Poisson stoplist (df>10 and af>5*kf and dfe/df<1.2) which gave a recall of 68.69%, being this the best result. We call it the *RAKEm-Poisson stoplist*.

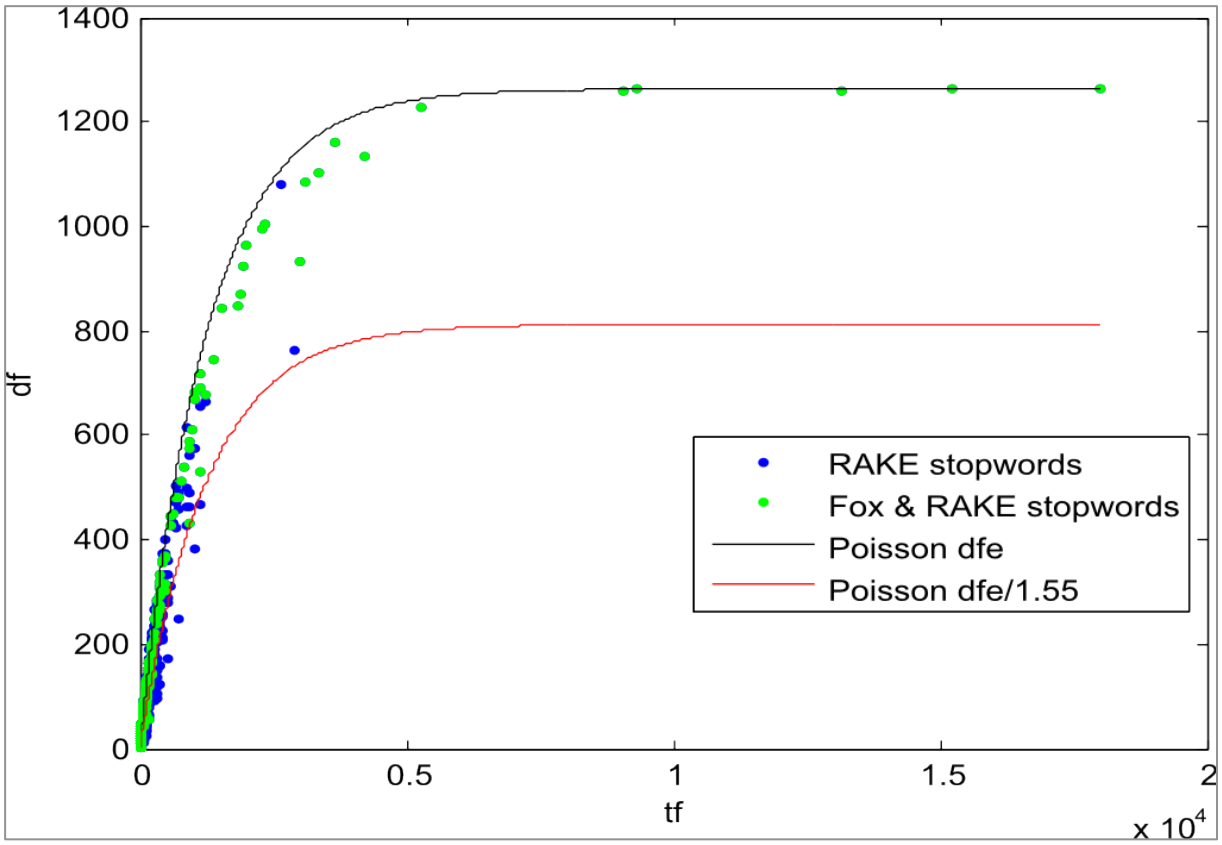

Figure 2. RAKE and Fox stop words. We can see that the Fox stop words follow the Poisson distribution better than the RAKE stop words, which appear more concentrated at low df values.

Conclusion

Our aim is to obtain stop words that help to provide meaningful and significant keywords that summarize the texts; the validation of the stoplists we did was based using the author given key phrases which most of the times had fewer words than the ones obtained using RAKE. We think that this circumstance is favouring standard stoplists since they will still produce single word keywords given by authors and end up yielding overall recall values similar to specific domain stoplists. Therefore we plan as a future work to use measures that evaluate semantic value of the key phrases.

We would like to remark that the RAKE-Poisson stoplist can be obtained from the word frequencies and the author keywords, without further human intervention. Our future work involves also the automatization of the computation of the best af/kf and dfe/df thresholds to generate the *RAKEm-Poisson stoplists*.

Abstract
We continue our quest for measures of epistemic diversity that fit the inherent properties of thematic structures in science. Starting from theoretical considerations, we argue that currently available measures of diversity are not applicable to the epistemic diversity of published scientific knowledge because topics are fluid and overlap. Consequently, we abandon attempts to assign papers to topics and instead explore opportunities to measure diversity based on paper dissimilarities. Considerations of the exploitation of information and signal-to-noise ratios in networks of papers let us dismiss an earlier attempt to base a dissimilarity measure on the resistance distance between papers in the network of papers and their cited sources. In this paper, we explore a dissimilarity measure based on papers' 'views' on the whole network, with the 'view' of a paper consisting of all other papers in the network ranked according to the length of their shortest paths to the paper. We present test results on the diversity of topics, journals and country outputs for information science (2008) as well as on the diversity of country outputs in astronomy and astrophysics (2010).

Conference Topics
Methods and techniques; Indicators

Introduction
The epistemic diversity of research – the diversity of empirical objects, methods, problems, or approaches to solving them – has become a matter of concern for science policy. Attempts by science policy to increase the selectivity of research funding and the growth in strength and homogeneity of incentives for universities have led to concerns about an undue reduction of the diversity of research. Several specific warnings refer to the UK's research assessment exercise (Gläser et al., 2002, Molas-Gallart & Salter, 2002, Rafols et al., 2012). A similar concern has been raised in Germany, where profile-building activities at all universities may make the small subjects disappear (HRK, 2007). Laudel & Weyer (2014) observed in the Netherlands that universities' uniform responses to political signals contributed to the disappearance of one field and the stagnation of another.

Discussions about dangers to the epistemic diversity of research have in common that they lack both theoretical backing and empirical evidence. Epistemic diversity is an ill-understood topic in science studies. It is rarely clear what the concept is intended to refer to, how epistemic diversity might affect research, and how it can be operationalized. Theoretical reasoning drawing on analogies to biodiversity assumes diversity is good for science (e.g. Rafols et al., 2012). However, arguments lack empirical grounding, and no specific arguments about necessary and sufficient levels of diversity or about dangers of too much diversity can be made. The empirical studies of interdisciplinarity (e.g. Bordons et al., 2004; Rafols & Meyer, 2007; Rafols et al., 2012) were forced to use rather coarse indicators such as the journal classification of the web of science, and could not theoretically justify the measures they applied.

The aim of our paper is to present a systematic approach to the measurement of diversity that derives possible bibliometric measures of diversity from properties of the system whose diversity is to be measured, namely scientific knowledge.

We start from a theoretical definition of 'topics' in science and demonstrate that the properties of topics do not match the built-in assumptions of current indicators. While this does not necessarily invalidate the indicators, the assumptions underlying the measurement of diversity in science must be made explicit, and their applicability be argued. We suggest two additional strategies that may alleviate the problems resulting from the mismatch between properties of topics and prerequisites of indicators. The first strategy abandons the explicit identification of topics and measures the diversity of paper networks rather than scientific knowledge. We propose a measure of paper similarity that takes some of the properties of scientific knowledge into account, and demonstrate our approach by applying the measure to two data sets. The second strategy, which is outlined in this paper but not applied, uses the same similarity measure for determining the disparity of topics, thereby enabling the application of existing diversity measures.

Theoretical background

In the most general sense, 'diversity' is the property of a system, namely its heterogeneity, which is caused by the disparity of its elements. Among the many aspects of a science system to which the concept diversity can be applied, we are interested in the diversity of published scientific knowledge. Other aspects of a field's diversity such as the diversity of informal knowledge, instrumentation, empirical objects, or scientific training of researchers, will not be considered here. The *epistemic diversity of a research field* is thus defined here as the diversity of published knowledge claims about scientific problems, solutions, empirical objects, approaches and methods, which are communicated by the field's researchers in publications.

The definition of epistemic diversity as a property of published knowledge suggests using bibliometric methods for its measurement. These methods must support the reconstruction of knowledge structures from publications in a way that is both valid (i.e. returns knowledge structures researchers work with) and supports the measurement of diversity. Fulfilling both requirements is made difficult by inherent properties of knowledge structures in science. In the following, we first discuss the built-in assumptions of current measures of diversity. We then argue that properties of scientific knowledge and of its representation in publications do not meet these assumptions, and discuss opportunities to reconstruct knowledge structures from publications and to measure the epistemic diversity of research.

Built-in assumptions of current approaches to the measurement of diversity

Diversity has been an important topic of biological and environmental research for some time. These fields are mainly concerned with the impact of diversity on the stability and development of biotopes and species. Two approaches to the measurement of biodiversity can be distinguished:

a) The diversity of biotopes[1] composed of several species is measured with a three-level hierarchical approach. Biotopes are considered as consisting of species, which in turn consist of individuals. Three factors contribute to the diversity of such a system, namely

- variety (the number of species in the biotope),
- disparity (the extent to which the species differ from each other), and
- evenness (the distribution of individuals across the different species).

Depending on the research question, these factors can be assessed separately (e.g. if only the number of species is measured) or be combined in synthetic measures such as Shannon's Entropy (combining variety and evenness) or the Rao-Index (combining all three measures).

[1] A biotope is a physical environment (habitat) with a distinctive assemblage of conspicuous species (Olenin & Ducrotoy, 2006: 22).

This approach to diversity is applied in fields outside the biosciences as well (see Rafols et al., 2012, Stirling, 2007). It requires that

- the system whose diversity is to be measured can be analytically decomposed in three levels (system, categories, and elements),
- the contribution of differences between individuals of the same species to the biotope's diversity can be neglected,
- the categories can be constructed as disjunct by assigning each element to exactly one category or by fractional assignments of elements to categories, and that
- all categories share a property that can be used to calculate disparity.

b) The diversity of species composed of individuals is measured on the basis of a two-level approach. In this approach, variety and evenness become meaningless because there is no intermediate level of categories to which elements can belong. The only remaining basis for measuring the diversity of the system is the disparity of individuals. While this approach is used less frequently, it can be considered to be more fundamental because it conceptualizes diversity as the degree to which the elements of a system (here: a species) differ from each other. This approach is applicable as long as a system can be delineated and elements share a property that can be used to calculate disparity.

Both approaches share a premise concerning the disparity of categories and elements. Categories and elements are conceptualized as stable, and their pairwise disparities as independent, i.e. not affected by other categories respectively elements. New elements entering the system (i.e. individuals of a species being born or migrating to a biotope) do not affect the disparity between existing elements or between the categories, and new categories (i.e. species migrating to a biotope) do not affect the disparity between the categories or between the elements that are already present. The same applies to the disappearance of elements or categories.

Properties of topics in scientific knowledge

If the approaches to the measurement of diversity are to be applied to scientific knowledge, the system, categories and elements must be determined. For the three-level approach, the system would be the knowledge of a field, topics in this field would serve as categories, and knowledge claims (the claim for some empirical, theoretical or methodological statement to be true) would constitute the elements of the system. For the diversity measures discussed above to be applicable, these knowledge structures would need to fulfil the built-in assumptions of the measures. We therefore begin by briefly discussing the properties of scientific knowledge in its structures.

Scientific knowledge is produced by scientific communities whose members

- observe the community's shared body of knowledge,
- interpret this knowledge in the light of their own research experience,
- identify gaps in that knowledge and design research processes for producing the knowledge that closes the observed gap, and
- offer their interpretation and the new knowledge to their community.

The interpretation of the community's knowledge and claims about new knowledge are fully or partially shared by some members of the community. We define a topic as *a focus on theoretical, methodological or empirical knowledge that is shared by a number of researchers and thereby provides these researchers with a joint frame of reference for the formulation of problems, the selection of methods or objects, the organization of empirical data, or the interpretation of data* (on the social ordering of research by knowledge see Gläser, 2006). This definition resonates with Whitley's (1974) description of research areas but abandons the assumption that topics form a hierarchy. The only demand the definition makes is that some scientific knowledge is perceived similarly by researchers and influences their decisions.

Due to this nature as shared and collective perspectives, topics have structural and dynamic properties that affect the opportunities for measurement. *Structural properties* include the following:

1) All topics are *emergent meso- or macro-structures*, i.e. they are collective-level products of autonomous interpretations and uses of knowledge by individual researchers.

2) From this follows that topics are *local* in the sense that they are primarily topics to the researchers whose decisions are influenced and who contribute to them, and only secondarily topics to those colleagues who are outside observers.

3) Given the multiple objects of knowledge that can serve as common reference for researchers, it is inevitable that topics *overlap*. Overlaps are ubiquitous because any research is likely to address several topics at once, e.g. by including theories about an object, methodologies for investigating it, and empirical information about an object. They also occur when a knowledge claim belongs to several topics at once (e.g. formulae used in bibliometrics belonging to mathematics but also expressing bibliometric relationships).

4) Knowledge has a *fractal structure* (e.g. van Raan, 2000), and topics can have any size between small (emerging topics that in the beginning may concern just two or three researchers) and very large thematic structures such as bibliometrics. The 'size' of a topic can be defined in various ways – as scope (range of phenomena covered), level of abstraction (which is again linked to the range of phenomena covered), or number of research processes or researchers influenced by it. In all these dimensions there is a continuum from very small to very large topics.

5) The degree to which knowledge influences researchers' actions, and the strength of links between new findings and existing knowledge that are constructed by researchers, also vary between 'very weak' and 'very strong'. As a result, the '*distinctiveness'* of topics varies. Some topics are unambiguously seen as being different from other knowledge by most researchers of a field and are thus well separated from surrounding knowledge, while others are much less pronounced.

These structural properties of topics let them form an inconsistent poly-hierarchy for which not even meaningful levels can be determined. This also implies that no field or collection of papers has exactly one definite thematic structure. Different perspectives can be applied to fields and collections of papers and will return different topical structures. Topics may overlap in their boundaries or pervasively. They vary considerably in their size and 'distinctness', i.e. the extent to which they actually constitute a shared concern of researchers.

Dynamic properties of topics are shaped by their role in the knowledge production process. As coinciding perspectives of researchers, topics are perpetually changing. Researchers constantly revise their perspectives on the existing knowledge and thus the relationships of their perspectives to those of their colleagues. They also utilize and contribute to more than one topic (e.g. theoretical, methodological and empirical ones). Hence, their production of new knowledge may instigate at least one and in many cases all of the following changes:

* Enrichment: Since new knowledge is added to the system, the community's knowledge on a topic is likely to grow.

* Restructuring: The new knowledge is linked to existing knowledge and thereby links existing knowledge, i.e. the density of connections in the system of knowledge increases.

* Reduction: The new knowledge may devalue existing knowledge by proving it to be wrong or may reduce it by subordinating it to a generalisation.

Through these processes, the size of topics, their distinctness and relations between them are constantly changed. New topics may emerge at any time, and existing topics may disappear or radically change.

Representation of knowledge in publications and reconstructions of topics

Since bibliometric methods reconstruct knowledge structures from publications, the representation of knowledge in publications provides the opportunities and constraints for a bibliometric measurement of diversity, which we now discuss in more detail. In the sociology of science, knowledge claims are treated as the basic unit through which new knowledge is communicated (e.g. Cozzens, 1985, Pinch, 1985). Knowledge claims are claims that some new knowledge produced by the author is true; a publication usually contains several such claims.

For the new knowledge claims to be added to the community's body of knowledge, they must be used by other community members in their subsequent knowledge production. This requires the new knowledge to be available to all potential users, which is achieved by publication. With each publication, researchers construct

- an account of the state of the current knowledge on a topic,
- the claim that there is a specific gap in that knowledge,
- the claim to have developed an approach whose application can close that gap,
- the new knowledge produced with this approach, which is claimed to close the gap, and
- in many cases conclusions concerning implications of the new knowledge including the necessity of further specific research (Gläser, 2006: 125-126, Swales, 1986: 45).

These claims embed the new knowledge that is offered to the community in the existing knowledge. However, they do so selectively and *ad hoc*. The claims in a publication are organised in a way that maximises the chances of the new knowledge's further use by emphasizing originality, relevance, validity and reliability of the new knowledge. Links to the existing knowledge are crafted to further this impression.

The new knowledge claims shape subsequent knowledge production processes if they inform the formulation of problems, choice of methods or interpretation of results by readers of the publication. If they do so, the researchers using them are likely to indicate the link of the new knowledge they offer to these knowledge claims, thereby treating them as part of the community's knowledge. This 'elementary process' of adding knowledge causes the dynamic properties described in the previous section. If a new knowledge claim is added, the community's knowledge becomes enriched, and its structure changes because the claim creates new links between, reinforces or remove existing links. New knowledge claims may also invalidate existing claims or subsume them to more general statements if they are used by other community members in this way.

Consequences for the measurement of diversity

The properties of knowledge claims and topics affect the opportunities to reconstruct topics from publications with bibliometric methods, i.e. by using properties of publications such as authors, journals, references, or terms. To begin with, no method for the bibliometric reconstruction of individual knowledge claims has been proposed so far. Knowledge claims are represented in series of sentences and clauses that are distributed across a publication. Reconstructing them would be a task for linguistics but is still impossible for that field, too.

Bibliometric methods are better suited for the reconstruction of topics because the latter are larger and span many publications. However, from the properties of topics described earlier follows that none of the bibliometrically usable properties of a paper can be assumed to be thematically homogeneous in the sense of representing only one topic. Since research processes are influenced by and address more than one topic, topics overlap in research processes, publications (and thus references), terms, journals, and authors. Furthermore, researchers apply their individual perspectives on the scientific knowledge when constructing

and linking topics, which is why links to topics may occur unpredictably in a variety of scientific fields. Consequently, any finite sub-set of papers is unlikely to include all publications addressing a specific topic, which means that any hierarchy of topics is also only partially covered by the paper set.

Owing to the mismatch between properties of publications that can be used for the reconstruction of topics and the representation of topics in publications, bibliometric methods inevitably reduce the complexity of the underlying knowledge structures. This is not a problem in itself because all models reduce complexity. The question is not how the reduction of complexity can be avoided but whether a specific reduction of complexity is appropriate to the purpose. Answers to this question should be part of a bibliometric methodology that links specific purposes of topic reconstruction to specific strategies that are applied. The absence of such a methodology is one of the major obstacles for bibliometrics.

When we apply these methodological considerations to the measurement of epistemic diversity, we can distinguish three strategies for solving the problems posed by properties of scientific topics. The first strategy, which has been applied in all attempts to measure epistemic diversity so far, constructs distinct topics to which papers are assigned. The three-level approach is then used for the measurement of diversity.

A second possible strategy would be to construct overlapping topics to which papers belong partially. In order to apply three level-diversity measures, the topics would have to be made disjunct by fractionalising the papers. The disparity of topics would need to be measured based on the difference in paper membership. While this strategy still has some problems in the case of pervasive overlaps of topics, it would create a more precise representation of topics and still enable the application of three-level diversity measures.

The third strategy, which we apply in the remainder of the paper, circumvents the problem of topic reconstruction by applying the two-level approach. Since knowledge claims cannot be reconstructed from publications, the strategy measures paper diversity as a proxy for knowledge diversity. This strategy requires a similarity measure for published papers, which should reflect the properties of thematic structures in science discussed above.

Methods and Data

Network-based measures of paper similarity

Diversity measures for the two-level approach aggregate the pairwise similarities of all elements. Among the many ways in which the similarity of two papers in a network can be determined, we need to find those that strike a balance between utilizing as much information as possible and avoiding the inclusion of irrelevant information that contaminates the measure.

Bibliographic coupling is well-established, and is commonly considered as one of the best bibliometric measures of paper similarity (Ahlgren & Jarneving, 2008: 274-275). The strength of bibliographic coupling between two papers can be used directly as a measure of their similarity. However, bibliographic coupling is not a useful measure for the similarity of papers that are not coupled. All these papers must be considered equally dissimilar, which they are certainly not. Thus, bibliographic coupling is unsatisfactory as a measure of paper similarity in networks.

An alternative to using bibliographic coupling is the utilization of all connections in a network, e.g. by measuring similarity as resistance distance in networks of papers and their cited sources or in bibliographic coupling networks. In this approach, indirect links between papers are taken into account, i.e. information about the whole network is utilized for the calculation of all pairwise paper similarities (see Gläser et al., 2013 for an example). However, this approach inevitably uses information about detours through a network – i.e.

about connections that exist and can technically be made but are not meaningful in terms of paper similarities. In other words, the measure is distorted by paths that do not reflect thematic similarity. Furthermore, our own experiments showed the measure to favour papers with a high degree. Finally, using all paths in a paper network for the measurement of its diversity makes the measure particularly sensitive to changes in the network structure. If measures of paper similarity are based on the resistance distance, each paper that is added to the network changes the resistance distance and thus the similarities of all papers in the network. This is an extremely unrealistic assumption about the impact of new publications on the epistemic diversity of a field.

Between the use of only information about direct coupling and the use of information about all possible connections between papers lie measures such as length of the shortest path between two nodes. This measure makes little sense in networks of papers and their cited sources because each reference two papers have in common creates a path of the length two between them. For networks in which links reflect the relative strength of bibliographic coupling, the length of shortest paths captures more information.

By determining the length of the shortest path between two papers in a network, other connections are taken into account indirectly by dismissing them as longer paths. Still, the environment of a paper is largely neglected by such a measure. However, the length of shortest path can be used to construct an indirect measure of paper similarity that takes the environment of papers into account. We can construct the 'view' of a paper on its environment by ranking all other papers in the network according to their distance to that paper. The 'view' describes how dissimilar other papers in the network are in terms of their shortest paths. The similarity between two papers can be defined as the similarity of the two papers' 'views' on the network, which is measured by calculating the rank correlation of the two lists.

Thus, we measure the similarity of two papers by:

- determining the shortest paths between all pairs of papers in a bibliographically coupled network (weighted with the arccosine of Salton's Cosine),
- creating a 'view' of each paper by ranking all other papers according to increasing lengths of their shortest paths,
- calculating the similarity of two papers as the rank correlation (Spearman) between the two lists, and
- transforming the rank correlation in a similarity measure.

This measure, which can be interpreted as the similarity of the 'views' of the two papers on their scientific environment, avoids the influence of degrees. It is similar to the use of "preferences" in an "affinity" system by Balcan et al. (2012) in their construction of overlapping endogenous communities.

Data

To test our measure, we used two data sets. The first data set is the main component of publications (articles, letters and proceedings papers) in six information science journals, which consists of 492 papers (see Havemann et al., 2012 for a description of this data set). The second data set is the main component of 14,770 publications (articles, letters, and proceedings papers) published 2010 in 53 astronomy and astrophysics journals (see Havemann et al., 2015 for a description of this data set). For each data set, we constructed and analysed the bibliographic coupling network.

Methods

For each data set, we calculated pairwise paper similarities as transformed Spearman's rank correlation of the papers' 'views' on the network. The 'view' of a paper p_i on the network is the vector of shortest paths between p_i and the papers p_1 to p_n of the network. Thus, the dissimilarity of two papers – their distance – is calculated as

$$dist\ \left(view(p_i i), view\left(p_j j\right)\right) = 1 - \frac{r_{sp}\left(view(p_i), view\left(p_j\right)\right) + 1}{2}$$

Where r_{sp} is the Spearman's rank correlation coefficient of the two views.

We tested this similarity measure on our information science data set by using it for a Ward clustering and comparing the best matching Ward clusters to three topics we had previously identified by inspecting titles and keywords of the articles.

We then calculated the distributions of paper similarities for country subsets and journal subsets of papers in both data sets, and used the median of the distributions as single-number value of the subset's diversity.

Our diversity measure also enables the construction of 'collective views', i.e. of 'views' of paper sets on each other. We exploited this opportunity in a third step and constructed similarities between countries and journals in information science.

Results

Information science

Our Ward clustering with the similarity measure led to results that compare well to previous experiments with other algorithms (Table 1).

Table 1. Salton's Cosine of precision and recall of pre-defined information science topics by five algorithms.[2]

Table	*MONC*	*HLC*	*FHC*	*RDDC*	*SPBC*
h-index	0.71	0.93	0.59	0.92	0.95
Bibliometrics	0.79	0.82	0.83	0.87	0.86
Webometrics	0.58	0.60	0.46	0.65	0.53

The three best performing algorithms – HLC, RDDC and SPBC – perform best for the h-index, good for bibliometrics including the h-index, and worst for Webometrics. These differences may be linked to the topics' internal diversity (Figure 1). Internal diversity is lowest for the h-index (all papers are very similar) and highest for webometrics (a high proportion of webometrics papers is not very similar). The differences in internal diversity may explain the differential success of algorithms in recapturing the topics.

[2] MONC= Merging overlapping natural communities, HLC=Hierarchical link clustering, FHC=Fuzzification of hard clusters (see Havemann et al., 2012). RDDC= Ward clustering with a similarity measure using the rank correlation of 'views' based on the resistance distance in direct citation networks (Gläser et al., 2013). SPPC= Ward clustering with a similarity measure using the rank correlation of 'views' based on the length of shortest paths in bibliographic coupling networks (algorithm presented in this paper). Among the three topics, bibliometrics also includes the h-index papers.

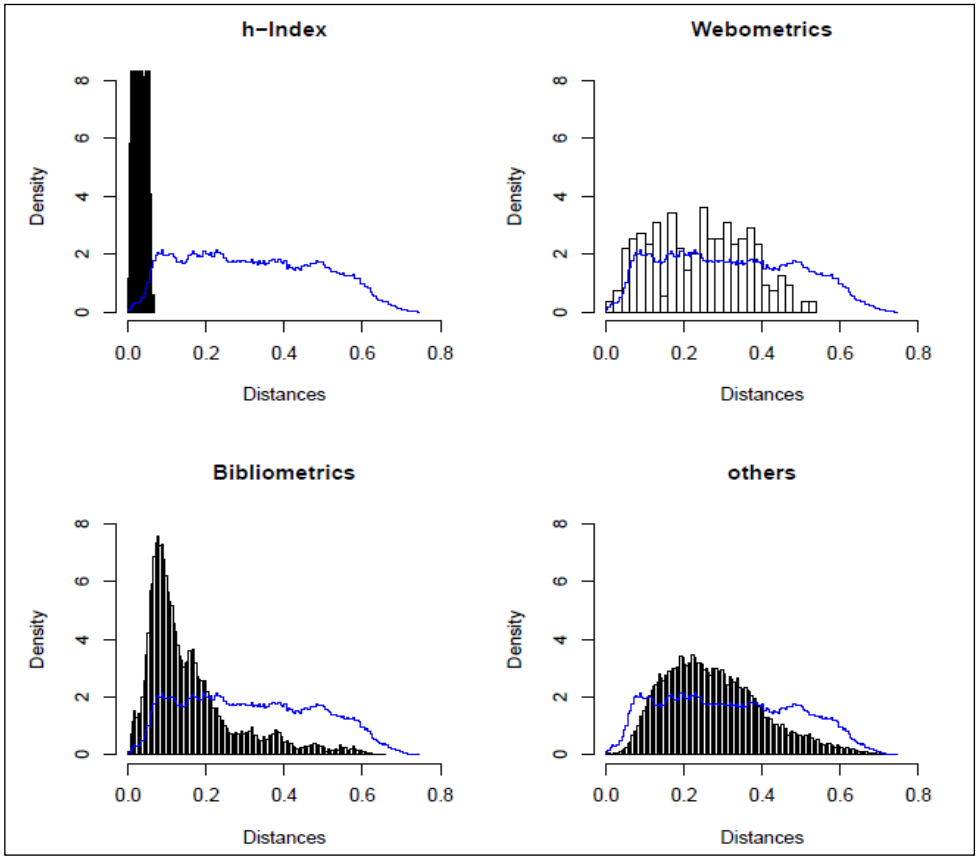

Figure 1. Internal diversity of three topics in the information science network (the blue lines represent the distribution for the whole network, the areas always equal one).

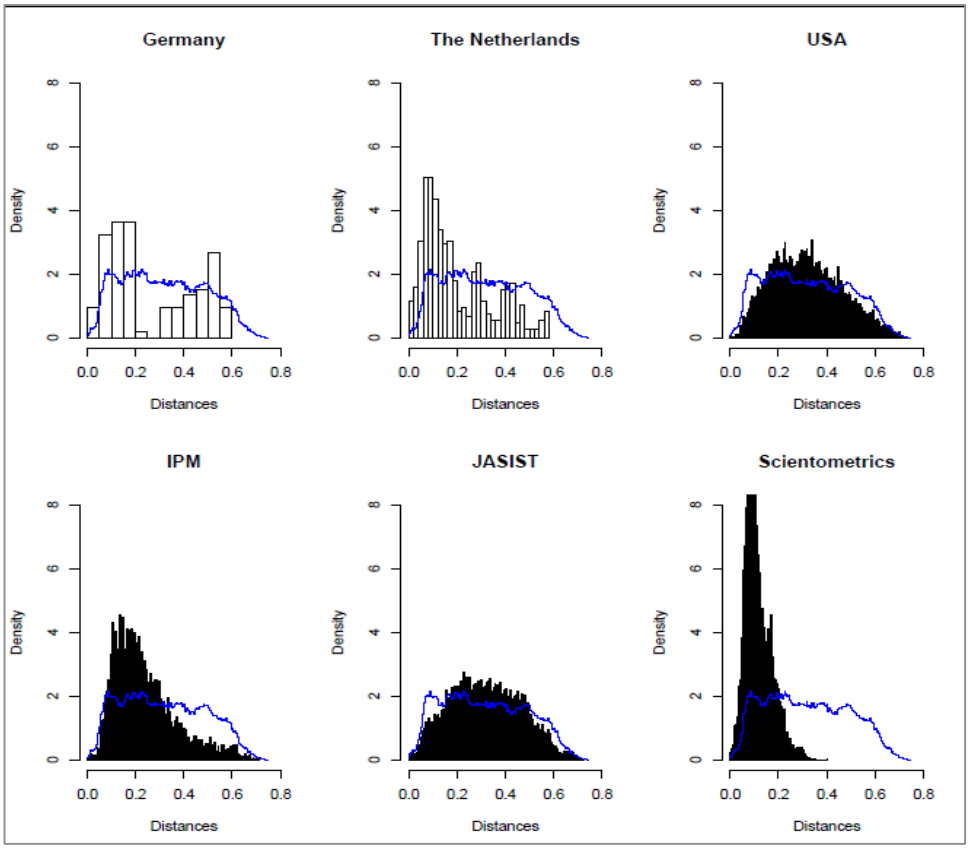

Figure 2. Diversity of information science publications from three countries and three journals.

Figure 2 shows the diversity of information science publications in three journals and of three countries. According to these distributions of distances,

a) Dutch information science publications are less diverse than the few German publications and the publications from the USA; and

b) *Scientometrics* was the least diverse (most focused) journal, followed by *JASIST* and *Information Processing and Management*.

Astronomy and astrophysics

The astronomy and astrophysics publication network is less diverse than the information science network. Taking the median as a single-number measure of diversity, the information science network (median = 0.32) is much more diverse than the astronomy and astrophysics network (median = 0.27). Owing to space limitations, we can provide only one comparison. Figure 3 compares the distribution of paper similarities for Chilean and US-American publications. Astronomy and astrophysics publications from Chile appear to be much less diverse (much more concentrated on one or few topics) than those from the USA.

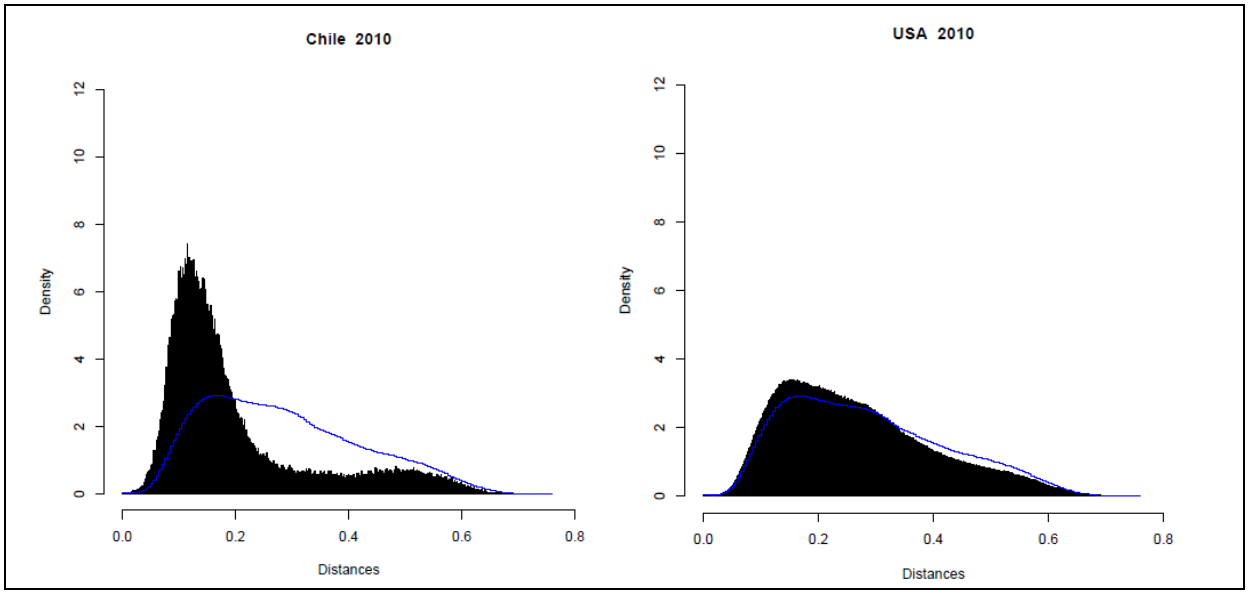

Figure 3. Diversity of astronomy and astrophysics publications from Chile and the USA (the blue lines represent the distribution for the whole network).

Discussion

A small but noxious problem for the application of our diversity measure is the occurrence of direct citations between publications from the same year. Direct citations can be considered a strong indicator of thematic similarity. However, it is not known how strong an indicator a direct citation is, and how it should be treated in comparison with bibliographic coupling of two publications. Our current solution is to add the citing and cited publication to each other's reference lists, i.e. integrating direct citation into bibliographic coupling. This solution is, however, as arbitrary as any other solution would be.

A more consequential limitation stems from our use of networks of papers as models of published knowledge. Adding a node with at least two links to a network indirectly changes connections between all nodes. This is not true for added knowledge, which can induce changes in similarities that remain local in that they affect only the knowledge to which it links directly. Although the length of the shortest path between two papers is not as sensitive to changes in networks as the measure we tried before (resistance distance), it remains to be seen whether time series of diversity constructed with our distance measure can be

interpreted. Since the literature in most fields keeps growing, time series of diversity have to cope with ever-growing paper networks.

Finally, a third limitation is inherent to our measure. Measuring the diversity of any set of papers with the approach suggested in this paper requires the set of papers to be embedded in a connected subgraph. If a research organisation has publications in many unrelated fields (as most universities do, providing an aggregate measure of the diversity of this organisations published output would be impossible. However, such an aggregate measure is likely to be meaningless in any case.

Conclusion

While further tests are of course necessary, the diversity measure proposed in this article appears to enable comparisons of paper sets from topics, journals, specialised organisations, or countries. The measure appears to use enough information to provide meaningful results without being sensitive to the noise created by network connections that have no bearing on the similarity of two papers. It is also compatible with sociological findings that ground the publication process in an author's personal experience and perspective. The 'view' of a paper on the network can easily be interpreted as the scientific perspective of its author.

Our discussion of diversity measures and their applicability to the epistemic diversity of published knowledge suggests two lines of further work. First, the problem of time series must be solved, i.e. the diversity of a field must be measured for networks of different sizes. This requires assessing the sensitivity of our diversity measure for changes in networks that are unrelated to epistemic diversity.

Second, a solution must be found for the measurement of diversity with a three-level approach. This is both theoretically and practically important because changes in the diversity of research are caused by the selective growth and shrinking of topics. Understanding the role of epistemic diversity for research requires causally attributing changes in the epistemic diversity to such processes of growth and decline, which in turn requires linking publications to topics. The obvious solution is making topics disjoint by fractionally assigning papers to overlapping topics. However, this does not solve all problems posed by thematic structures in science. Consider the following simple example: A paper on the h-index is simultaneously a paper in bibliometrics because the topic h-index is fully included in bibliometrics. How would one assign such a paper to the two topics?

Developing three-level measures for the diversity of overlapping topics might mean abandoning all established measures, and might prove a very challenging task.

Abstract
A hybrid search strategy, using lexical and citation based methods, is presented in this paper as a robust method to delineate the broad field of cardiovascular research. Overall, this study aims to provide scientifically reliable and accurate data driven evidence about cardiovascular research by establishing a dataset of published research in this field. A workflow is presented that outlines the methods carried out to establish a core dataset based on a core set of journals, to identify and use search terms to detect a broader dataset, and then to apply measures of similarities between the citations of these two datasets to ensure relevance of the final dataset. The final core set of journals established comprises of 120 unique journals covered in Thomson Reuters *Web of Science Core Collection* (WoS) database including a total of 320,647 documents from 1991 to 2013. The search terms utilised include 107 cardio-specific terms that initially identify 1.8 million unique documents when searching the title, abstract and keywords. Upon application of the citation-based similarity measures the final combined dataset consists of 845,071 publications. Overall, establishing a relevant dataset of cardiovascular research means placing a greater emphasis on having a precise dataset, reducing recall in the process.

Conference Topic
Methods and techniques

Introduction
Experts in the cardiovascular field are concerned that there is a decline in quality and innovation in cardiovascular research and that fragmentation of this broad field is leading to loss of cross-pollination and missed opportunities for translation of research from bench to bedside. In this context we have launched a project to examine cardiovascular research output over a 23 year period to provide rigorous and reliable scientific information about cardiovascular research activities. The findings of this project are expected to serve as a complement to expert opinion and previously published studies (Huffman et al., 2013; Jones, Cambrosio, & Mogoutov, 2011; Sipido et al., 2009; van Eck, Waltman, van Raan, Klautz, & Peul, 2013; Yu, Shao, He, & Duan, 2013), to provide scientifically reliable and accurate data driven evidence about cardiovascular research.
The objectives of the project are to:

- Characterise the size, growth, topics and visibility of research outputs over 23 years;
- Analyse the geographical distribution of research outputs and its evolution;
- Visualise and analyse research collaboration; and
- Identify emerging topics in cardiovascular research.

To gain a comprehensive view of research in this field a broad scope and definition has been applied to include papers published in scientific journals from basic, clinical and epidemiological studies related to the cardiovascular system, including the heart, the blood vessels and/or the pericardium. The main source of data is the *Web of Science Core Collection*. The purpose of this paper is to describe the methods utilised, and the roadmap set, to establish a dataset of published research undertaken in the cardiovascular field.

Methods

Hybrid search strategies for subject delineation, previously described and published (Bolaños-Pizarro, Thijs, & Glänzel, 2010; Glänzel, Janssens, & Thijs, 2009; Zitt & Bassecoulard, 2006), have been adapted to establish a dataset of cardiovascular research. This includes (1) establishing a core dataset based on a core set of journals and core search terms, (2) identifying a broader dataset of publications through the use of search terms, and then, (3) applying measures of similarities by citations between the documents in these datasets to select a final dataset with acceptable precision and recall. A workflow/roadmap was developed to outline the main steps taken to establish the dataset, as can be seen in Figure 1.

Core Journal Dataset

All data have been retrieved from Thomson Reuters Web of Science Core Collection. The core set of journals was selected through expert review of the scope/aim of all 183 journals included in the 'Cardiac & Cardiovascular Systems' and the 'Peripheral Vascular Disease' Web of Science Categories. The scope/aim for each journal was obtained through online web-based searches. Using an online survey tool, two experts reviewed the title and scope/aim of each journal to assess the relevance of the journal and indicate whether they had experience with each journal (e.g. reading, editing, reviewing, submitting a document for publication). Journals that were assessed by at least 1 expert as being a core cardiovascular journal – defined as a journal publishing greater than 90% of its articles, reviews, letters and notes on the cardiovascular domain – were included in the core journal dataset. Disagreements between the experts were reviewed by the project team. Journals were excluded from the core dataset only when the expert excluding the journal was the only one that had previous experience with the journal. The final dataset was obtained by identifying all articles, letters, notes and reviews published journals that are covered in the 1991–2013 volumes of the WoS database.

Search Terms Datasets

A number of sources were reviewed to identify relevant cardiovascular-specific search terms, including:

- Medical Subject Headings (MeSH)
- International Classification of Diseases (ICD)-10
- Cochrane Hypertension/Heart/Peripheral Vascular Disease Groups/Systematic Reviews
- Cardioscape project taxonomy (European Society of Cardiology, 2014)
- Recent published research (Bolaños-Pizarro et al., 2010; Huffman et al., 2013; Jones et al., 2011; van Eck et al., 2013)

Subsequently, a group of eight topic experts representing a mix of clinical scientists, basic scientists and epidemiologists were invited to review the combined list of 105 search terms to assess their relevance in identifying as broad a range of cardiovascular research publications as possible. All search terms were included where at least half of the reviewers agreed that they were relevant search terms to include in the search strategy.

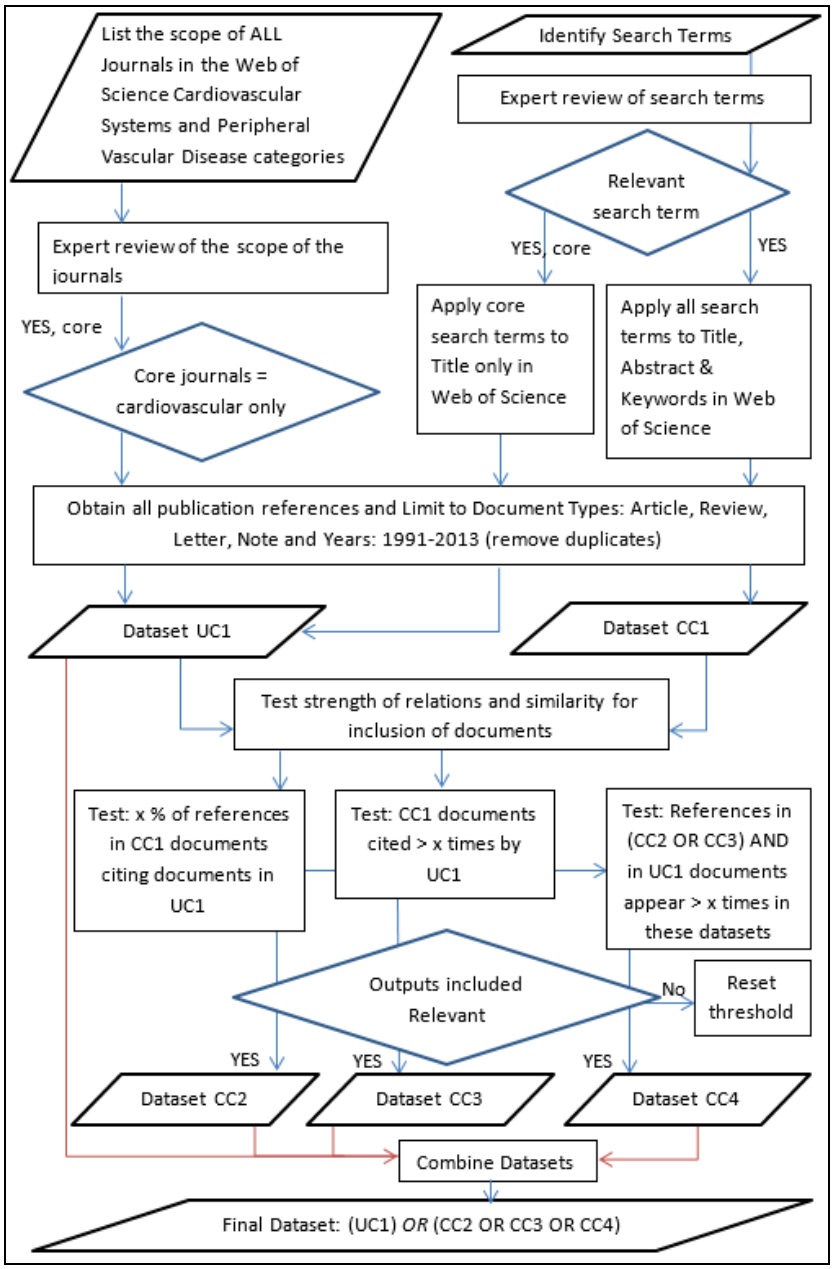

Figure 1. Workflow of field delineation of Cardiovascular Research

In addition, experts were asked to suggest any potentially missing search terms. New search terms suggested and disagreements were reviewed by the project team. The broad search terms dataset was obtained by applying the full search strategy to the complete Web of Science database, to identify all articles, letters, notes and reviews published between 1991 and 2013. To add to the core journal dataset, highly cardiovascular specific or core search terms were selected that when searched in the title would identify core cardiovascular publications.

Similarity Measures and Thresholds

For the extension of the core dataset, i.e., the seed of relevant literature, we followed an algorithm using a logical combination of *unconditional* and *conditional* criteria (Glänzel, 2014). In the present project we have linked literature retrieved based on conditional criteria (the broad search terms set) to the set of surely relevant documents (the core journals and core search terms set), using citation-based similarities. In particular, three measures of similarity

between the core dataset and the broad search terms dataset were utilised: a) the share of references of broad search terms documents that cite the core documents, b) the number of references of the core documents that cite the broad search terms documents and c) the number of shared references between the core dataset and the restricted search terms dataset. The thresholds for each measure were set following iterative testing, whereby a low threshold was first applied and a random sample of the titles and abstracts of 500 documents was reviewed for relevance to the cardiovascular field. The threshold was altered until the sample contained a high precision and the level of noise (peripheral and irrelevant documents) was reduced to an acceptable level, defined as a 5% level of noise. To confirm the relevance of the documents identified, the random samples considered to have acceptable thresholds were reviewed by one topic expert.

Findings

Core Dataset

After expert review, 120 journals were included as core journals. The two expert reviewers agreed on the exclusion of 61 journals and disagreed on the inclusion of 39 journals (21% of all 183 journals), of these only two journals were excluded as the expert who had experience with the journal was the one that excluded it. For the remaining 37 journals, they were included since both experts had previous experience for three journals and neither expert had experience for 34 journals. The final core journal documents therefore consist of 320,647 articles, letters, notes and reviews from 1991 to 2013. Thirteen of the search terms, identified below, were considered to be highly cardiovascular specific. The core search terms when searched only in the title, added 141,676 documents to the core journal documents, resulting in a core dataset of 462,323 documents. Review of this dataset confirmed that it provides a precise sample of cardiovascular-specific documents for this study.

Broad Search Terms Dataset

After expert review by 6 topic experts and the project team, 107 search terms were included in the final search strategy. Of the original 105 terms reviewed, three search terms were removed since more than half of the experts suggesting to remove them. A total of 22 unique terms were also suggested by three of the topic experts. The project team assessed and included four of these new terms. Then one additional term was added to the search strategy to include this term with and without its common prefix. The final broad search terms dataset consists of 1,656,278 unique articles, letters, notes and reviews from 1991 to 2013 where the search terms could be identified in the abstract, keywords or title. All documents in the core dataset were removed from this broad search term dataset.

A comparison of all documents obtained by searching the abstract, keywords and title is presented in Figure 2.

As a validation of the search strategy and selection of core journals, when the search strategy was applied to the 120 core journals, 95% of all core journal dataset documents were identified by the search terms.

Similarity Measures and Thresholds

An initial test was undertaken to limit the search terms dataset by removing all documents that had no links with the core journal documents. A total of 228,000 documents had no links meaning they did not cite the core journal set, they were not cited by the core journal set *and* they did not have any common references with the core journal set. This reduced the search terms set to less than 1.6 million documents, however upon review of random samples it was

clear that stronger measures of similarity would be needed to further restrict the search terms dataset to include the most relevant documents in the final dataset.

Iterative testing and review of random samples led to the selection of a combined dataset where at least 12% of the references in the broad search documents cited documents in the core dataset or where the broad search documents where cited greater than 4 times by the core documents. For this chosen dataset, no more than 10% of the random samples were considered not relevant or peripheral to the cardiovascular field. Documents from the third measure of similarity using bibliographic coupling was not included in the final dataset since it was not possible to achieve less than a 10% noise level through iterative testing and review of random samples. The final restricted broad search terms dataset consists of 382,748 unique articles, letters, notes and reviews from 1991 to 2013.

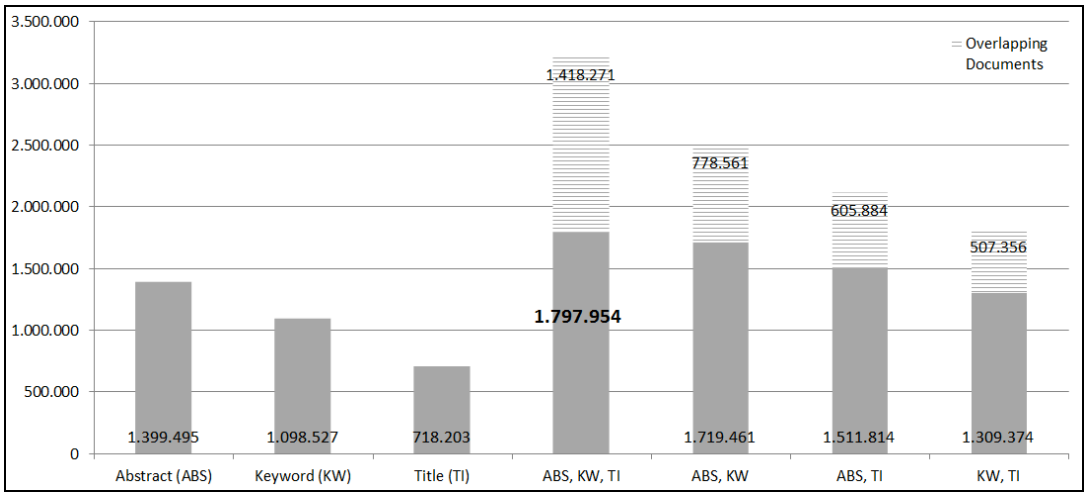

Figure 2. Number of documents identified when searching 107 search terms in Abstracts, Keywords and Titles [Data sourced from Thomson Reuters Web of Science Core Collection].

Final Combined Dataset

Combined, the core and restricted datasets create a final dataset of 845,071 unique documents from the cardiovascular field. Overall, the combined dataset has a 4.5% noise level (estimated).

Discussion

Only one previously published bibliometric study of cardiovascular research used a hybrid search strategy to establish its dataset (Bolaños-Pizarro et al., 2010). However, due to the broad scope of this study, which aims to include all types of research – from basic to clinical research, a broader list of cardio-specific search terms was created. Attention was also placed on ensuring that the search terms selected could identify cardiovascular research over the long time period of the study, as well as, enable the identification of new and emerging fields in cardiovascular research. The 107 search terms greatly increases the recall of documents, though this also means that a greater amount of noise was present in the broad search terms dataset. Hence, the importance of utilising measures of similarity between the two datasets to restrict the broad search terms dataset to include only the most relevant documents. This was done through testing various thresholds of citation-based similarities, as the final step of this robust method to delineate complex fields of research. Including both directions of citation-based similarities (ie. documents from core journals dataset citing documents in search terms dataset and vice versa) also ensures that the distribution of documents sampled is representative over time. The initial threshold of 5% noise was re-evaluated through testing

and due to the broad nature of the cardiovascular field a higher level of noise (10%) was considered acceptable as this includes peripheral research that has a component linked to cardiovascular research. The broad search terms dataset has been reduced to less than a quarter of initial documents identified to ensure the final dataset is as precise as possible and can be considered a representative sample of cardiovascular research over the 23 year period.

Conclusions

Bibliometrics-aided retrieval is a robust method to delineate the field of cardiovascular research. Through using this method, a representative dataset of cardiovascular research was established irrespective of changes in the field, such as vocabulary used, over the time-frame of this study. Overall, establishing a relevant dataset of cardiovascular research means placing a greater emphasis on having a precise dataset, reducing recall in the process.

Acknowledgments

Thank you to Bart Thijs for his input into the study methods.

Locating an Astronomy and Astrophysics Publication Set in a Map of the Full Scopus Database

Kevin W. Boyack[1]

[1] *kboyack@mapofscience.com*
SciTech Strategies, Inc., 8421 Manuel Cia Pl NE, Albuquerque, NM 87122 (USA)

Abstract
A dataset containing 111,616 documents in astronomy and astrophysics has been created and is being partitioned by several research groups using different algorithms. In this paper, rather than partitioning the dataset directly, we locate the data in a previously created model in which the full Scopus database was partitioned. Given that the other research groups are partitioning the data directly, use of this method will allow comparisons between using local and global data for community detection. In other words, use of this method will allow us to start to answer the question of how much the rest of a large database affects the partitioning of a journal-based set of documents. We find that the astronomy document set, while spread across hundreds of partitions in the Scopus map, is located in only a few regions of the map. Thus, the use of a global map to partition astronomy documents is likely to give very similar results to partitioning using local approaches because of the insularity of the field of astronomy. However, we do not expect local and global data to give as similar results for other fields, because most other fields are less insular than astronomy.

Conference Topic
Methods and techniques

Introduction
Partitioning of a dataset into groups of similar objects – alternatively known as clustering, community detection or topic detection – is a current research topic in a number of fields, including scientometrics and network science. A number of different algorithms are used to partition scientific literature into topics or clusters. While many of these are based on the property of modularity (cf., Blondel, Guillaume, Lambiotte, & Lefebvre, 2008; Newman & Girvan, 2004; Waltman & van Eck, 2013), others are based on graph layout and pruning (Martin, Brown, Klavans, & Boyack, 2011) or on complex network flows (Rosvall & Bergstrom, 2008). Despite the obvious differences between these algorithms, they are all based on a common principle – that of dividing a literature set into partitions where the within-partition signals are much stronger or denser than the between-partition signals.

It is well known that different topic detection algorithms give somewhat different results for the same data set. What is not known is the specifics of why particular algorithms give particular results, or exactly what operations of a particular algorithm lead it to give different results than those obtained by another algorithm. In general, we know very little about what types of features result from different algorithms, and how these affect the output structures. This can make it difficult to interpret the partitions and maps that are produced by an algorithm. Are the partitions produced by an algorithm representative of actual structures in science, are they merely artifacts resulting from the algorithm and its parameters, or are they something in between? This is a difficult question to which, we suspect, the answer is far beyond the scope of even a large study. Nevertheless, we are hopeful that a comparison of partitioning methods and their results using a single dataset might lead to some general understanding of the types of features that result from different methods and algorithms. This type of understanding has the potential to enable both researchers and decision makers to more clearly understand and interpret the results of a particular partitioning.

To this end, a number of researchers (see papers from this special session) have come together to explore this question. As a first step, each research group has created a partitioning of a

single dataset using their own algorithms. The work-in-progress papers in this session describe the partitioning algorithms and results from each group. The multiple results will be combined and compared in a next phase of the project to determine similarities and differences in the features resulting from the different methods and algorithms. Beyond that, we collectively hope to learn more about both common and unique structural features that result from the different algorithms.

This paper details the method used by SciTech Strategies to partition an "astronomy and astrophysics" literature dataset. It differs from the other methods in one significant aspect – the other groups have all created local solutions (partitioning the dataset directly), while we have created a global model (partitioning the entire Scopus database) and have located the astronomy dataset within those partitions (Klavans & Boyack, 2011). Use of this method enables us to start to answer the question of how much the rest of the database affects the partitioning process.

Global Model

Our global model of science consists of 48,533,301 documents from Scopus. Of these, 24,615,844 documents are indexed source documents from Scopus 1996-2012, while the remaining 23,917,457 are non-source documents that were each cited at least twice by the set of source documents. The method used to generate the document set and citing-cited pairs list is very similar to that used for the recent "non-source" map of Boyack and Klavans (2014).

The model was created by taking the over 582 million citing-cited pairs within this set of 48.5 million documents, calculating similarity values between pairs of documents based on direct citation, and then partitioning the documents using the new CWTS smart local moving algorithm (Waltman & van Eck, 2013). The citing-cited pairs were provided by SciTech Strategies (STS) to Ludo Waltman at CWTS, who ran the similarity calculation and partitioning steps. The CWTS smart local moving algorithm was used to create a four-level hierarchical solution, with resolution values chosen to result in a solution with roughly 100k, 10k, 1000, and 100 clusters. Details of the partitioning are given in Table 1.

Table 1. Multi-level partitioning of the Scopus database using the CWTS smart local moving algorithm.

Level	*Partitions Desired*	*Resolution*	*Partition Min Size*	*# Partitions*	*Partitions > Min Size*	*# Pubs*	*% Pubs Lost*
1	100000	3e-5	50	114679	91726	48399235	0.28%
2	10000	3e-6	500	13157	10059	47323189	2.49%
3	1000	3e-7	5000	1048	849	46929303	3.30%
4	100	5e-8	50000	122	114	46705047	3.77%

Visual maps of the partition solutions at level 1 and level 2 were created using the following process. At each level, 1) pairwise similarity between partitions was calculated from the titles and abstracts of the documents in each partition using the BM25 textual similarity measure, 2) each resulting similarity list was filtered to retain the top-n (5-15) similarities per partition, and 3) layout of the partitions on the x,y plane was done using the DrL algorithm. These steps are ones we commonly use to create science maps, and are described in more detail in Boyack & Klavans (2014). In each case, only those partitions that were of the minimum size desired (91,726 for level 1, and 10,059 for level 2) were included in the map. Field counts for each cluster in each map were calculated using UCSD map of science journal-to-field assignments (Börner et al., 2012), and each cluster was assigned to its dominant field and correspondingly colored in the map. The two maps are similar in that they show that the 12 large fields (see

legend at the bottom of Figure 1) occupy similar positions in both maps. The change in granularity of the partitions does not change the overall look and feel of the map.

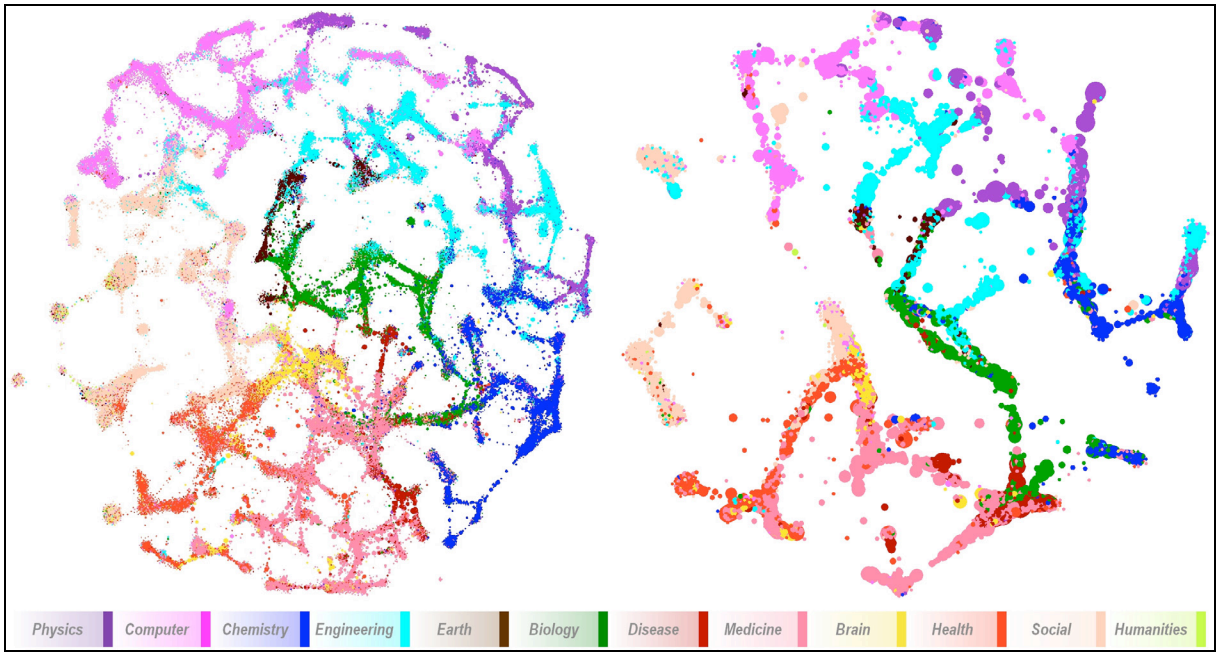

Figure 1. Visual maps of the Scopus database using level 1 (left) and level 2 (right) partitions.

Astronomy Dataset

The astronomy dataset used by each research group consists of 111,616 document records with accompanying data from the Web of Science. This dataset was created by researchers at Humboldt University for use by project participants, and is comprised of documents published from 2003-2010 in a set of 59 astronomy and astrophysical journals, limited to articles, letters, and proceedings papers. Over half of the documents were from four journals, as shown in Table 2.

Table 2. Dominant journals in the astronomy and astrophysics dataset.

Journal	Count
Astrophysical Journal	19582
Physical Review D	19061
Astronomy & Astrophysics	14668
Monthly Notices of the Royal Astronomical Society	11599

In order to use the Scopus-based global model and map, Scopus identifiers for the WoS records were identified to the extent possible by matching source data (journal, title, volume, page, year). Definitive matches were obtained for 107,888 (96.66%) of the documents. Of the 3,728 documents that were not matched, roughly half were in source titles that are not covered by Scopus (such as the IAU Symposium), and thus could only be matched if they were cited non-source materials. The remaining unmatched records were in source titles that are covered by Scopus, but that we could not match. This lack of uniformity between databases is primarily due to differences in the way titles are listed (particularly for non-ASCII characters) and missing records. Despite the unmatched records, we consider a match rate of nearly 96.7% to be very good, and certainly sufficient for reasonable comparison with the partitions from other groups. Once the matching was done, documents from the astronomy dataset were located in global map at three levels (1, 2, and 3 from Table 1).

Astronomy is known to be a relatively insular discipline, with fewer links (percentage basis) to and from other disciplines than for most other disciplines. Thus, we expected the effect of including an additional 48 million documents in a cluster solution to have only a modest effect on the partitioning of the astronomy document set. We did not expect the astronomy documents to be scattered throughout the map. As expected, the astronomy documents are heavily concentrated in the global model. At level 1, 50% of the astronomy documents are in partitions where the astronomy set documents comprise at least 66.5% of the partition contents (limited to the years of study, 2003-2010). In other words, when sorting partitions by concentration of the astronomy document set within the partition, 50% of the total papers are accounted for in partitions with a concentration of over 66.5%. Using an alternative measure, when partitions are sorted by the number of papers from the astronomy document set, the number of non-set papers equals the number of set papers only when 90,000 of the 111,616 papers are accounted for, as shown in Figure 2.

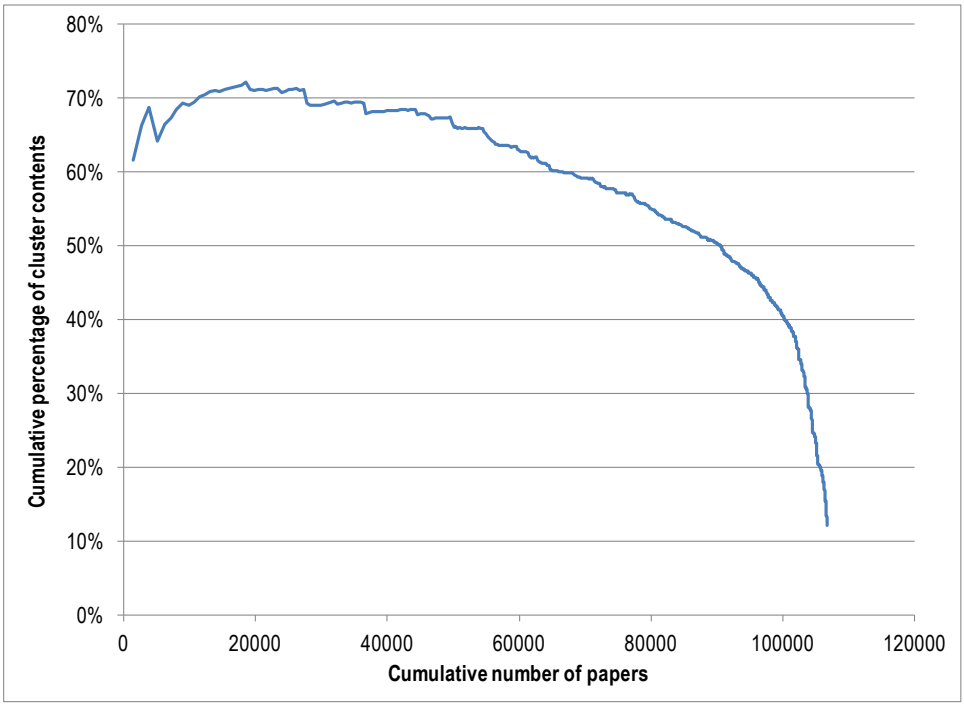

Figure 2. Distribution of the astronomy dataset across partitions in the level 1 solution.

Overlays showing the positions of the partitions with at least 50 documents from the astronomy set are shown for both the level 1 and level 2 maps in Figure 3. For level 1, this comprises 408 partitions and 90,763 documents (84.1% of the matched documents), while for level 2 it comprises 119 partitions and 101,895 documents (94.4% of the matched documents). Both maps make it clear that while the documents are parsed out into hundreds of partitions, each representing distinct topics, these topics are concentrated in only a few areas in the map.

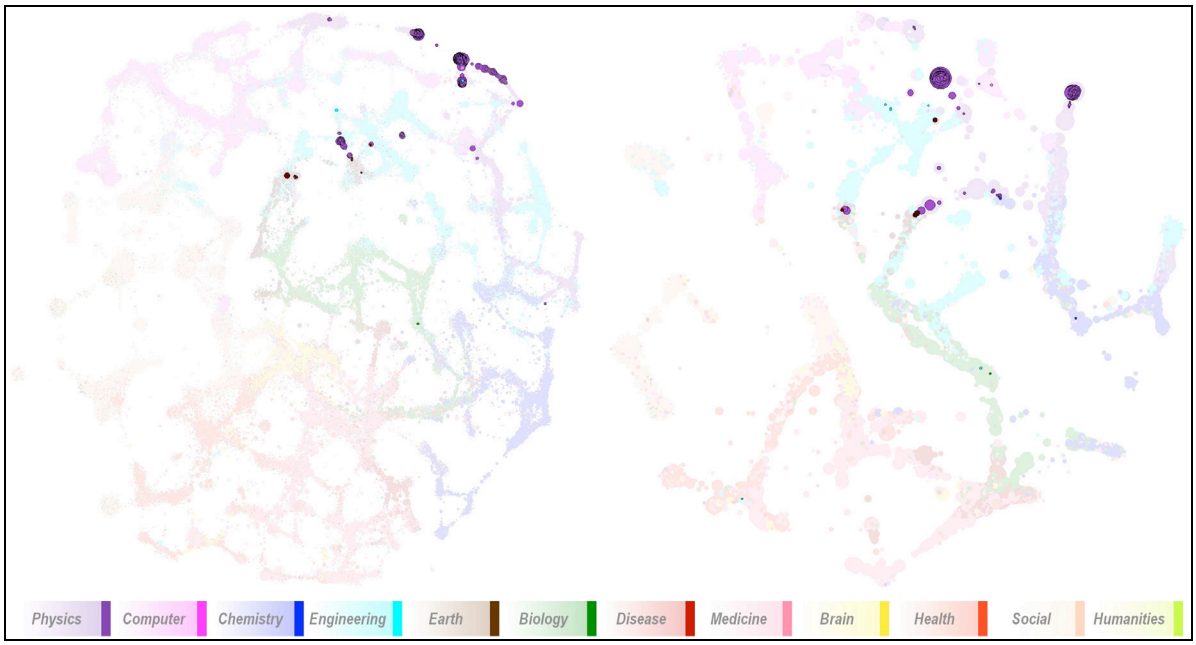

Figure 3. Overlays of the positions of the astronomy set documents on the Scopus level 1 (left) and level 2 (right) maps of Figure 1.

Discussion

Recalling that the astronomy document set was based on a set of journals, the high level of concentration of the overlays shown in Figure 3 suggests that use of journals is a very reasonable strategy for building a dataset in the field of astronomy. Astronomy journals have a very tight profile on a document-based map. By contrast, high profile journals in other fields, such as JACS, Physical Review Letters, and New England Journal of Medicine, have very broad profiles, and overlays for these journals (not shown here) spread across large regions of the map. Thus, while a dataset based on journals is useful to characterize astronomy, journals may be far less useful for characterizing other fields. Correspondingly, the use of a global map to partition astronomy documents is likely to give very similar results to partitioning using local approaches because of the insularity of the field of astronomy. We would not expect the use of a global map to partition a local document set from another field to work as well. Or, rather, we would expect the journal-based approach to fall short in other fields because it would leave out so much of the relevant contextual literature.

Abstract
Scientific workflows organize the assembly of specialized software into an overall data flow and are particularly well suited for multi-step analyses using different types of software tools. They are also favourable in terms of reusability, as previously designed workflows could be made publicly available through the myExperiment community and then used in other workflows. We here illustrate how scientific workflows and the Taverna workbench in particular can be used in bibliometrics. We discuss the specific capabilities of Taverna that makes this software a powerful tool in this field, such as automated data import via communication with Web services, smooth data extraction from XML by XPath and various data analyses and visualizations with the statistical language R. The support of the latter allows integration of a number of recently developed R packages for bibliometric analysis. A number of simple examples illustrate the possibilities of Taverna in the field of bibliometrics and scientometrics.

Conference Topic
Methods and techniques

Introduction
Information processing permeates the scientific enterprise, generating and organizing knowledge about nature and the universe. In the modern era, computational technology enables us to automate data handling, reducing the need for human labor in information processing. Often information is processed in several discrete steps, each building on previous ones and utilizing different tools. Manual orchestration is then frequently required to connect the processing steps and enable a continuous data flow. An alternative solution would be to define interfaces for the transition between processing layers. However, these interfaces then need to be designed specifically for each pair of steps, depending on the software tools they use; which compromises reusability. Whether the data flow is automated or done by the researcher manually, the latter still has to deal with many low-level aspects of the execution process (Gil, 2008).

Scientific workflow managers connect processing units through data and control connections and simplify the assembly of specialized software tools into an overall data flow. They smoothly render stepwise analysis protocols in a computational environment designed for the purpose. Moreover, the implemented protocols are reusable. Existing workflows can be shared and used by other workflows, or they can be modified to solve different problems. Several general purpose scientific workflow managers are freely available, and a few more optimized for specific scientific fields (De Bruin, Deelder, & Palmblad, 2012). Most of these managers provide visualization tools and have a graphical user interface, e.g. KNIME (Berthold et al., 2007), Galaxy (Goecks, Nekrutenko, & Taylor, 2010) and Taverna (Oinn et al., 2004). Not surprisingly, scientific workflows are now becoming increasingly popular in data intensive fields such as astronomy and biology.

In this paper, we describe the use of scientific workflows in bibliometrics using the *Taverna Workbench*. Taverna Workbench is an open source scientific workflow manager, created by

the myGrid (Stevens, Robinson, & Goble, 2003) project, and now being used in different fields of science. Taverna provides integration of many types of components such as communication with Web Services (WSDL, SOAP, etc.), data import and extraction (XPath for XML, spreadsheet import from tabular data), and data processing with Java-like Beanshell scripts or the statistical language R (Wolstencroft et al. 2013). Beanshell services allow the user to either program a small utility from scratch and towards a specific goal, or to integrate already existing software in the workflow. The R support is a particularly powerful feature of Taverna. Although R was initially developed as a language for statistical analysis, its widespread use has seen it adopted for many tasks not originally envisioned—a fate not unlike its commercial cousin, MATLAB. One such task is text mining. The R package *tm* (Feinerer, Hornik, & Meyer, 2008) provides basic text mining functionality and is used by a rapidly growing number of higher-level packages, such as *RTextTools* (Jurka, Collingwood, Boydstun, Grossman & van Atteveldt, 2014), *topicmodels* (Grün & Hornik, 2011) and *wordcloud* (Fellows, 2013). Similarly, there are many toolkits and frameworks for text mining in Java that could also be called from within a Taverna workflow.

An Example Workflow

We designed a simple workflow, *compare_two_authors* (see below), to generate a histogram for the number of publications over time and a co-word map for the titles of the two authors' publications. The workflow takes as inputs PubMed results in XML, the names of two authors, a list of excluded words and a minimum number of occurrences.

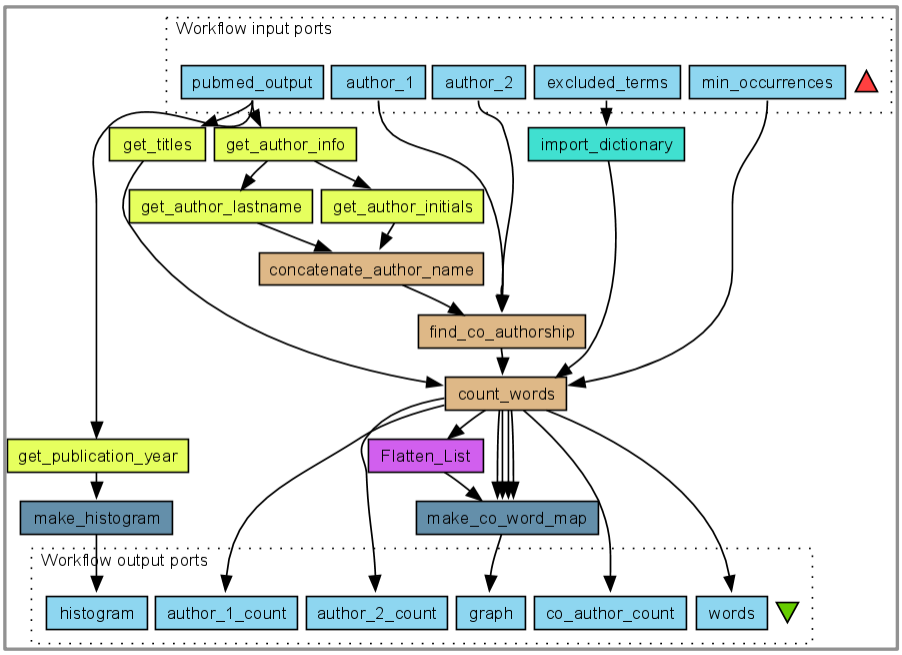

Figure 1. A workflow designed in Taverna for analyzing scientific output over time and comparing word usages of two authors.

The excluded terms are contained in a text file, so the *spreadsheet import* service in Taverna is used to extract each word in the file, line by line. The PubMed results are in XML format, and the extraction of publication years, titles and author names are done by *XPath* services. XPath is a query language for selecting elements and attributes in an XML document. The XPath service in Taverna eases this process by providing a configuration pane to render an XML file of interest as a tree and automatically generate an XPath expression as the user

selects a specific fragment from the XML (Fig. 2). The results of the query can either be passed as text or as XML to other workflow components.

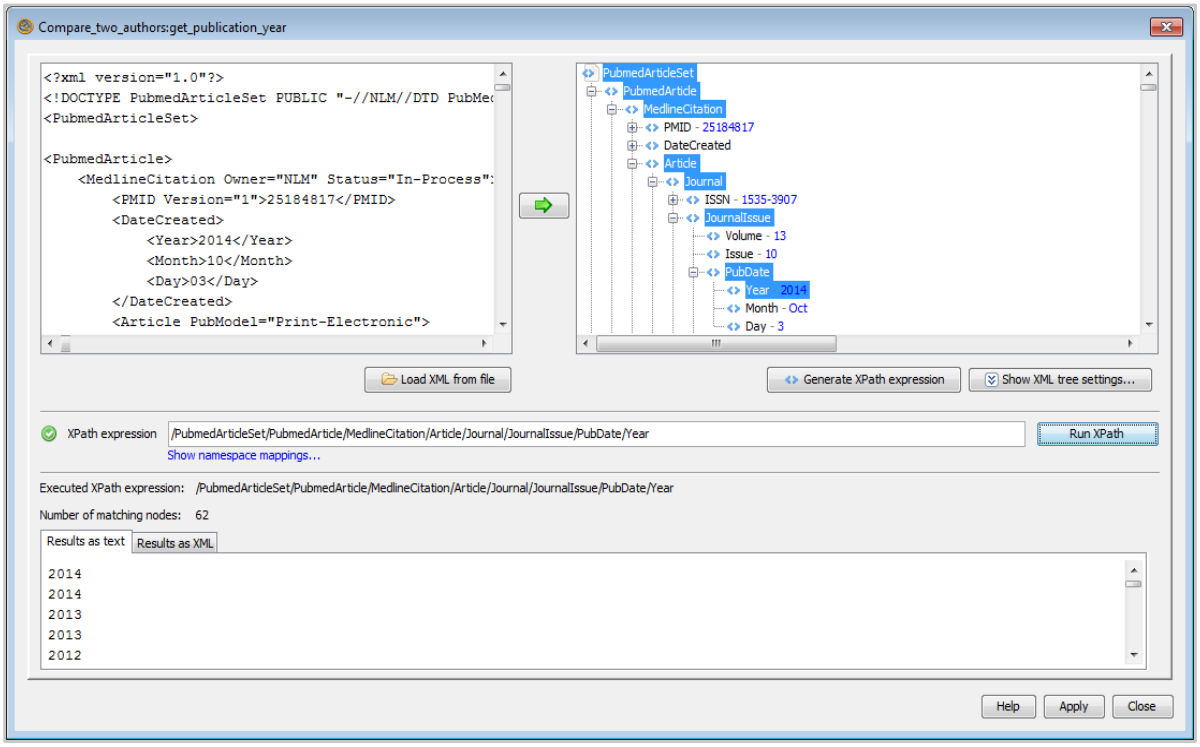

Figure 2. XPath configuration pane for extracting publication year from PubMed XML.

The data extracted by the spreadsheet import and XPath services is fed to a series of Beanshell components that find co-authorships and count co-occurrence of words in the extracted titles. Beanshell is a light-weight scripting language that interprets Java. In our workflow, the Beanshell services do simple operations on strings, such as concatenation of surnames and initials that are extracted separately using XPath (*concatenate_author_names*), matching strings to find co-authorships (*find_co_authorship*) and counting the number of words occurring in each title authored by one or both authors (*count_words*). The two authors' usage of the words, excluding *excluded_terms*, that appear at least *min_occurrences* times in total, are then used to draw a co-word map using the *igraph* (Csárdi & Nepusz, 2006) R package. It is generally up to the workflow designer what part of the workflow to code in Java (Beanshell), in R, or in third language called via the *Tool* command-line interface. More types are available for data connectors between R components (logical, numeric, integer, string, R-expression, text file and vectors of the first four types) than between Beanshell components, where everything is passed as strings. When dealing with purely numerical data, we recommend R over Beanshells within Taverna.

After all the necessary inputs are provided, the workflow is ready to be executed. In the Taverna Workbench *Results* perspective (Fig. 3), each completed process is grayed out to show the progress of the workflow run. The execution times, errors and results are also visible in this perspective.

We ran the workflow for two scientists active in our own field, mass spectrometry, Gary L. Glish and Scott A. McLuckey, whom we knew to have worked on similar topics and also co-authored a number of papers. However, the workflow will work on any two authors with publications indexed by PubMed. The co-word map in Figure 4 visualizes the co-occurrence of words in titles by the location and thickness of the connecting edge, while the relative frequency of usage by the two authors is indicated by the color (from white to gray).

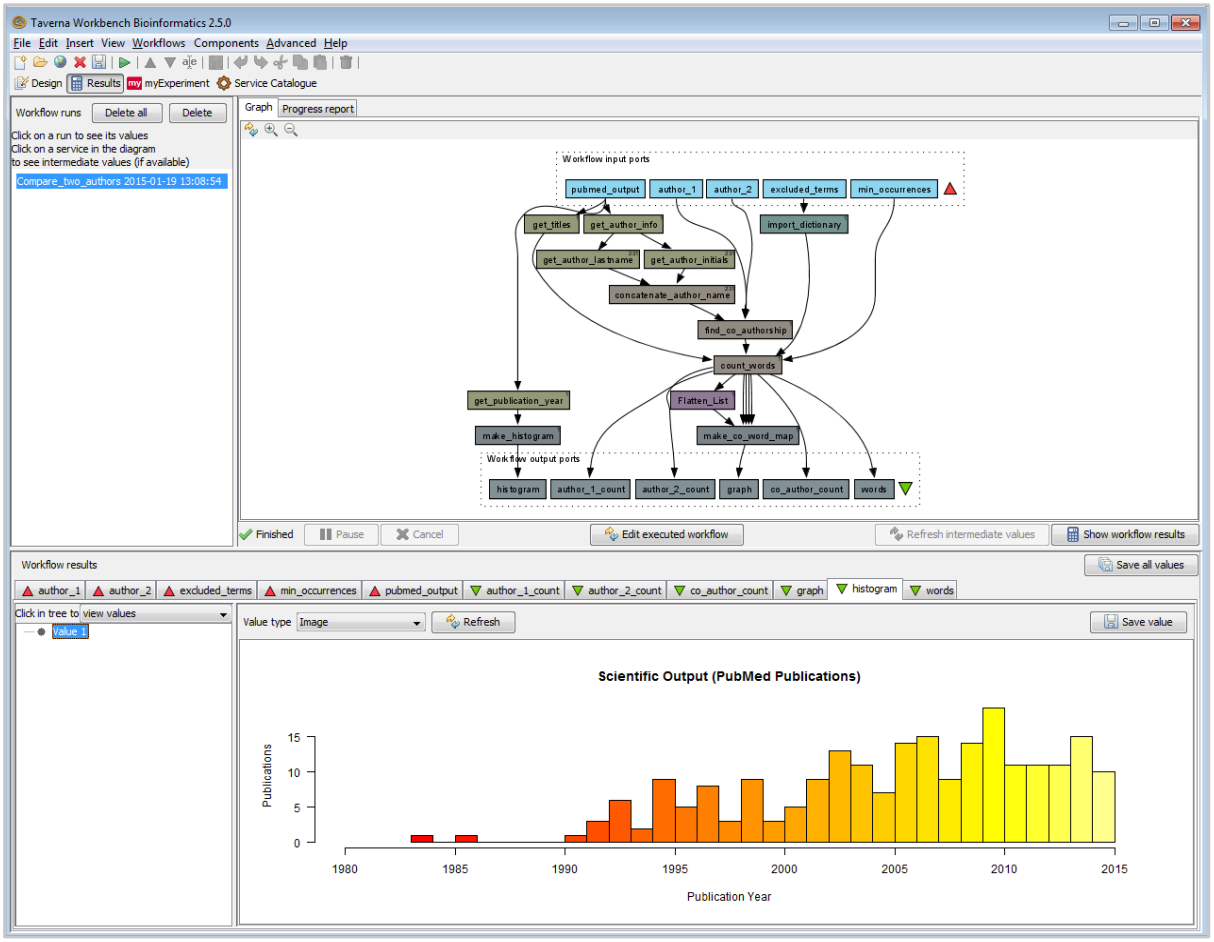

Figure 3. Workflow progress and output in the Taverna workbench Results perspective.

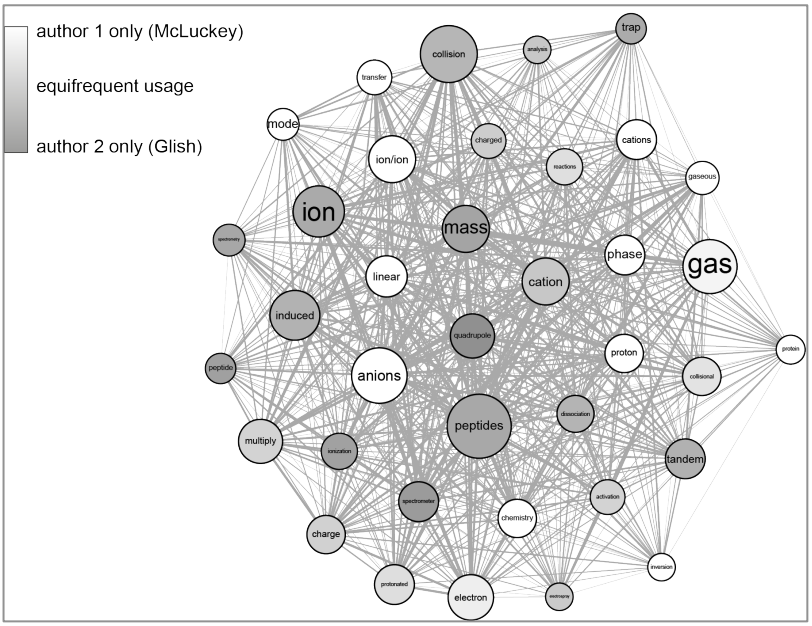

Figure 4. Co-word map output from the *compare_two_authors* workflow.

Connecting to Web Services and External Databases

Automatically generating networks directly from online data is also possible in Taverna workbench. Taverna can invoke WSDL (Web Services Description Language) style Web services given the URL of the service's WSDL document. The WSDL is an XML-based interface description language often used together with a SOAP (Simple Object Access protocol) to access the functions and parameters of a service. Many bibliographic resources are available through Web services, such as Web of Science (WoS). Some services, including the WoS, require authentication. An entire bibliometric study can be contained inside a single Taverna workflow that takes the user queries, or questions of the study, generate the Web service requests, execute these, retrieve the data and proceed with further (local) bibliometric and statistical analysis, and visualization.

A Taverna workflow that invokes WSDL services from WoS to automatically execute a query may look like in the figure below. This Taverna workflow takes as input common search parameters and a generic WoS query string, and passes these to the Web service via the WoS WSDL interface. Values that have only one possible value, such as the language (English, "en") are here hard-coded in the workflow as *Text constants*.

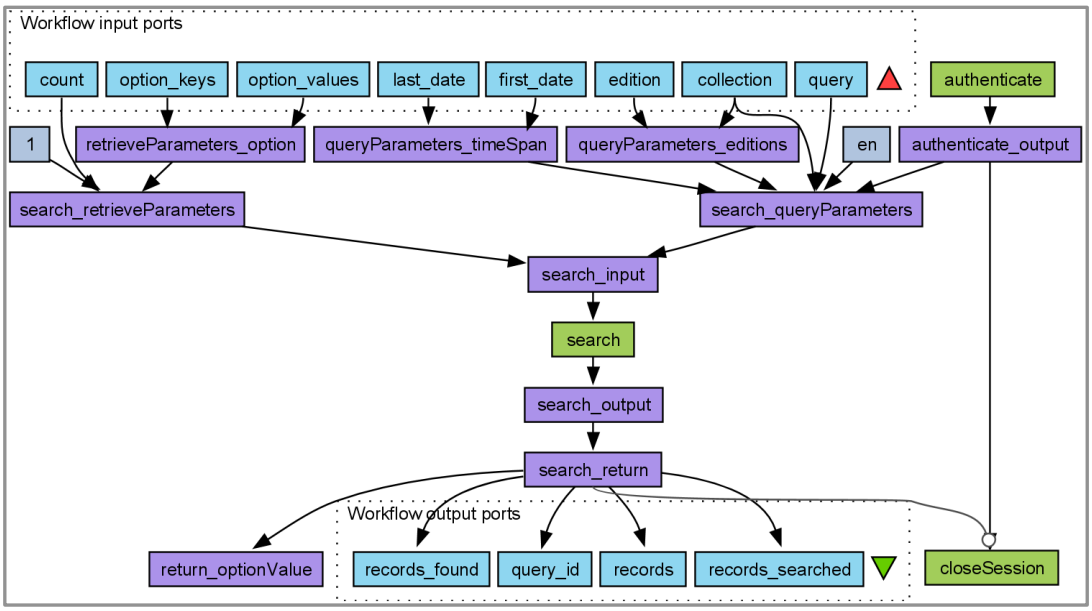

Figure 5. A simple workflow for retrieving bibliometric data using Web services.

Future Work

The use of scientific workflows in bibliometrics is still in its infancy. Modules that accomplish basic bibliometric tasks could be designed and combined in various ways for different studies, thus benefiting from modularity and reusability of scientific workflows. As mentioned above, the direct support of R inside Taverna workflows is particularly useful for bibliometrics. A number of R packages for bibliometric analysis have recently been released, ranging from simple data parsers such as the *bibtex* package (Francois, 2014) for reading BibTeX files to libraries or collections of functions for scientometrics, such as the *CITAN* package (Gagolewski, 2011). The latter package contains tools to pre-process data from several sources, including Elsevier's Scopus, and a range of methods for advanced statistical analysis. The *igraph* package itself comes with some functions specifically for bibliometric analysis, e.g. *cocitation* and *bibcoupling*. Clustering or rearranging the graph spatially so that strongly connected words appear closer together is possible with *igraph*, but may also be assisted by other packages. More crucially, the example workflow here does not yet

implement any advanced text mining functionality for homonym disambiguation or natural language processing. The *openNLP* R package provides an interface to openNLP (Hornik, 2014) and may be used to extract noun phrases and clean up the co-word maps.

Several of our Taverna workflows for bibliometrics and scientometrics, including the two workflows in Figure 1 and Figure 5, can be found in the myExperiment (Goble et al., 2010) group for Bibliometrics and Scientometrics (http://www.myexperiment.org/groups/1278.html). As always, we are grateful for any feedback on these workflows.

Abstract
There are no available methods to measure overlap in expertise between a panel of experts and evaluated research groups in discipline-specific research evaluation. This paper explores a bibliometric approach to determining the overlap of expertise, using the 2009 and 2011 research evaluations of ten Pharmaceutical Sciences and nine Biology research groups of the University of Antwerp. We study this overlap at the journal level. Specifically, journal overlay maps are applied to visualize to what extent the research groups and panel members publish in the same journals. Pharmaceutical Sciences panel members published more diversely than the corresponding research groups, whereas the Biology research groups published more diversely than the panel. Numbers of publications in the same journals vary over a large scale. A different range of coverage was found for different research groups; there is also a significant difference between maximum and minimum coverage based on discipline. Future research will focus on similarity testing, and a comparison with other disciplines.

Conference Topic
Methods and techniques

Introduction
Expert panel review is considered the standard for determining research quality of individuals and groups (Nedeva et al., 1996; Rons, et al., 2008; Butler & McAllister, 2011; Lawrenz et al., 2012), but also, for instance, for research proposals submitted to research funding organizations. The principal objective of such evaluations is to improve the quality of scientific research. Currently, there are no available methods that can measure overlap in expertise between a panel and the units of assessment in discipline-specific research evaluation (Engels et al., 2013). Rahman et al. (2014) explored expertise overlap between panel and research groups through publishing in the same Web of Science subject categories. Since one category may comprise a wide array of different subfields and topics (Bornmann, et al., 2011), it is up for discussion how relevant it is to have panel members and research group members publishing in the same subject categories. This paper presents a journal level analysis to explore this issue. Journals cover more closely related subfields and topics (Tseng & Tsay, 2013). This paper uses overlay maps at the journal level (Leydesdorff & Rafols,

2012), with special attention to the quantification of similarity between groups and panel for two disciplines.
In 2007, the University of Antwerp (Belgium) introduced site visits by expert panels that promise communication and participation between expert and research groups. It is expected that each research group's expertise is well covered by the expertise of the panel members.
We have used the data collected in the frame of research evaluation by the University of Antwerp. This research in progress paper explores the expertise overlap between expert panel and research groups of the department of Biology and Pharmaceutical Sciences. Hence, the research questions are:

1) To what extent is there overlap between the panel's expertise and the expertise of the groups as a whole?
2) To what extent is each individual research group's expertise covered by the panel's expertise?

Data and Method

In this paper, we present an analysis of the 2009 assessment of ten research groups (2001-2008) of the Department of Pharmaceutical Sciences, and the 2011 assessment of the nine research groups (2004-2010) belonging to the Department of Biology, University of Antwerp. The citable items from the Science Citation Index Expanded of the Web of Science (WoS) published by the research groups in the reference period were considered.
Both panels were composed of five members (including the chair). All the publications of the individual panel members up to the year of assessment were taken into account. The combined publication output of the Pharmaceutical Sciences panel members is 1,029 publications. In total, these publications appeared in 300 different journals. The number of publications per panel member ranges from 124 to 353, in 39 to 93 different journals. The Biology panel members' publication output amounts to 786 publications in 217 different journals. The number of publications per panel member ranges from 76 to 262, in 36 to 76 journals. There are no co-authored publications between panel members in both cases.

Table 1: Publication profile of the Pharmaceutical Sciences and Biology research groups

Pharmaceutical Sciences research groups (2001-2008)			**Biology research groups (2004-2010)**		
Group code	**Number of Publications**	**Number of Journals**	**Group code**	**Number of Publications**	**Number of Journals**
PSRG - A	40	22	BRG - A	168	53
PSRG - B	62	32	BRG - B	58	33
PSRG - C	61	35	BRG - C	212	212
PSRG - D	32	17	BRG - D	175	68
PSRG - E	64	42	BRG - E	168	69
PSRG - F	34	21	BRG - F	58	35
PSRG - G	67	31	BRG - G	280	139
PSRG - H	39	27	BRG - H	67	42
PSRG - I	29	10	BRG - I	86	52
PSRG - J	11	09	**----**	**----**	**----**
All groups together	**372**	**180**	All groups together	**1,153**	**372**

PSRG = Pharmaceutical Sciences Research Group; BRG = Biology Research Group.

Table 1 lists the number of publications of the research groups. The Pharmaceutical Sciences research groups published 372 publications in 180 journals, including 67 joint publications

between the groups, while the Biology research groups generated 1,153 publications in 372 journals, and there are 119 joint publications between the groups.

For this paper, we adopted the overlay mapping methods based on a global journal map from Web of Science data (Leydesdorff & Rafols, 2012). Journals overlay maps were created for the panels, all individual research groups, and the combined research groups of each department. To this end, all Source titles (Journal titles hereafter) pertaining to the entire citable journal output of the panel members and the groups were retrieved and entered into network software, and overlay information was added to the global journal map. The overlap of research group and panel publications was visualized on a global journal map based on the retrieved journal titles, using the visualization program VOSviewer (van Eck & Waltman, 2010).

Analysis and Results

Panel profiles versus Group profiles

Pharmaceutical sciences panel publications are found in 300 different journals, whereas those of the combined Pharmaceutical Sciences groups cover 180 journals. The journal overlay maps for the Pharmaceutical Sciences combined groups (Fig. 1) and the panel (Fig. 2) clearly show that the publication scope of the panel is wider than that of the combined groups. The panel publications are strong (11.86%) in 'Pharmaceutical Research', 'British Journal of Clinical Pharmacology', and 'Archiv der Pharmazie' journals, whereas the research group publications are clustered (8.6%) in 'Kidney International', 'Planta Medica', 'Environmental Science & Technology' journals.

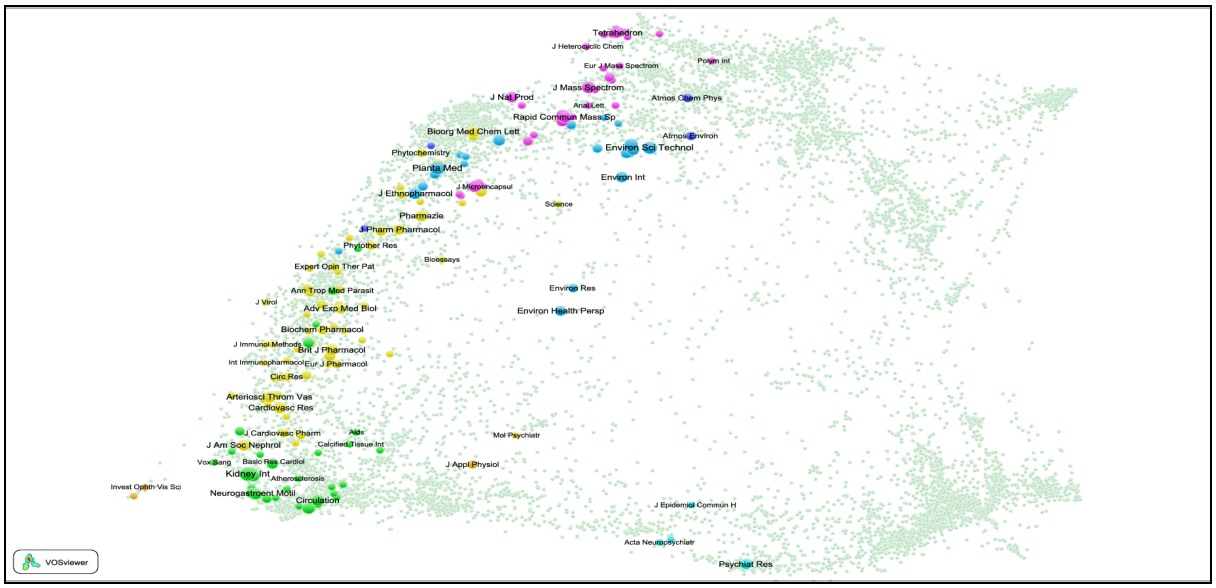

Figure 1. Pharmaceutical Sciences groups' publications overlay to the global journal maps.

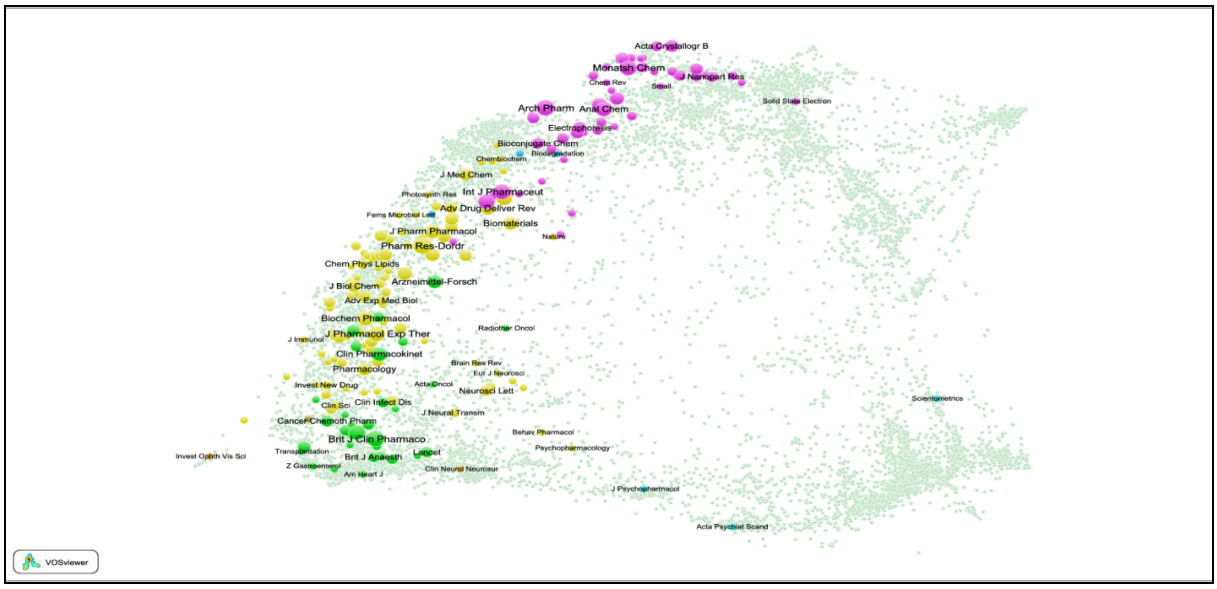

Figure 2. Pharmaceutical Sciences Panel publications overlay to the global journal maps.

Contrariwise, Biology panel publications appeared in 218 journals, while those of the combined Biology groups cover 372 journals. The overlay maps for the Biology department (Figs. 3 and 4) revealed a wider publication scope for the combined research groups compared to the Biology panel. The panel's publications are strong (8.58%) in 'Environmental Pollution', 'Biological Journal of the Linnean Society', and 'Journal of Experimental Biology', whereas the groups' publications tend to be mainly clustered (12.47%) in 'Experimental and Applied Acarology', 'General and Comparative Endocrinology', 'Journal of Experimental Biology'.

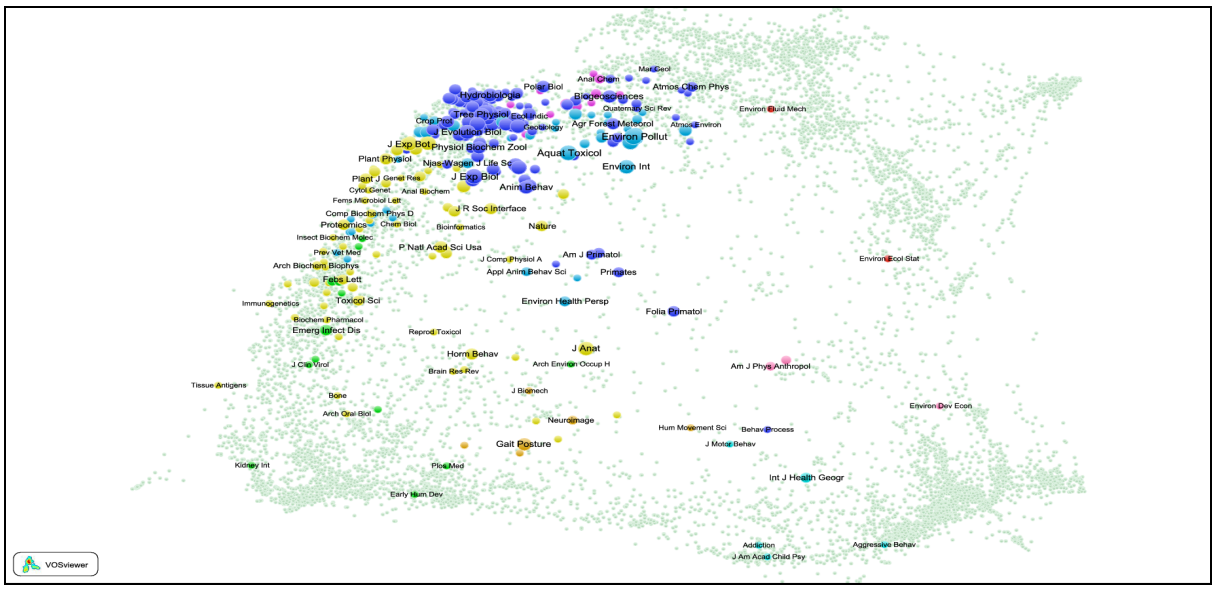

Figure 3. Biology groups' publications overlay to the global journal maps.

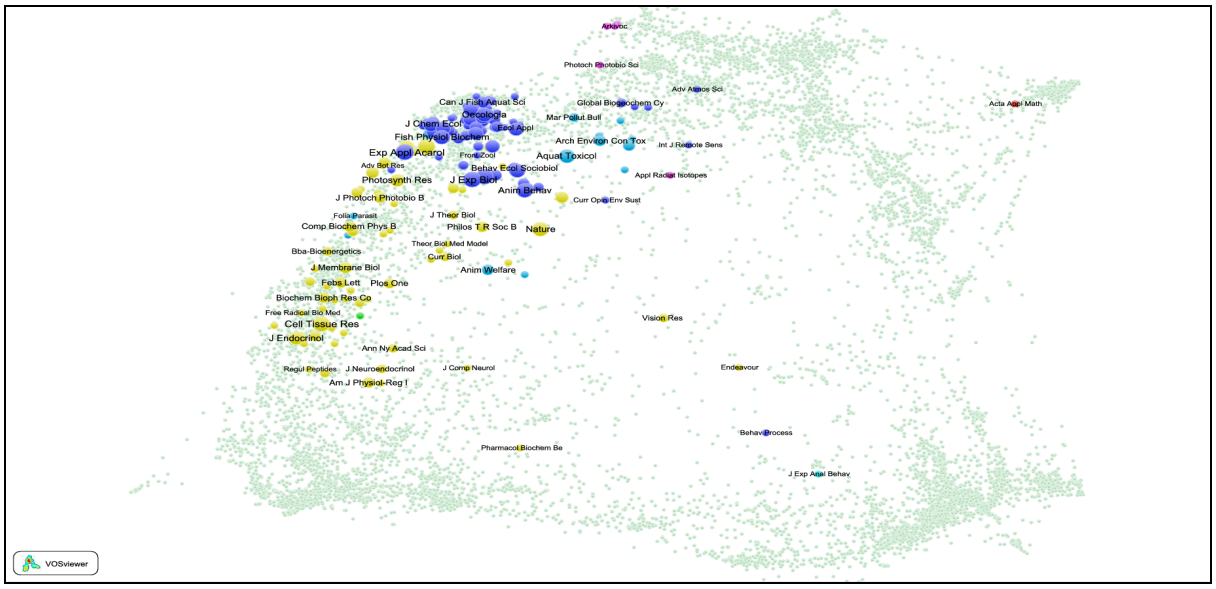

Figure 4. Biology Panel members' publications overlay to the global journal maps.

Table 2 shows that there is no common journal in the top five journals between the Pharmaceutical Sciences panel and groups. Table 2 further shows that there is only one common journal, *Journal of Experimental Biology*, (panel 3.82%, groups 2.26%) in the top five journals between Biology panel and groups.

Table 2: Top five Journals title for the panels and the groups

Panel publications			Group publications		
Pharmaceutical Sciences Department					
Journals Title	**Records**	**% of 1029**	**Journals Title**	**Records**	**% of 372**
Pharmaceutical Research	52	5.05	Kidney International	13	3.5
British Journal of Clinical Pharmacology	35	3.4	Planta Medica	11	2.96
Archiv der Pharmazie	35	3.4	Environmental Science Technology	8	2.15
Clinical Pharmacology Therapeutics	27	2.62	Journal of Mass Spectrometry	7	1.88
Monatshefte Fur Chemie	23	2.23	Chemosphere	7	1.88
Biology Department					
Journals Title	**Records**	**% of 786**	**Journals Title**	**Records**	**% of 1153**
Experimental and Applied Acarology	35	4.45	Environmental Pollution	40	3.47
General and Comparative Endocrinology	33	4.2	Biological Journal of the Linnean Society	33	2.86
Journal of Experimental Biology	30	3.82	Journal of Experimental Biology	26	2.26

New Phytologist	22	2.8	Environmental Science Technology	22	1.91

Together, the Pharmaceutical Sciences panel and groups have 60 journals in common. In addition, 240 journals have panel publications but no group publications, while 120 journals contain group publications but no panel publications. Further, Biology panel and group publications were common in 93 journals. Moreover, 125 journals contained panel publications but no group publications and 279 journals have group publications but no panel publications.

These findings demonstrate that Pharmaceutical Sciences panel published more diversely than the groups, whereas the opposite is true for the Biology department. However, the Pharmaceutical Sciences panel overlaps in one third of the journals of groups' publications, whereas the Biology panel overlaps almost half the journals where biology groups have publications too.

Panel profile versus Individual group profile

Overlay maps of the publications of the individual groups were created, and subsequently compared with the two panel overlay maps. Most Pharmaceutical Sciences research groups have at least one journal in common with the panel; this is the case for PSRG-A (50%), PSRG-B (40.63%), PSRG-C (31.42%), PSRG-D (58.82%), PSRG-E (40.78%), PSRG-F (61.9%), PSRG-G (16.13%), PSRG- H (37.03%), and PSRG-J (20%). Only PSRG-I has none. All Biology research groups have one or more journals in common with the panel: BRG-A (41.51%), BRG-B (18.75%), BRG-C (33.33%), BRG-D (35.29%), BRG-E (42.65%), BRG-F (48.57%), BRG-G (35.97%), BRG-H (19.05%), BRG-I (25%).

These data show that the research outputs of three of the ten Pharmaceutical Sciences research groups (A, D, F) are 50–62 percent, four groups (B, C, E, H) are 30–40 percent, two groups (G, J) are 20 to 15 percent covered by the panels' expertise thematically, whereas one group (group I) is not covered at all. At the same time, three out of nine Biology research groups (A, E, F) are 40-50 percent, three research groups (C, D, G) are 30-40 percent, and another three research groups (B, H, I) are below 25 percent covered by the panel's expertise.

Conclusion

The results indicate that the Biology research groups published more diversely than the panel, which is similar to the findings in Rahman et al. (2014). However, the Pharmaceutical Sciences panel published more diversely than research groups, which is opposite to what was found in Rahman et al. (2014) where the research groups published more diversely in Web of Science subject categories than the panel did. The most likely reason is that all panel members' publications are taken into account (published over the course of over 20 years, often working in different countries and on different topics), whereas the research groups have a specific focus and choose the journals accordingly.

Pharmaceutical Sciences panel overlaps in one third of the journals of the corresponding group's publications, whereas the Biology panel overlaps in close to half the journals where Biology groups have publications. In addition, the number of publications in the same journals by the expert panel and research group varied, and a different range of coverage was found for different research groups. There is also a significant difference between maximum and minimum coverage based on discipline. To quantify which overlap leads to the best standard for evaluation, a considerable range of percentage of common journals between the panel and research group needs to be identified. The considerable range of percentage will express a well-covered, partially covered, and hardly covered expertise based on journal level matching. In subsequent analysis, we will compare results with corresponding results for other disciplines and explore other criteria for adequate relations between evaluation panels and groups.

Acknowledgments

This investigation has been made possible by the financial support of the Flemish Government to ECOOM, among others. The opinions in the paper are the authors' and not necessarily those of the government. The authors thank Nele Dexters for assistance.

Abstract
This paper builds on an innovative Information Retrieval tool, *Ariadne*. The tool has been developed as an interactive network visualization and browsing tool for large-scale bibliographic databases. It basically allows to gain insights into a topic by contextualizing a search query (Koopman et al., 2015). In this paper, we apply the Ariadne tool to a far smaller dataset of 111,616 documents in astronomy and astrophysics. Labeled as the *Berlin dataset*, this data have been used by several research teams to apply and later compare different clustering algorithms. The quest for this team effort is how to delineate topics. This paper contributes to this challenge in two different ways. First, we produce one of the different cluster solutions and second, we use *Ariadne* (the method behind it, and the interface - called *LittleAriadne*) to display cluster solutions of the different group members. By providing a tool that allows the visual inspection of the similarity of article clusters produced by different algorithms, we present a complementary approach to other possible means of comparison. More particularly, we discuss how we can - with *LittleAriadne* - browse through the network of topical terms, authors, journals and cluster solutions in the *Berlin dataset* and compare cluster solutions as well as see their context.

Conference Topic
Methods and techniques; Mapping and Visualization

Introduction
What are essence and boundary of a scientific field? How can a topic be defined? Those are questions that are core to bibliometrics. Rigour and stability in defining boundaries of a field are important for research evaluation and funding distribution. However, if you as a researcher would seek for information about a certain topic of which you are not an expert yet, your information needs are quite different. Among the many possible hits for a search query you might want to know which are core works (articles, books) and which are rather peripheral. You might want to use different rankings (Mutschke & Mayr, 2014) or get some context. On the whole you would have less need to define a topic and a field in a bijective, univocal way. The same holds if you want to compare different clustering algorithms. Here again, you are in need to illustrate similarities and differences between different allocations of documents to clusters. Ways to contextualize them and browse through these contexts would be desirable. This is our starting point.
Decades of bibliometrics research have produced many different algorithms to cluster bibliographic records. They often focus on one entity of the bibliographic record. For example, articles and terms those articles contain (in title, abstract and/or full text) form a

[1] This paper is submitted as part of the Special Session at the ISSI conference 2015 "Same data – different results? The performative nature of algorithms for topic detection in science".

bipartite network from which we can either build a network of related terms (co-word analysis) or a network of related articles (based on shared words). The first method, sometimes also called lexical, has been often applied in scientometrics to produce so-called topical or semantic maps. The same exercise can be applied to authors and articles, articles and journals, in effect each element of the bibliographic record for an article (Havemann & Scharnhorst, 2012). If we extend the bibliographic record with the list of references, we enter the area of citation analysis. Here two methods are widely used: direct citations (known as delivering often sparse matrices) and co-citation maps (known as a good method to identify research fronts). Hybrid methods combine citation and lexical analysis (e.g., Zitt & Bassecoulard, 2006; Janssens et al., 2009). The majority of studies applies one technique. But, sometimes analysis and visualization of multi-partite networks can be found (cf. Van Heur, Leydesdorff, & Wyatt 2013).

Each of the possible different network representations of articles stands for another aspect of connectivity between published scientific works. Co-authorship networks shed light on the social dimension - the invisible colleges - of knowledge production (Mali et al., 2012; Glänzel & Schubert, 2004). Citation relations are interpreted as traces of flows of knowledge (Price, 1965; Radicchi, Fortunato, & Vespignani, 2012). Depending on which element of the bibliographic record is used, we obtain different perspectives on how a field or a topic is to be conceived - as conceptional, cognitive unit; as a community of practice; or as institutionalized in journals. We can call this a *measurement effect*. Another source of variety next to differences resulting from what to analyze is how to analyze it. Finding clusters is part of network analysis. But, clusters can be defined in different ways, and aside of different possible definitions of cluster to determine them for a large-scale network can be algorithmically challenging. Consequently, we find different solutions for one algorithm (if parameters in the algorithm are changed) and different solutions for different algorithms. One could call this an effect of the *choice of instrument for the measurement*. Last but not least, we can ask ourselves, if topics clearly delineated from each other really exist. Often in science very different topics still are related to each other. There exist unsharp boundaries and almost invisible long threads in the *fabric of science* (Boyack & Klavans, 2010), which might inhibit to find a contradiction-free solution. There is a seeming paradox between the fact that experts often can rather clearly identify what belongs to their field or a certain topic, and that it is so hard to quantitatively represent this with bibliometrics methods. However, a closer look into science history and science and technology studies reveals that what belongs to a field or a topic can still differ substantially also in the opinions of different experts; it changes over time; and even a defined canon or body of knowledge determining the essence of a field or a topic might be still subject to controversies and changes.

In the quest to define a topic two things collide. The principal, methodological and data-based ambiguity of what a topic is and the necessity to define a topic for purposes of education, knowledge acquisition and evaluation. This makes it such an intriguing problem to be solved. Because different perspectives can be valid, there is also a need to preserve the above sketched diversity or ambiguity. Having said this, for the sake of scientific reasoning it is also necessary to be able to further specify the validity and appropriateness of different methods to define topics and fields. This paper contributes to the development of methods to compare algorithms and to visualize their different results.

We contribute to this sorting out process in two different ways. First, we apply standard clustering techniques to a specific article matrix built in a specific way from what we call a semantic matrix, in which rows are formed by entities from the bibliographic records of the articles (author names, journal ISSNs, topical terms, subjects, and other characteristics), columns by reduced dimensions from co-occurrence of entities and topical terms (one subset of the entities) over the whole set of articles. While we explain this in detail later, let us note

here that the approach is conceptually more similar to classical information retrieval techniques based on Salton's vector space model than to usual bibliometrical mapping techniques (Salton & McGill, 1983).
In a second step, we present an interactive visual interface called *LittleAriadne* that allows to display the context around those extracted and networked entities. The interface responds to a search query with a network visualization of most related terms, authors, journals and (other) cluster numbers. The query entry can be words, authors, but also cluster solutions. The displayed nodes or entities around a query term represent to a certain extent the context of this query. Depending on the query entry, we will see more or less other terms, journals, or authors. The interface allows to foreground one of entity types by selecting them. The interface has been originally developed for a much larger bibliographic database. In this paper our research questions are:

- Q1: How does the *Ariadne* algorithm work on a much smaller, field specific dataset? What possibility do we have to relate the produced contexts to domain knowledge?
- Q2: Can we use *Ariadne* to label the clusters produced by the different methods?
- Q3: Can we use *Ariadne* to compare different cluster assignments of papers, by treating those cluster assignments as additional entities? What can we visually learn about the topical nature of these clusters?

Data

The dataset used in this paper – called *Berlin dataset* - entails papers published in the period 2003-2010 in 59 astrophysical journals. Those papers have been downloaded from the Web of Science in the context of a German-funded research project called "Measuring Diversity of Research," conducted at the Humboldt-University Berlin - hence the coined name *Berlin dataset*. It contains 120,007 records in total. Eventually, 111,616 records of the document types Article, Letter and Proceedings Paper have been treated with different clustering methods (see the other contributions for this special session).
Some of those cluster outcomes have been shared and are later displayed in the visual interactive interface. Table 1 shows the label of the different sets of clusters *x* we have included in *LittleAriadne*, whereby *x={a, b, ..., f}*. We have noted by which group cluster solutions were produced in the *Source* column. Each clustering method produced a set of clusters, whereby *y* stands for the number of clusters in a set. In our paper we used cluster solutions from CWTS (label: cwts 1.8), Cornell, Humboldt-University Berlin (hu), SciTech (sts-rg), KU Leuven (bc15) and one of our own (oclc_20). Except of cluster set *e*, they are all of the same order of magnitude. Because *Ariadne* relies on statistics across a corpus of articles as large as possible to produce semantic relatedness, we decided to discard clusters with less than 4 articles. But, from the solutions with many clusters (*d, e*) we decided not to display all. The last column in Table 1 gives the final numbers of the clusters from different clustering solutions.

Method

Ariadne - an interactive visualization to navigate entities from large bibliographic databases

The *Ariadne* algorithm has been developed on top of the article database, *ArticleFirst* of OCLC. The interface, accessible at http://thoth.pica.nl/relate, allows users to visually and interactively browse 35 thousand journals, 3 million authors, 1 million topical terms associated with 65 million articles (Koopman et al., 2015). For the purpose of this paper, we applied the same method on the Berlin dataset and built an instantiation, *LittleAriadne*, accessible at http://thoth.pica.nl/astro/relate.

Table 1. Statistics of clusters generated from different methods.

x	Source	*y=#Cluster*	*#Cluster in Ariadne*
a	cwts 1.8	23	23
b	cornell	23	23
c	oclc_20	20	20
d	hu	139	48
e	sts-rg	5664	229
f	bc15	15	15

Table 2. An article from the Berlin dataset.

Article ID	ISI:000276828000006
Title	On the Mass Transfer Rate in SS Cyg
Abstract	The mass transfer rate in SS Cyg at quiescence, estimated from the observed luminosity of the hot spot, is log M-tr = 16.8 +/- 0.3. This is safely below the critical mass transfer rates of log M-crit = 18.1 (corresponding to log T-crit(0) = 3.88) or log M-crit = 17.2 (corresponding to the ""revised"" value of log T-crit(0) = 3.65). The mass transfer rate during outbursts is strongly enhanced

Table 2 shows for one example article from the *Berlin dataset* those fields of the bibliographic record that we used for *LittleAriadne*. It also shows which categories of entities we have. The ISI record ID has been used among the teams to compare solutions. For *Ariadne* as an interface, it does not matter. *Ariadne* is different from a usual Information Retrieval search engine because it does not primarily deliver lists of documents matching a query, but a network of those entities which profile in the whole corpus 'resonate' most with the query entry. We come back to this aspect later. We further define so-called topical terms. Topical terms are frequent single or two-word phrases extracted from all titles and abstracts, for example, "mass transfer" and "quiescence" in our example. Next to the topical term, each author name is treated as an entity. In Table 2 we display the author name (and other entities below) in a syntax that can be used in the search field of the interface to search for a specific author. The next type of entities is the ISSN number of a journal. One can search for a single journal using the ISSN number, in the visual interface the journal title is used as label for a node representing a journal. Further, we have so-called subjects as separate entity type. Those subjects origin from the fields "Author Keywords" and "Keywords Plus" of the original Web

of Science records. As last type of entities we add - and this is specific for *LittleAriadne* - to each of the articles cluster labels from their assignments to clusters produced by different teams. For example, the article in Table 2 has been assigned to cluster number 19 by source a (cwts 1.8) number 16 by source b (cornell), and so on. In other words, we treat the cluster assignments of articles as they would be classification numbers or additional subject headings.

With the above detailed parsing of the bibliographic records we then build the matrix C (see Figure 1). In C, frequent topical terms, subjects, author names, cluster labels and journals appearing in the *Berlin dataset* form the rows, and topical terms as well as subjects are listed in columns. The relatedness between all entities is computed based on the *context* they share, instead of direct co-occurrences in the data. The context of these entities is captured by their co-occurrences with topical terms and subjects, that is, we count how often an author, or a cluster label co-occurs with a certain topical term or subject in an article, summing up over all articles in the corpus. In the Berlin dataset, we have in total 90,343 entities, including 59 journals, 27,027 author names (single instances, no author disambiguation applied), 358 cluster IDs, 39,577 topical terms and 23,322 subjects. This would produce a sparse matrix of roughly 90K x 63K that is expensive for computation.

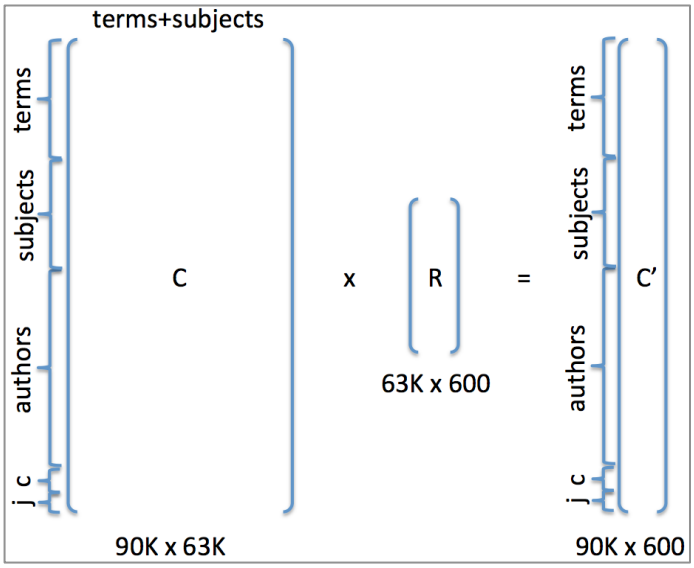

Figure 1. Dimension reduction using Random Projection.

To make the algorithm scale and produce a responsive visual interface, we applied *Random Projection* (Johnson & Lindenstrauss, 1984; Achlioptas, 2003) to reduce the dimensionality of the matrix. As shown in Figure 1, by multiplying C with a 63K x 600 matrix of randomly distributed -1 and 1, the original 90K x 63K matrix C is reduced to a *Semantic Matrix C'* of the size of 90K x 600, with each row vector representing the semantics of an entity. With this Semantic Matrix, the interactive visual interface dynamically computes the most related entities (e.g. ranked by cosine similarity) to a search query and presents a networked visualization of the context of a query term whereby entities are positioned closer to each other if they are more related to each other.

OCLC clusters production - Clustering the Berlin dataset using the Semantic Matrix

The Ariadne interface provides a networked view about entities associated with articles, but it does not produce article clusters straightaway. In order to cluster articles, we need to build a semantic representation of each article. We receive the semantic representation for an article by the following steps. For each article, we look up all entities related to this article in the

Semantic Matrix C'. For our example in Table 2 we have one vector representing the single author of that article in the whole Semantic Matrix, 12 vectors representing the subjects, one vector for the journal, 6 vectors representing the cluster labels and *n* vectors for all extracted topical words. In other words, each article is represented by a subset of vectors and the vector components correspond to the dimensions of the Semantic Matrix. We then take the average of those single entity vectors as the semantic representation of a specific article. All articles together form a matrix M with 111,616 rows and 600 columns. We applied a standard clustering technique - the MiniBatchKmeans method (Sculley 2010) - to M. We used the scikit-learn python library (http://scikit-learn.org/) for this. Applied to the *Berlin dataset* we receive a cluster solution with a comparable size of k=20 clusters, labeled as oclc_20, and a unique assignment of articles to this cluster.

Results - The Berlin dataset in *LittleAriadne*

We used the visual, interactive interface built for the *Berlin dataset* to the context around a specific cluster solution and the similarity between different ones. For this we performed different experiments, which correspond to the research questions Q1-Q3 of the introduction

- Experiment 1: We used *LittleAriadne* as information retrieval tool. We searched with query terms, inspected and navigated through the resulting network visualization. (Q1)
- Experiment 2: We used the semantic matrix to provide the most related topical terms for each cluster as an approximation of cluster labels. (Q2)
- Experiment 3: We used the query syntax to display two or more cluster solutions together in one overview. (Q3)

Experiment 1 - Information retrieval

In *LittleAriadne* we can now study the *Berlin dataset* as any other dataset. Figure 2 gives a snapshot of the context about "magnetic flux" used as query term.[2] The most related topical terms and subjects are shown, together with 3 most related clusters provided by CWTS, Cornell and SciTech (coded in different colors). Each node is clickable which leads to another visualization of the context of the selected node. When mousing over a node, one sees how often this entity occurs in the whole corpus. Given that different statistical methods are at the core of the Ariadne algorithm, this gives an indication of the reliability of the suggested position and links. In the interface one can further refine the display. For instance, one can choose the number of nodes to be shown or decide to limit the display to only authors, journals, topical terms or clusters. Within the interface, one can navigate the context of entities in the *Berlin dataset* by seamlessly travelling between authors, journals, topical terms and clusters in a visual and interactive way.

Experiment 2 -Labeling clusters

Please note, that in *LittleAriadne* we cannot see the position of articles in relations to the different entities. One could say that the articles produce the elements of the networked context, but they themselves are distributed over it. What we can do is to switch to a view that shows most related topical terms, subjects, journals, authors, and other clusters. The outcome of such a *click-through* action is shown in Figure 3.[3] In this example, the most related topical terms, subjects, one journal, and four other clusters are presented as the contextual information about the cluster "a 2".

[2] Figure 2 is accessible at http://thoth.pica.nl/astro/relate?input=magnetic+flux.

[3] Figure 3 is accessible at http://thoth.pica.nl/astro/relate?input=%5Bcluster%3Aa+2%5D.

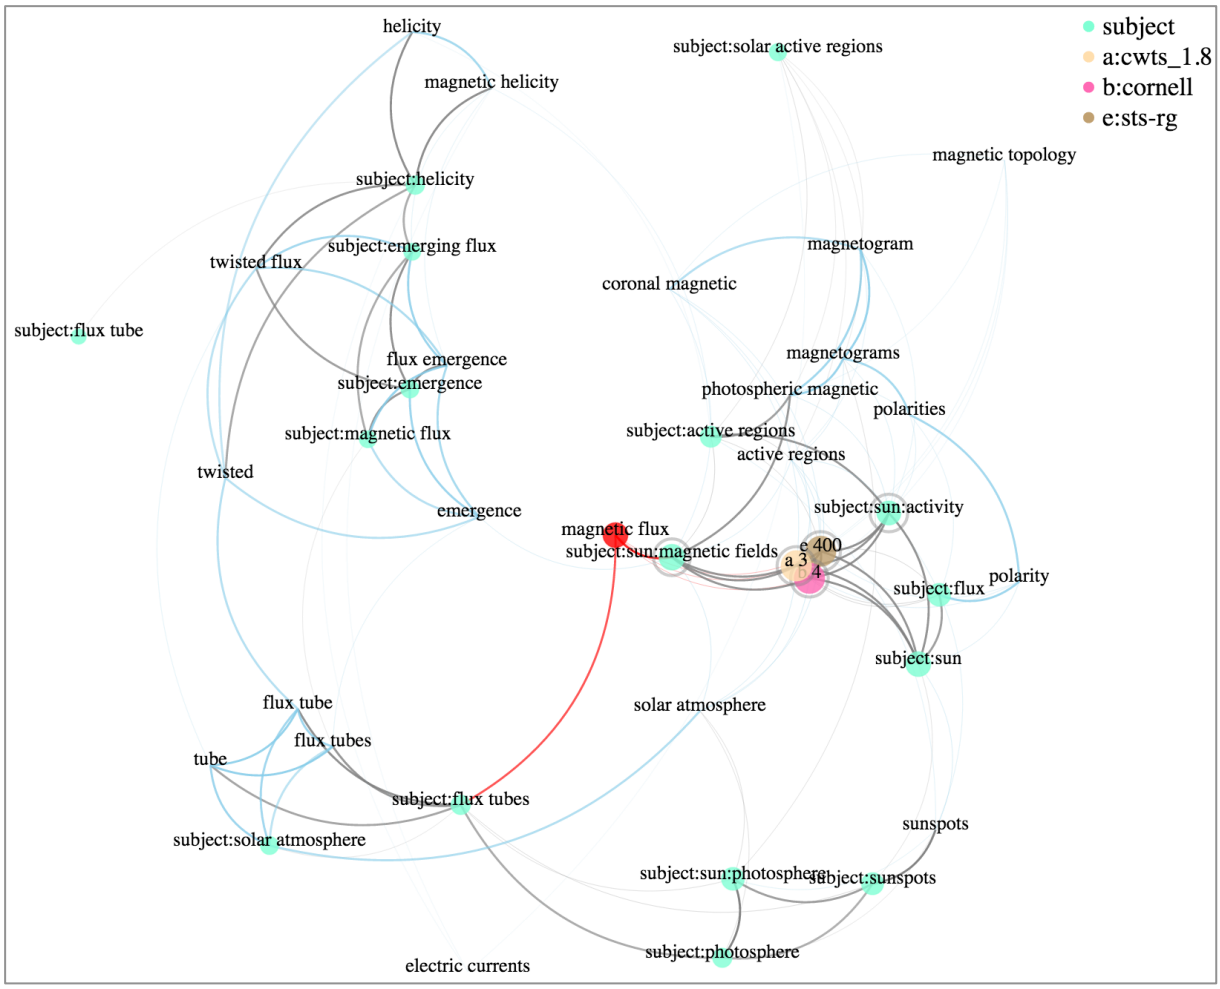

Figure 2. Context around "magnetic flux".

It is now possible to label each cluster using the most related topical terms. As shown in Table 3, the 9 topical terms most related to cluster "a 2" are "cosmology," "dark energy," "density perturbations," "cosmologies," "planck," "cosmological," "spatial curvature," "inflationary," and "inflation." Together they give a rough idea about what this cluster with 8,954 articles is about, but it requires domain expertise to evaluate and transform them into real cluster labels, meaning representing names of specialties, topics or fields used by the scientific community, a well-known problem of bibliometric mapping (Noyons, 2005).

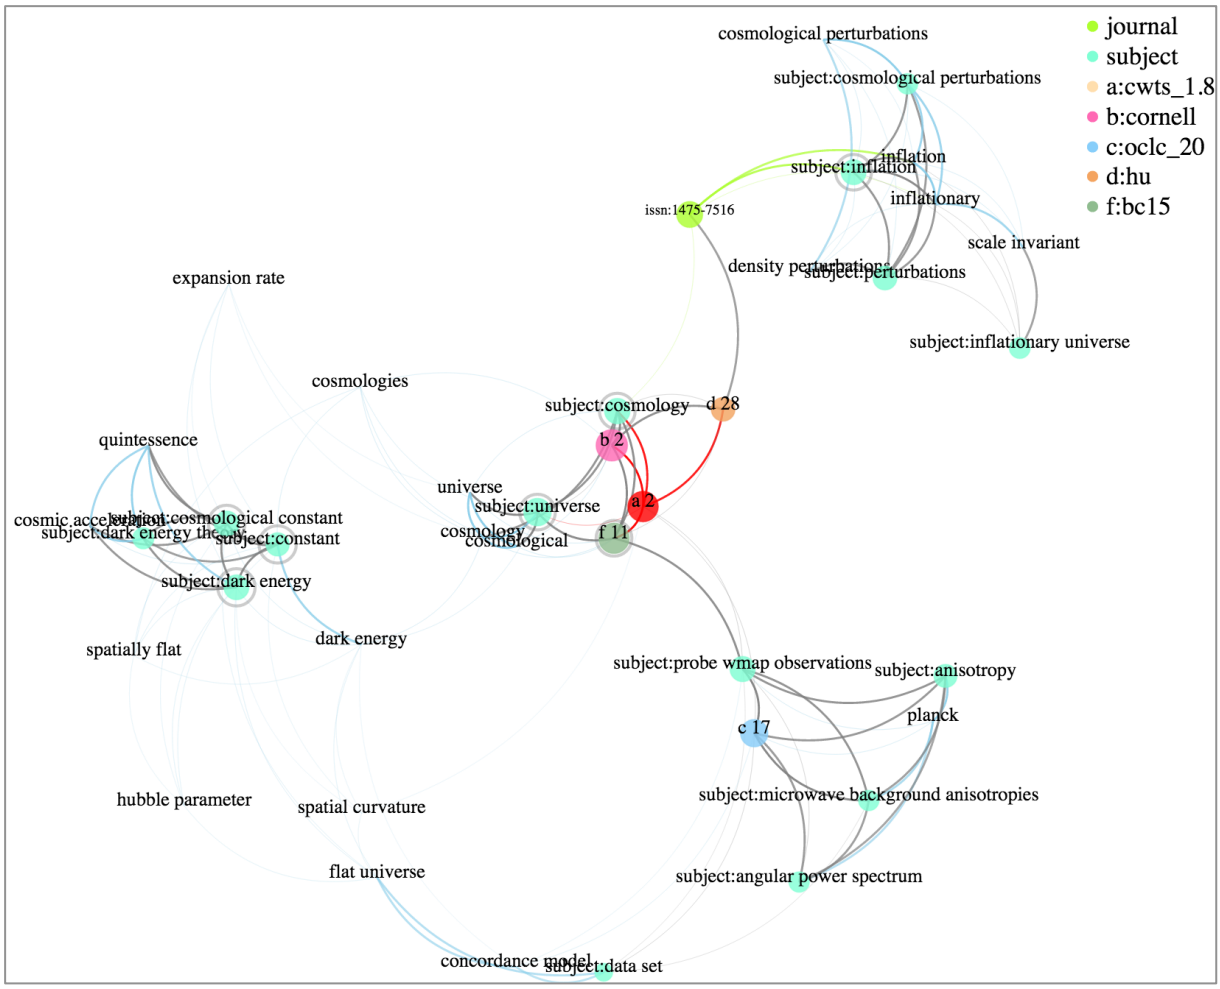

Figure 3. The contextual view of cluster “a 2”.

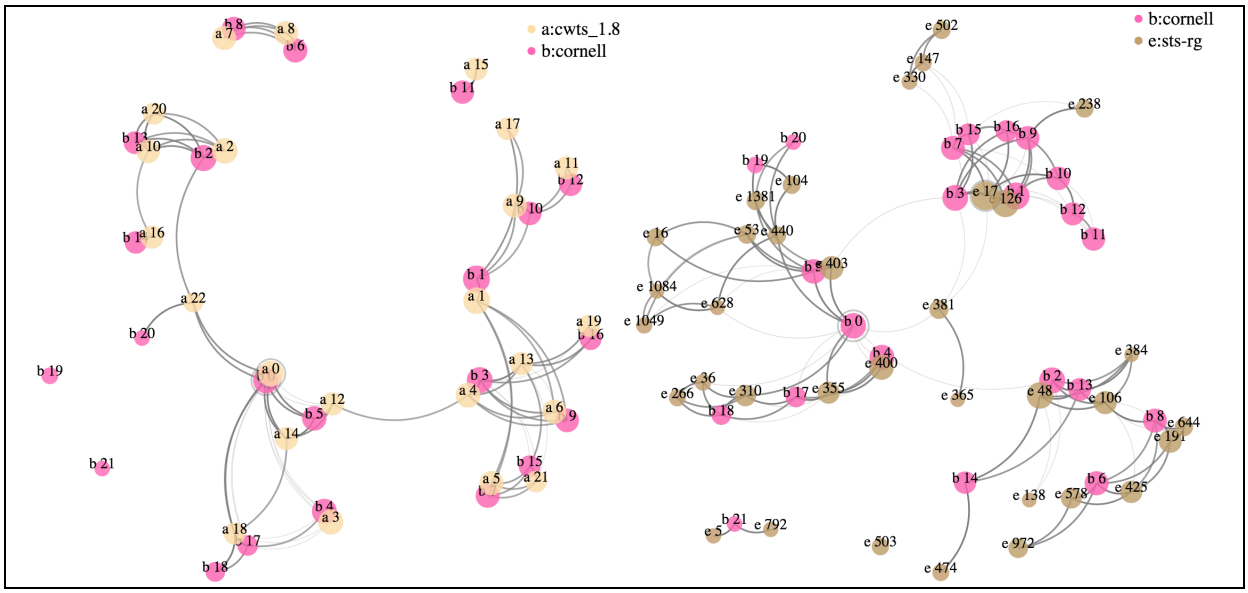
Table 3. Top related topical terms.

Cluster ID	Top 9 most related topical terms
a 2	"cosmology" "dark energy" "density perturbations" "cosmologies" "planck" "cosmological" "spatial curvature" "inflationary" "inflation"
b 2	"cosmology" "cosmological constant" "cosmologies" "cosmological" "universes" "dark energy" "quadratic" "tensor" "planck"
c 17	"power spectrum" "cosmological parameters" "cmb" "last scattering" "anisotropies" "microwave background" "power spectra" "planck" "cosmic microwave"
d 28	"density perturbations" "inflationary" "inflation" "dark energy" "scale invariant" "spatial curvature" "cosmological perturbations" "inflationary models" "cosmologies"
f 11	"cosmology" "cosmological" "dark energy" "universe" "planck" "density perturbations" "cosmologies" "spatial curvature" "flat universe"

Experiment 3 - Comparing cluster solutions

In *LittleAriadne* we extended the interface with a possibility to compare sets of clusters. In Figure 4 (a) we can visually see the high similarity between clusters from CWTS and those from Cornell.[4] Nearly each CWTS cluster is accompanied by a Cornell cluster. Figure 4 (b) shows two other sets of clusters which partially agree with each other but also clearly have different capacity in distinguishing different clusters.[5] Figure 5 shows all the cluster entities from all six clustering solutions. Given the amount of the clusters, it is difficult to grasp the detailed difference between solutions. However, this visualization does provide a general overview of all the clustering solutions, based on their similarities to each other.



(a) Highly similar (between CWTS 1.8 and Cornell)

(b) Partially agreeing (between Cornell and SciTech)

Figure 4. Comparison between sets of clusters.

Discussion and Conclusion

We present a method and an interface that allows browsing through the contexts of entities, such as topical terms, authors, journals and subjects associated with a set of documents. We have applied the method to the problem of topic delineation addressed in this special session. Because the tool shows (local) context and not the position of single documents in relation to clusters we think it has a potential to be complementary to any other method of cluster comparison. In particular, we have asked how the *Ariadne* algorithm works on a much smaller, field specific dataset. Not surprisingly, compared with our exploration in the ArticleFirst interface, we find more consistent representations. That means that specific vocabulary is displayed, which can be cross-checked in Wikipedia or Google Scholar, for which the interface offers a direct click through.

[4] Figure 4(a) is accessible at http://thoth.pica.nl/astro/relate?input=%5Bcluster%3Aa%5D%5Bcluster%3Ab%5D&type=S&show=50.

[5] Figure 4(b) is accessible at http://thoth.pica.nl/astro/relate?input=%5Bcluster%3Ae%5D%5Bcluster%3Ab%5D&type=S&show=300.

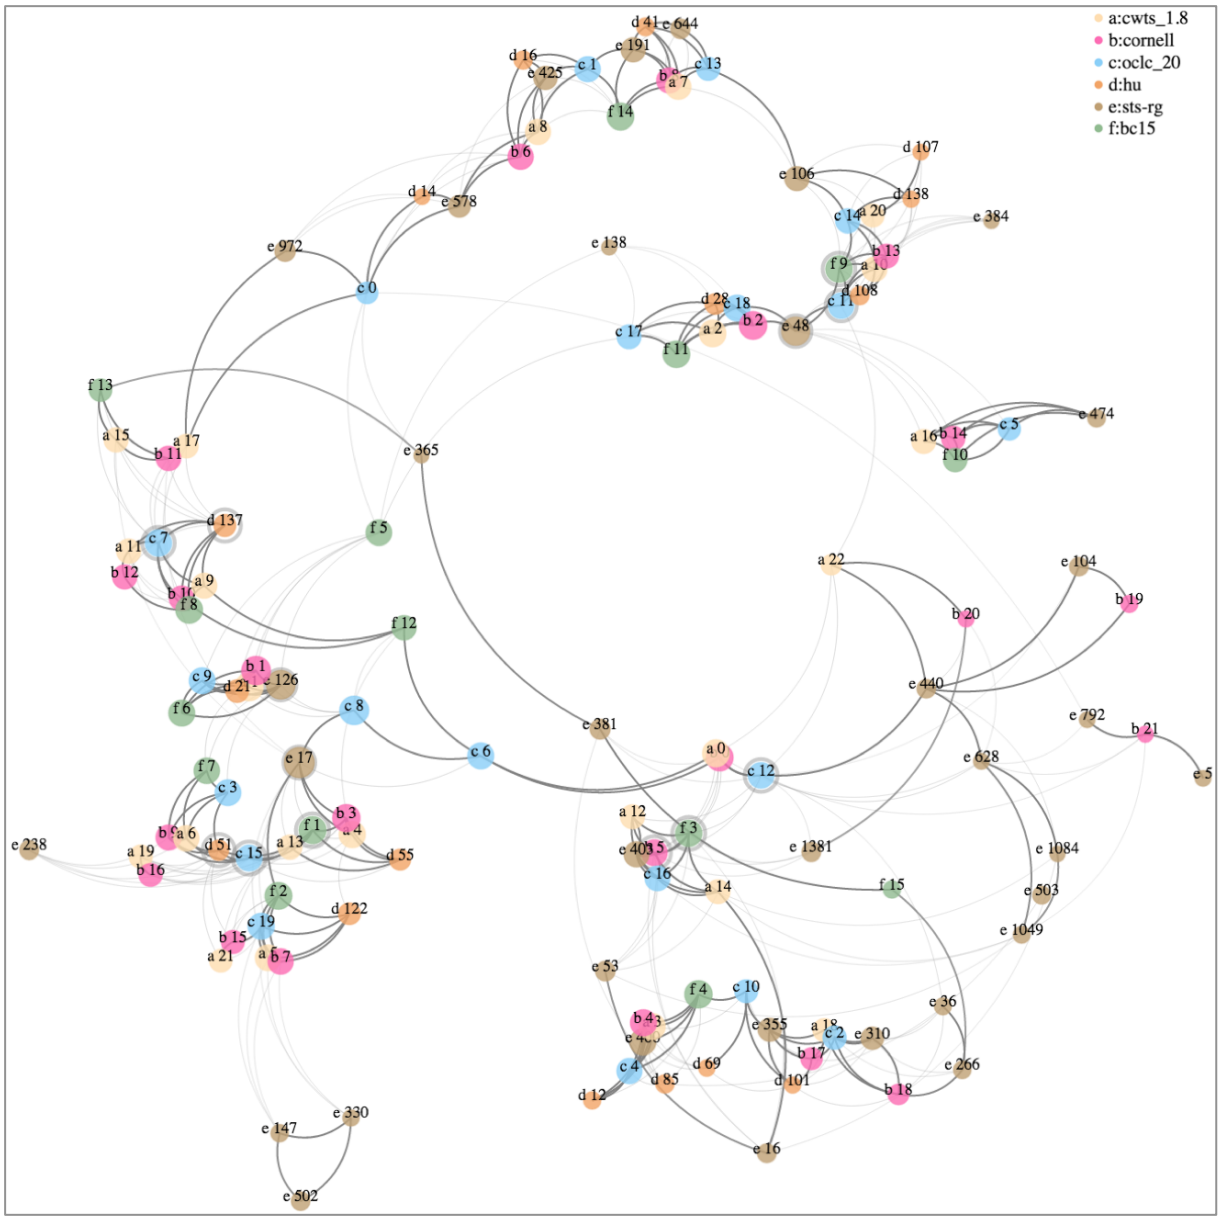


Figure 5. Comparing clusters from 6 clustering solutions.

On the other hand, the bigger number of topical terms in the larger database leads to a situation where almost every query term produces a response. In *LittleAriadne* searches for e.g., literary persons such as Jane Austen retrieve nothing - a blank screen. In preparation of this paper we surfed through the interface, and compared the most relevant topical terms around a cluster to other classifications used in Astrophysics, such as Physics and Astronomy Classification Scheme (PACS®[6]). In this punctual exploration we did find correlations between the names of PACS classes (subclasses, and related controlled vocabulary) and the selected topical terms in *LittleAriadne*. We will further compare the context around clusters and the suggested related topical terms with labels produced by other teams in this special session. Ultimately, the discussion with domain experts belongs to a proper evaluation of the interface. We demonstrated that we can use *LittleAriadne* to compare different cluster solutions mutually and even generate a wider overview. We will discuss in the special session how Ariadne can further be of use in the comparison of clustering and delineation of topics.

[6] http://www.aip.org/publishing/pacs/pacs-2010-regular-edition

At least, we hope that this interactive tool supports discussion about different clustering algorithms and helps to find the right meaning of clusters, and appropriate labels for them.
We also have plans to further develop the Ariadne algorithm. The Ariadne algorithm is general enough to accommodate additional types of entities to the semantic matrix. In the future, we plan to add citations, publishers, conferences, etc. with the aim to provide a richer contextualization of entities. We also plan to add links to articles that contribute to the contextual visualization, this way strengthening the usefulness of *Ariadne* not only for the associative exploration of contexts similar to scrolling through a systematic catalogue, but also as a direct tool for document retrieval. In this context we plan to further compare *LittleAriadne* and *Ariadne*. In a first attempt, we 'projected' the astrophysical documents into *ArticleFirst* by looking them up in the large semantic matrix built for Ariadne. We found the resulting representations less consistent when browsing through. That is not a surprise, because when merging them you see how field-specific content fits and miss-fits into many other contextualizations. The advantage of *LittleAriadne* is the confinement of the dataset to one scientific field and topics within. We hope by continuing such experiments also to learn more about the relationship between genericity and specificity of contexts, and how that can be best addressed in information retrieval.

Abstract
In spite of recent advances in field delineation methods, enduring problems such as the impossibility to justify necessary thresholds and the difficulties in comparing thematic structures obtained by different algorithms leave bibliometricians with a sense of uneasiness about their methods. In this paper, we propose and demonstrate a new approach to the delineation of thematic structures that attempts to fit the methods for topic delineation to the properties of topics. We derive principles of topic delineation from a theoretical discussion of thematic structures in science. Applying these principles, we cluster citation links rather than publication nodes, use predominantly local information and grow communities of links from seeds in order to allow for pervasive overlaps of topics. The complexity of the clustering task requires the application of a memetic algorithm that combines probabilistic evolutionary strategies with deterministic local searches. We demonstrate our approach by applying it to a network of 14,954 Astronomy & Astrophysics papers and their cited sources.

Conference Topic
Methods and techniques (special session on algorithms for topic detection)

Introduction
The identification of thematic structures (topics or fields) in sets of papers is one of the recurrent problems of bibliometrics. It was deemed one of the challenges of bibliometrics by van Raan (1996) and is still considered as such despite the significant progress and a plethora of methods available. Major developments since van Raan's paper include approaches that cluster the whole Web of Science based on journal-to-journal citations, co-citations, or direct citations, the advance of hybrid approaches that combine citation-based and term-based techniques, and term-based probabilistic methods (topic modelling). However, methodological problems endure and leave bibliometricians with a sense of uneasiness about their methods. Advanced methods still apply thresholds that must be arbitrarily set and adapted to the specific structures that shall be obtained. The relevance of the structures identified by bibliometric methods are difficult to verify independently, and the relationships between thematic structures are difficult to assess. A recent analysis by Hric et al. (2014) found that current algorithms for the detection of communities in network of papers respond to topological properties of networks but not necessarily to the underlying real-world properties of nodes clustered. This observation casts further doubts on the fundamental assumption underlying bibliometric methods for topic delineation, namely that the topics reconstructed using *structural properties of networks of papers* reflect *thematic properties of the research published in those papers*.

In this paper, we propose and demonstrate a new approach to the delineation of thematic structures. We derive principles of topic delineation and criteria for the assessment of algorithms from a theoretical discussion of properties of thematic structures in science. Applying these principles, we cluster citation links rather than publication nodes, use predominantly local information, and grow communities from seeds in order to allow for

pervasive overlaps of topics. The complexity of the clustering task requires the application of a memetic algorithm that combines nondeterministic evolutionary strategies with deterministic local searches. We demonstrate our approach by applying it to a network of 14,954 Astronomy & Astrophysics papers and their cited sources.

Strategy, Methods and Data

Theoretical considerations and strategy

We define topics as theoretical or empirical knowledge about objects or methods of research that is a common focus for a set of research processes because it provides a reference for the decisions of researchers – the formulation of problems, the selection of methods or objects, the organisation of empirical data, or the interpretation of data (on the social ordering of research by knowledge see Gläser 2006). This definition resonates with Whitley's (1974) description of research areas but abandons the assumption that topics form a hierarchy. It only demands that some scientific knowledge is perceived similarly by researchers and influences their decisions.

This weak definition is linked to three properties of topics that create the problems for bibliometrics:

1) The fractal nature of knowledge has been described by van Raan (1991) and Katz (1999). Topics can have any 'size' (however measured) between the smallest (emerging topics that just concern one researcher) and very large thematic structures (fields or even themes cutting across several fields). Methods for topic identification should thus not be biased against any particular topic size.

2) Given the multiple objects of knowledge that can serve as common reference for researchers, topics inevitably overlap. Publications commonly contain several knowledge claims, which are likely to address different topics (Cozzens, 1985; Amsterdamska & Leydesdorff, 1989). Methods for topic identification should thus take into account that bibliometric objects (publications, authors, journals, and cited sources) are likely to belong to several topics simultaneously. Methods also should enable the reconstruction of topics that overlap pervasively (i.e. not only in their boundaries).

3) All topics emerge from coinciding autonomous interpretations and uses of knowledge by researchers (see e.g. the case studies discussed by Edge and Mulkay, 1976, pp. 350-402). While individual researchers may launch topics and advocate them, the latter's content and fate depends on the ways in which they are used by others. From this follows that topics are local in the sense that they are primarily topics to the researchers whose decisions are influenced by and who contribute to them. Methods for topic identification can reconstruct this insider perspective by using local information. Global approaches create different representations of topics by finding a compromise between insider perspectives and all outsider perspectives on topics.

Methods

For a detailed description of the method see Havemann, Gläser, & Heinz (2015). We operationalise 'topic' as a set of thematically related papers but cluster citation links instead of papers because the former can be assumed the thematically most homogenous bibliometric objects (see Evans & Lambiotte, 2009; and Ahn, Bagrow & Lehmann, 2010 on link clustering).

Cost Function: We followed the suggestion by Evans and Lambiotte (2009) to obtain link clusters by clustering vertices in a network's line graph and defined a local cost function $\Psi^*(L)$ of link set L in the line-graph approach. The internal degree $k_i^{\text{in}}(L)$ of node i is defined as the number of links in L attached to i. The external degree of a node is obtained by

subtracting the internal from the total degree: $k_i^{\text{out}}(L) = k_i - k_i^{\text{in}}(L)$. External degrees k_i^{out} are weighted with subgraph membership-grade k_i^{in}/k_i of boundary node i to obtain a measure of external connectivity of link set L:

$$\sigma(L) = \sum_{i=1}^{n} \frac{k_i^{out}(L) k_i^{in}(L)}{k_i} \quad (1)$$

where n is the number of all nodes. The sum can be restricted to boundary nodes because only for boundary nodes of L is $k_i^{\text{out}} k_i^{\text{in}} > 0$. A simple size normalization that accounts for the finite size of the network is achieved by adapting the ratio cut suggested by Wei and Cheng (1989) for link communities, which leads us to the cost function *ratio node-cut* $\Psi^*(L)$:

$$\Psi^*(L) = \frac{\sigma(L)}{k_{in}(L)(1 - \frac{k_{in}(L)}{2m})} \quad (2)$$

where m is the number of all links and $k_{in}(L)$ is the sum of all internal degrees $k_i^{\text{in}}(L)$. $\Psi^*(L)$ essentially relates external to total connectivity of link set L. It can be used to identify link communities (sets of links that are well connected internally and well separated from the rest of the graph) by finding local minima in the cost landscape.

Since the cost landscape is often very rough—has many local minima that sometimes correspond to very similar subgraphs—the resolution of the algorithm must be defined by setting a minimum distance (number of links that differ) between subgraphs corresponding to different local minima. We define the range of a community as the environment in which no subgraph exists that has a lower Ψ^* value. For our experiments with the citation network of astrophysical papers we set a community's minimum range at one third of its size.

Algorithm: The cost function Ψ^* is used in a clustering algorithm that grows communities from seeds. This approach fulfils two more principles derived from our definition of a topic. The independent construction of each community prevents a size bias of the algorithm and enables pervasive overlaps.

```
choose a connected subgraph as a seed
initialize population P by mutating the seed with high variance several times and adapt mutants
while the best community is not too old do
    mutate the best community with low variance and adapt the mutants
    if a mutant is new and its cost is lower than highest cost then
        add it to population P
    end if
    cross the best community with other communities and adapt the offspring
    if offspring is new and its cost is lower than highest cost then
        add it to population P
    end if
    select the best individuals so that the population size remains constant
    if there is no better best community for some generations and innovation rate is low then
        renew the population (mutate the best community with high variance and adapt it)
        select the best individuals so that the population size remains constant
    end if
end while
```

Figure 1. Pseudocode of memetic evolution.

The task of finding communities in large networks is always very complex and requires the use of heuristics. We chose a memetic algorithm that accelerates the search by combining non-deterministic evolution with a deterministic local search in the cost landscape (Neri,

Cotta, & Moscato, 2012). In our algorithm, populations of subgraphs evolve because after a random initialization of a population of some definite size, the genetic operators of crossover, mutation, and selection are repeatedly applied (Fig. 1). Each crossover and mutation is followed by a local search.

Data

The algorithm is applied to the citation network of 14,954 papers published 2010 in 53 journals listed in the category Astronomy & Astrophysics of the Journal Citation Reports 2010 (the journal *Space Weather* with 45 articles was accidentally left out). We downloaded all articles, letters and proceedings papers from the Web of Science. Reference data had to be standardised with rule-based scripts. To reduce the complexity of the network, we omitted all sources that are cited only once because they do not link papers and their removal should not unduly influence clustering. We excluded 184 papers that are not linked to the giant component of the citation network and proceeded with a network of 119,954 nodes that are connected by 536,020 citation links. We neglected the direction of citation links and analysed an undirected unweighted connected graph.

Experiments and Preliminary Results

Constructing the seed population

Since topics can assume all possible sizes, the algorithm should start from differently sized seed graphs. In our experiments, we combined two strategies for obtaining seeds. First, we used Ward clustering with a similarity measure derived from theoretical considerations (Gläser, Heinz & Havemann, 2015). We ordered all hard clusters by their stability (the length of their branch in the dendrogram) and selected the most stable but not too large clusters (a total of 63) as seeds. In addition, we used the citation links of 969 randomly selected papers as seed graphs.

Each seed was first adapted by a local search and then used to initialise the population of 16 different communities by mutating the seed with a variance of 15%.

Owing to the randomness of the evolutionary mechanisms the choice of seed graphs is unlikely to affect the clustering results. However, it is likely to effect the efficiency of the algorithm.

Running the memetic algorithm

Up to ten experiments were run with each seed. The standard mutation variance in each experiment was 5%, i.e. up to 5% of the nodes were randomly exchanged. The variance was increased to 15% for one mutation if Ψ^* values did not improve for 10 generations. Again, we assume these parameters to effect the algorithm's efficiency rather than its outcomes.

Table 1. Examples of experiments with the memetic algorithm.

Community	*Seed sub-graph*		*Number of generations*	*Community*		*Remaining nodes from seed*
	Size	*Ψ* value*		*Size*	*Ψ* value*	
1	13,469	.0692	339	10,586	.0339	10,380
2	19,697	.1174	233	35,159	.0397	18,860
3	35	.4075	232	33	.0047	0
4	76	.5498	203	28	.0975	0

Experiments with the seeds described above resulted in a total of 3,944 distinct communities, 1,375 of which were disregarded because there were better communities within a distance of

less than one third of their size. The remaining 2,569 communities were ordered by increasing Ψ^* values. Table 1 provides exemplary descriptions of some of the experiments. We then calculated the relative coverage of the network as a function of Ψ^* by successively uniting the *L*-sets of the ranked communities. Relative coverage is the ratio of the union's size to the number of all links *m* (Fig. 2). This function has a sharp bend at Ψ^*=0.10458, shortly below maximum coverage. We used this Ψ^* value as cutoff point, which gives us a preliminary result of 154 communities that cover 98.9 % of all links.

Currently, each of these 154 best communities is used as a seed for a refined local search that adds or removes single links instead of nodes with all their links. For some of the 154 communities this additional local search has already led to better communities.

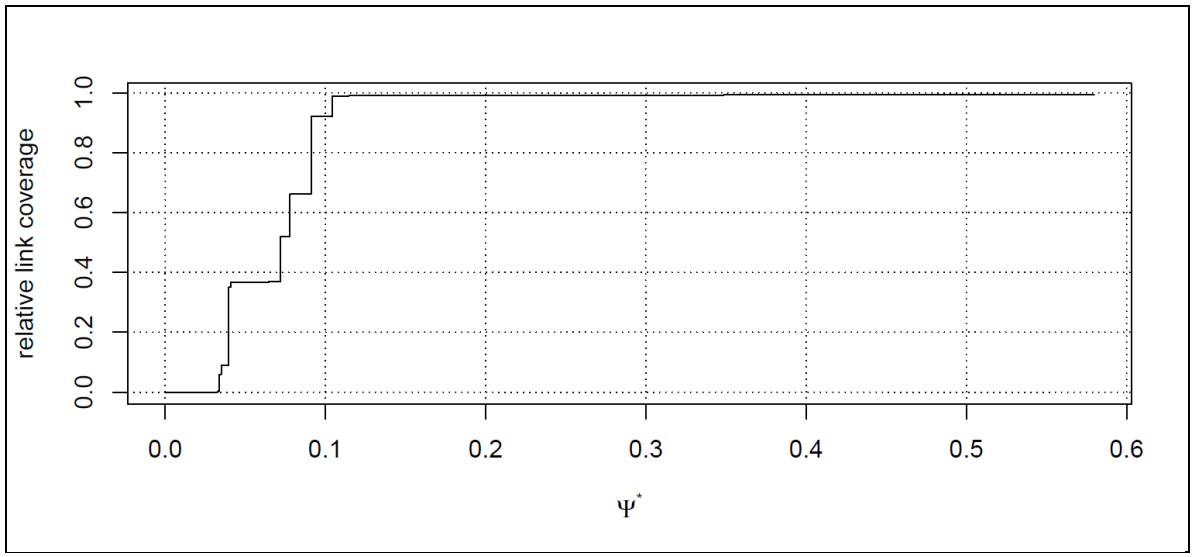

Figure 2. Relative coverage of the network by communities as a function of a Ψ* threshold.

Preliminary results

The 154 communities vary in their size between 9 and 49,324 nodes. Some of the communities overlap pervasively. Seventy communities were not a subset of any other community. The other 84 communities were subsets of one (12 communities) to 28 other communities (1). In Figure 3 we plot sizes and cost of the 154 best communities. Blue circles represent communities that are subsets of others. Green circles represent communities that overlap with another community in 95% of their nodes. All other communities are represented by red circles. The numbers in four circles refer to the communities described in Table 1.

The communities form a poly-hierarchy because some smaller communities are subsets of two larger communities that have no hierarchical subset relation. A community can also have a rest of nodes which are not members of any of its sub-communities.

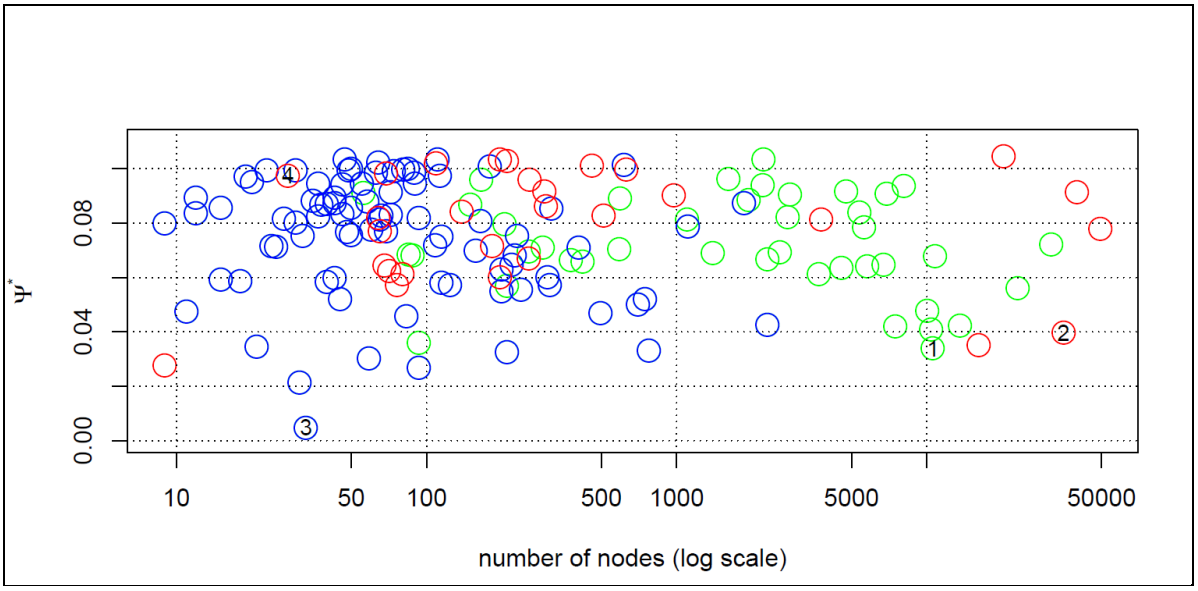

Figure 3. Sizes and Ψ* values of a set of communities covering 98.9% of the graph.

Conclusions

The communities have the structural properties of topics that were derived from the definition. Comparisons with other cluster solutions and tagging of communities will show whether the communities are consistent. We will test the dependence of results on parameter and seed choice with a smaller network. Ultimately, only a discussion with experts can show whether the communities obtained provide one of the possible scientifically meaningful cluster solutions of the astronomy and astrophysics dataset.

Acknowledgments

The work published here was funded by the German Research Ministry (01UZ0905). We thank Andreas Prescher for programming a fast C++-based R-package for parallel node-wise memetic search in the Ψ^* - landscape.

Abstract
Citation analysis is used in research evaluation exercises around the globe, directly affecting the lives of millions of researchers and the expenditure of billions of dollars. It is therefore crucial to seriously address the problems and limitations that plague it. Central amongst critiques of the common practice of citation analysis has long been that it treats all citations equally, be they crucial to the citing paper or perfunctory. Weighting citations by their value to the citing paper has long been proposed as a theoretically promising solution to this problem. *Re-citation analysis* proposes to tune out the large percentage of perfunctory citations in a paper and tune in on crucial ones when performing citation analysis, by ignoring uni-citations (mentioned just once in a paper) and counting and analyzing only re-citations (used again and again in a citing paper). By focusing on core connections in knowledge networks, re-citation analysis can help research evaluation become more sensitive to the distinction between essential and perfunctory impact of research. It may benefit citation-link based knowledge representation and retrieval systems with improved precision by better capturing "aboutness" of articles, the essence of subject indexing in knowledge representation and retrieval, rather than merely providing "relatedness" information.

Conference Topic
Theory; Methods and techniques

Introduction
Citation analysis is used in research evaluation exercises around the globe, directly affecting the work and lives of millions of researchers and the expenditure of billions of dollars. It is therefore crucial to seriously address the problems and limitations that plague it. Central amongst critiques of the current practices of citation analysis has long been that it treats all citations equally, be they crucial to the citing paper or perfunctory. This problem is especially serious when tracing or assessing research impact.

Weighting citations by how they are used in the citing paper has therefore long been proposed as a theoretically promising solution to this problem, but in practice it has not been studied closely at a large scale until recently. Increasingly available digital full-text documents and advances in text processing technologies are now making it feasible to conduct large-scale studies on citation counting weighted by in-text citation frequency, location or context. As a result, interest in this type of studies is growing.

Re-citation analysis as defined here may be viewed as a large sub-class of the class of in-text frequency weighted citation analysis schemes, a class which has recently been found to be the most effective one among many features of in-text citations at characterizing essential citations (Zhu, Turney, Lemire, & Vellino, 2014). We discuss in this paper why we consider re-citation analysis a promising method for improving citation analysis for research evaluation, knowledge network analysis, knowledge representation and information retrieval.

Weighted Citation Counting

Citation analysis examines citation patterns and networks in the scholarly literature through statistical analysis and network visualization. It is applied widely in the social sciences to trace knowledge flows, to evaluate research impact, to study the characteristics of scholarly communities and knowledge networks, and to create citation link based knowledge representation and retrieval systems (Borgman & Furner, 2002; Hall, Jaffe, & Trajtenberg, 2005).

The basic assumption underlying citation analysis is that a citation represents the citing author's use of the cited work, and that it therefore indicates that the citing and cited works are related in subject matter or methodological approach (Garfield, 1979; White, 1990). The total number of citations that a document or any aggregate of documents (e.g., author oeuvre, journal) receives (or a score derived from it, e.g., h-index) is therefore used to assess its impact on research in research evaluation. Citation links are used to signify knowledge flow from the cited to the citing group and, along with scores derived from these links, to measure the relatedness between documents or their aggregates in the study of knowledge networks and in the representation and retrieval of related documents.

The assumptions of citation analysis are believed to be in line with Merton's normative view of science (Garfield, 1979; Merton, 1942; White, 1990). Like other activities of science, citation behaviour is assumed to be governed by a set of norms which require authors to cite documents that have influenced them in developing their current works in order to give credit where credit is due (Edge, 1979; Griffith, 1990; Peritz, 1992; Tranöy, 1980). Although citations for reasons other than giving due credit do exist (Cronin, 1984; Edge, 1979), citation analysis has generally been found to produce valid results because it is based on a statistical analysis of the collective perceptions of large numbers of citing authors, most of whom do adhere to the norms most of the time (Small, 1977; White, 1990). This is especially true with citation network analysis and citation link based knowledge representation and retrieval, as even non-normative citations will not refer to unrelated works.

Researchers do cite for various reasons and citations do serve many different functions in citing papers, however (Brooks, 1985, 1986; Case & Higgins, 2000; Chubin & Moitra, 1975; Liu, 1993; Moravcsik & Murugesan, 1975; Shadish, Tolliver, Gray & Sengupta, 1995; Vinkler, 1987). Small (1982), for example, identified five typical distinctions in citation classification schemes: (1) negative or refuted, (2) perfunctory or noted only, (3) compared or reviewed, (4) used or applied, and (5) substantiated or supported by the citing work.

The importance of weighing citations by their role in the text has therefore long been recognized (Herlach, 1978; Narin, 1976). In recent years, with increasingly available digital full-text documents and advances in technologies for text processing, interest in studying weighted citations has finally picked up. Studies have experimented with weighing citations by the frequency with which they are referred to in the text (e.g., Ding, Liu, Guo, & Cronin, 2013; Hou, Li, & Niu, 2011; Zhu, Turney, Lemire, & Vellino, 2014), by the citation impact of citing papers (Ding & Cronin, 2011), or by the location and context in which they are cited (Boyack, Small, & Klavans, 2013; Jeong, Song, & Ding, 2014). It has been found that frequency-weighted citation ranking can outperform traditional citation ranking of top authors, and that in-text citation frequency was the best of many other full-text features to help spot citations that were considered crucial to the citing papers by their authors, at least in a hard science field studied (Zhu, Turney, Lemire, & Vellino, 2014).

Depending on what functions they serve in a given citing paper, citations likely appear more or less frequently there: perfunctory ones once only, negative or contrastive ones a couple of times, and used or substantiated ones many times. By weighing citations by their frequency of appearance in a scholarly paper, it is hoped that essential citations could be assigned greater weight than perfunctory ones so that citation analysis can focus on the more profound

influences and on organic relationships. If so, this could improve traditional citation analysis significantly as a high incidence of perfunctory citations has been observed (Small, 1982). For example, Teufel, Siddharthan, & Tidhar (2006) found that only a fifth of the references are essential for the citing papers, and Moravcsik & Murugesan (1975) noted that 40% references were perfunctory, frequently simply copied from other papers without ever having been read (Dubin, 2004).

Re-citation analysis: motivation and innovation

Perfunctory citations can thus be considered a serious source of noise if the signal that one wants to detect is the direct and substantial flow of knowledge in the literature. There are two obvious types of approaches to dealing with this problem: (1) to amplify the signal or (2) to filter out the noise. The ultimately best approach is likely some combination of the two. All frequency-based weighing schemes studied so far used the former approach by assigning a weight based on the in-text citation frequency such as assigning a weight of N or N^2 to a citation that appears N times in a citing paper.

By contrast, re-citation analysis, a concept we introduced recently (Zhao & Strotmann, 2015), uses the latter approach: it attempts to filter out perfunctory citations from the analysis by removing uni-citations (i.e., documents referenced only once in the text of a work) in order to analyze only re-citations (i.e., references that appear more than once in the text of a citing paper). The degree to which a cited work is used or has impacted research can be further differentiated by assigning weights to different re-citation frequencies. Re-citation analysis can thus combine the noise filtering and signal amplification approaches, offering the potential to find an optimal weighing scheme for in-text citation frequency.

Thus, the fundamental difference between re-citation analysis and all other frequency-based weighing schemes and hence the innovation of re-citation analysis is that the former attempts to make the fundamental qualitative distinction between those citations that represent real use by, or core impact on, the citing paper (which it tends to retain for analysis) and those that are merely mentioned in passing as related work that the author is aware of but did not directly rely on (which it tends to remove). The basic assumption of re-citation analysis is that papers are very likely to be cited again and again in a publication that relies heavily on them, while perfunctory citations should appear once only in a citing paper almost by definition.

Re-citation analysis can also avoid potential technical problems associated with simply amplifying multi-citations. Since the noise created by perfunctory citations is very strong (40% or more), the signal amplification required to counter it tends to be so strong that it can cause serious distortions. For example, Zhao & Strotmann (2015) found that a simple weight of N does not suffice to make non-perfunctory citations stand out. N^2 is the minimal power of N that fulfills this requirement, but tends to be seriously affected by ultra-meticulous in-text citing styles of a few authors as it overweighs high in-text frequencies. Weighing re-citations avoids this problem.

Promises of Re-citation Analysis

Re-citation analysis can be expected to contribute significantly to the theory and methods of citation analysis. It addresses head-on an old and fundamental concern with citation analysis, especially with evaluative citation analysis. By proposing to filter out the strong noise caused by a high incidence of perfunctory citations rather than simply amplifying multi-citations, it also opens up a new way of thinking about weighing citations at a time when the study of weighted citation counting based on full-text analysis is still in its infancy.

Re-citation analysis is promising in improving citation analysis for research evaluation, knowledge network analysis, knowledge representation and information retrieval.

- Evaluative citation analysis ranks authors, journals, institutions or other components of the scholarly communication system by their citation counts or by derivative scores such as the h-index. Scores based on re-citation counting can be expected to boost those researchers or groupings whose publications receive close scrutiny and to introduce a bias against those whose work mainly provides convenient background information. Such re-citation metrics should thus be better at measuring research impact than traditional citation metrics.
- In citation-based knowledge network analysis and visualization, results based on re-citations can be expected to be significantly more detailed and "crisp" than those based on citations since re-citation based relations (e.g., direct re-citation, co-recitation, or re-citation coupling) should represent core relationships where citation-based relations include many peripheral ones. The price might be an underestimation of interrelatedness between distant parts of a science map.
- For information retrieval (IR), re-citation based similarity metrics can likely provide a considerably enhanced precision of the "Similar documents" or "More like this" feature that many IR systems provide nowadays, compared to citation-based ones. The latter can be expected to show better recall, however, so that a (weighted) combination of the two may work better than either one alone.
- For knowledge representation, it is well understood that citations in scholarly publications serve as concept symbols (Small, 1978). One would expect the presence of a certain set of citations in a paper to translate fairly straightforwardly to the assignment of that paper to a specific subject category. However, subject categories are meant to capture the paper's "aboutness", but a large percentage of citations merely provide "relatedness" information. We suspect that re-citations, on the other hand, do correspond to a considerable degree to concept symbols with an "aboutness" semantics. A re-citation based form of computer-aided subject indexing might therefore be feasible.

Re-citation analysis may thus have a profound impact on the future of the scholarly communication system and of Scientometrics as re-citation analysis values and thus encourages research that is worth following in depth, whereas traditional citation analysis has encouraged review publications that tend to be cited widely.

Finally, as they rely on access to the full text of scholarly publications rather than on citation databases such as Web of Science and Scopus, re-citation analysis methods and metrics are as easily available to the study and evaluation of the social sciences and humanities as to that of the natural and life sciences. Unlike the latter, the former have never been treated fairly by traditional citation analysis due to the insufficient coverage of their literature by these databases.

Topic Affinity Analysis for an Astronomy and Astrophysics Data Set

[1]Theresa Velden, Shiyan Yan, and Carl Lagoze

tvelden@umich.edu, shiyansi@umich.edu, clagoze@umich.edu

Abstract
In this paper we map the affinity between topics extracted from a body of literature published in Astronomy and Astrophysics journals between 2003-2010. The topics are extracted using the popular information theoretic Infomap clustering algorithm (Rosvall & Bergstrom, 2008) iteratively on the giant component of the direct citation network constructed from the data. The affinity network shows what topics are disproportionally well connected (by citations) to other topics. The topology of the network highlights a large division into astrophysics versus astronomically oriented publications. Bridging between those two domains is a population of smaller topics. Going forward, we plan to create and analyze topic affinity network maps for alternative solutions to the topic extraction challenge on that same data set that are produced by our colleagues and that will be discussed and compared at the proposed special session on 'Same data? Different results? The performative nature of algorithms for topic detection in science' at ISSI 2015. We expect that topic affinity mappings will help to examine the nature of differences between different topic extraction solutions.

Conference Topic
Methods and techniques (special session on algorithms for topic detection)

Introduction
The mapping of research topics and collaborative ties in scientific research fields (Morris 2008) is flourishing for a number of reasons. Increasingly, scholarly publications and their metadata are available from a variety of sources (digital libraries, institutional and disciplinary repositories, along with bibliographic abstracting services such as the long established Web of Knowledge and more recently, Scopus). Complementing this is the emergence of sophisticated algorithms for the analysis of complex networks (Newman 2003b) and the wide availability of advanced user-friendly network analysis and visualization tools like pajek, gephi, or VOS Viewer.

However, many different algorithms for community extraction and topic detection exist and offer different suggestions what the most prominent groupings of publications or authors may be. The special session at ISSI 2015 sets out to systematically compare and evaluate the origin, extent, and implication of differences between topic extraction methods. In this paper we describe the results of our approach to topic detection and topic affinity analysis to the shared 'astronomy and astrophysics' data set. This approach has emerged from research program on studying behavioral patterns in scientific communities and comparing them across fields, and may help to shed light on the nature of differences between topic extraction solutions.

Background
As described in (Velden 2009), we take a mixed method approach to studying field-specific practices and cultures of scientific communities, integrating ethnographic field studies with network analytic methods. The network analytic method we apply here to the 'astronomy and astrophysics' data set is part of an ongoing effort to combine network analytic with ethnographic methods (Velden, Haque & Lagoze, 2010; Velden, 2013). This evolves a tradition of close-up analysis of scientific networks and communication practices started by Crane's work (1972) on invisible colleges and taken up more recently by Zuccala (2006).

Scientific research specialties are a complex social and cognitive phenomenon. Sociologically, they can be characterized as collective production communities that emerge from the indirectly coordinated activity of autonomous actors (research groups) who aim to contribute to a shared knowledge base (Gläser, 2006; Velden, 2013). Therefore, the combined analysis of social and cognitive structures is of particular interest (Ding, 2011). In our work we achieve this in two steps: first by algorithmically extracting major research topics in a research specialty from the direct citation network and generating an affinity network that shows what topics are disproportionally well connected through citations to other topics. In a second step, we overlay the topic information on the group collaboration network (Velden, Haque & Lagoze, 2010) extracted from the co-author network of the research specialty. The resulting maps show how collaborative ties connect groups active in a particular topic area. This paper reports work in progress. At this point, we have produced and analyzed the topic affinity network. Producing the overlay with the group collaboration network will be one of the next steps.

Method

Our approach to topic extraction and topic affinity analysis is discussed in detail in Velden (2013). Below we briefly review the relevant details for the analysis reported in this paper.

Data

The data set used in this study includes papers published 2003-2010 in 59 astrophysical journals indexed by Web of Science. By accepting only documents of type 'Article', 'Letter', and 'Proceedings Paper', the data set comprised the bibliographic data of 111,616 publications.

Network construction

Various citation-based approaches have been used in the past to detect topics in research fields. These include bibliographic coupling, co-citation and direct citation, including or excluding citation environments. The advantages and disadvantages of these approaches have been discussed in Boyack (2010). We base our topic extraction on the direct citation network.

Clustering

We use the Infomap clustering algorithm (Rosvall & Bergstrom, 2008) twice to iteratively extract clusters of clusters of documents. The repeated clustering is necessary to obtain sufficiently large entities (topics) for further visual inspection and analysis. In the resulting topic network, nodes represent clusters of publications based on the direct citation links between them.

Topic affinity network

We evaluate the strength of citation links between topic areas relative to a null model that assumes a random distribution of citation links proportional to topic area sizes. Hence, the existence of a link between topics in the affinity indicates a surplus of connectivity between the two topic areas in question, whereas the absence of a link may either mean 'normal' (random) background connectivity or a negative affinity value ('antagonism').

The affinity between a source topic area and a target topic area is calculated as shown in Figure 1 below.

Assume:
A_{11-i}: Top 11 Areas expect area i
$N_{p(j)}$: Number of papers in topic area j
C_{ij}: Number of Citation from topic area i to topic area j

We define the citation based affinity A between two topic areas i and j as the residual:

$$A_{ij} = \frac{\text{Actual Count}_{ij} - \text{Expected Count}_{ij}}{\sqrt{\text{Expected Count}_{ij}}}$$

where:

$$\text{Actual Count}_{ij} = C_{ij}$$

$$\text{Expected Count}_{ij} = \frac{N_{p(j)}}{\sum_{k \in A_{11-i}} N_{p(k)}} \times \left(\sum_{k \in A_{11-i}} C_{ik}\right)$$

Figure 1. Affinity between a source topic area and a target topic

Topic affinity as defined here is a relative property. It expresses the relative preference for documents in one topic area to cite documents in another area given the choice of topic areas included in the data set and in the affinity calculation. Theoretically, the relative affinity to document clusters outside the set of topic areas selected for this analysis or even outside of the data set (external citations) could be greater than to the ones in the set.

Topic Labeling

To support the interpretation of the resulting topic affinity network, we use a semi-automatic approach to labeling topic areas. To this end, we analyze the frequency of journals that the documents in each topic area are published in. Using a measure based on the concept of *term frequency - inverse document frequency (tf-idf)* to combine popularity with distinctiveness of a journal title within the data set, we produce a ranked list of the 15 most popular journals in each topic area. From those journal titles we then derive labels that typically reflect sub disciplinary orientation of topic areas. A more detailed and specific identification of topic area content either algorithmically or through expert evaluation or would be desirable.

Results

The topic extraction from the giant component of the direct citation network results in 22 document clusters ('topics'). For pragmatic reasons, to support interpretation of the visualized network, we include only the largest eleven topic areas in the affinity network. Given the uneven size distribution of clusters (Fig. 1), these largest clusters account for the large majority of publications in the giant component of the direct citation network, namely 84% (see Table 1 for details on the sizes of various network components).

Table 1. Properties of direct citation network.

	# of nodes (documents)	**% of network**	**% of giant component**
entire network	111,616	100	N.A.
giant component	101,831	91.2	100
11 largest topic areas	85,562	84.0	76.7

The topic affinity network for the largest 11 document clusters is shown in Figure 2. The most striking topological feature regards the relationship between the three largest topics. Notably,

topic 3 (Astronomy/Solar System) is not directly connected with the other two topics, topic 1 (Astronomy/Astrophysics) and topic 2 (Gravitational Physics, Cosmology). Topic 2 has a strong directed link to topic 1, indicating that it borrows disproportionally from the literature in topic 2. Topics 1 and 3 are indirectly linked, via small, astronomically oriented 'proxy topics', essentially topics 7 and 9, and to l lesser degree topics 10 and 11. However, there exists only a very faint indirect affinity link between topic 2 and topic 3, via topic 11.

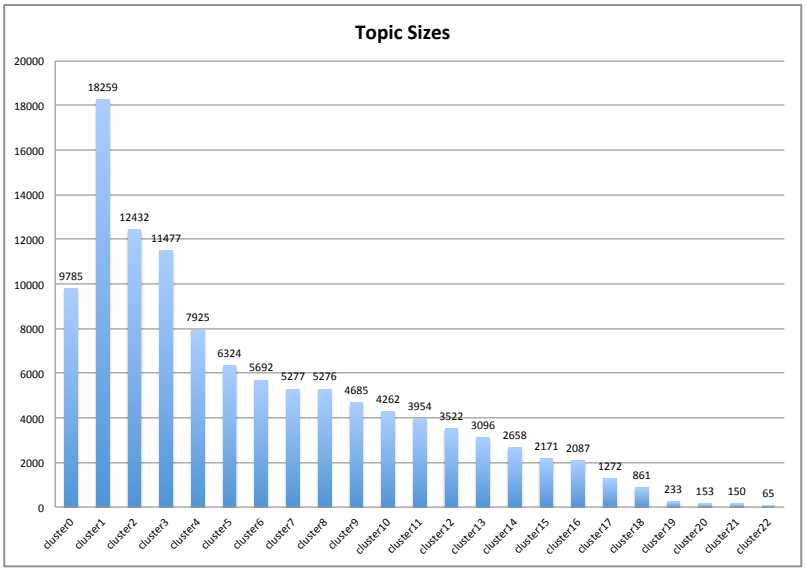

Figure 1. Sizes of the 22 document clusters ('topics') that constitute the giant component of the direct citation network. Cluster '0' shows the number of documents not included in the giant.

Discussion

Based on our own, if limited, expertise in this larger domain of research, we would offer the following speculations about the interpretation of the tripartite structure of the current 2003-2010 literature in the astronomy and astrophysics data set that is suggested by the topology of the affinity network in figure 2. The literature is subdivided into three large domains, with distinct research focus, namely astrophysics - the quest for developing a theoretical understanding of physical and chemical properties of celestial bodies (topic 1), gravitational physics - the quest for understanding the workings of gravitational forces in the universe (topic 2), and planetary science - the quest for understanding the composition, dynamics and history of planets and solar systems (topic 3). As reflected by the affinity network, in the 2003-2010 period, the three domains rely to varying degrees on astronomical observation; this is least the case for gravitational physics. An interesting open question is to what degree the observational astronomy literature has been integrated through citations into these larger topics rather than being identifiable as separate topics. The topic affinity network further underlines that whereas there are strong connections between astrophysics and gravitational physics (such as the role of gravitational forces in the formation of black holes and the puzzle of the nature of black matter), the cognitive links between gravitational physics and planetary science are weak.

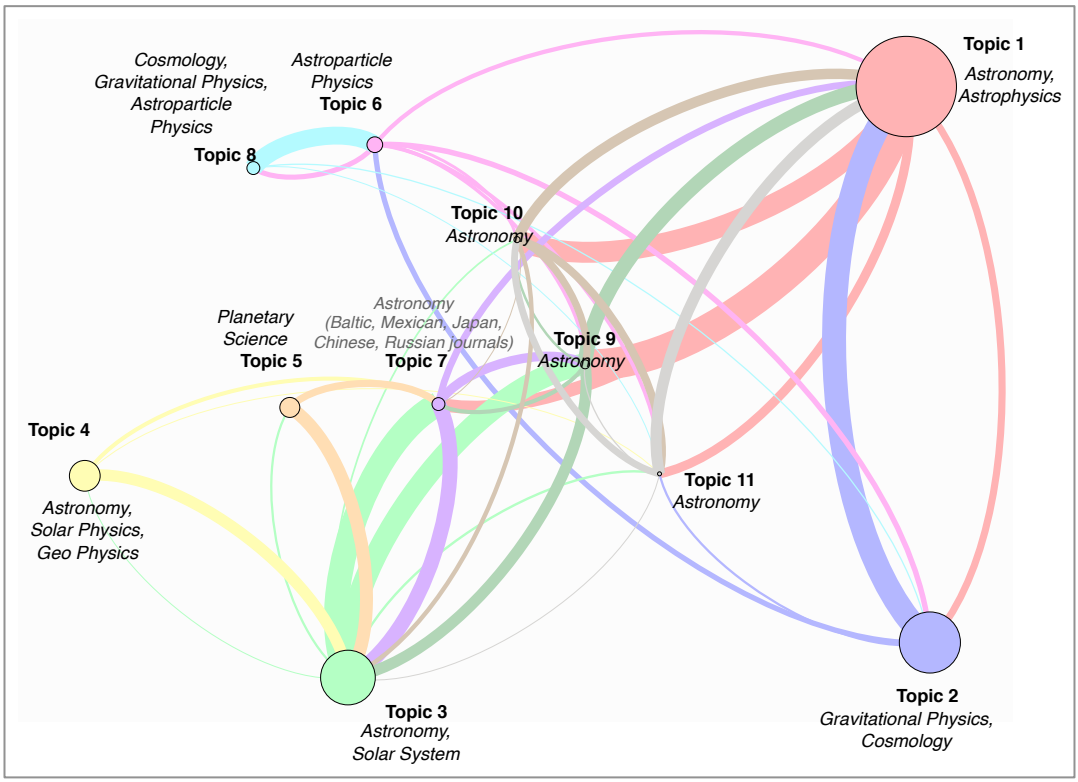

Figure 2: Topic affinity network. Node size indicates number of documents. Link strength indicates relative preference given by publications in one topic to cite publications in another. Links are directed: they are colored by their source node and curve clockwise away from it.

To further validate these hypotheses, a review of the topic contents and interpretation of the topic affinity links by experts could be insightful. Further, an extension of the data set backward in time to show the temporal evolution of affinity links could be informative. This would allow matching the evolution of affinity links over time to reports by experts about major research developments in this domain that may affect the interlinking between topics. One challenge in such an undertaking is that not just the linkages between topics evolve over time, but so does the identity of topics itself.

Conclusions

The topology of the affinity network highlights cognitive links between the topics extracted by our method from the astronomy and astrophysics data set. The interesting question in the context of the special session on the comparison of topic extraction algorithms will be what other cognitive features of this literature will be highlighted, if the affinity network is constructed for alternative groupings of documents into topics produced by other topic extraction algorithms. We suggest that this method of investigating the nature of differences between alternative topic extraction results is useful, in particular for cases where the topic size distribution is such that the large majority of documents, 80-90% is concentrated in 10-30 topics. For more granular topic extraction results the affinity network visualization is likely to become too unwieldy to interpret.

Time & Citation Networks

Abstract
Citation networks emerge from a number of different social systems, such as academia (from published papers), business (through patents) and law (through legal judgements). A citation represents a transfer of information, and so studying the structure of the citation network will help us understand how knowledge is passed on. What distinguishes citation networks from other networks is time; documents can only cite older documents. We propose that existing network measures do not take account of the strong constraint imposed by time. We will illustrate our approach with two types of causally aware analysis. We apply our methods to the citation networks formed by academic papers on the arXiv, to US patents and to US Supreme Court judgements. We show that our tools can reveal that citation networks which appear to have very similar structure by standard network measures, turn out to have significantly different properties. We interpret our results as indicating that many papers in a bibliography were not directly relevant to the work and that we can provide a simple indicator of the important citations. We suggest our methods may highlight papers which are of more interest for interdisciplinary research. We also quantify differences in the diversity of research directions of different fields.

Background
Bibliometrics has a long tradition of dealing with citation networks from a network point of view as Price's model (Price, 1965) shows. The recent explosion of interest in network analysis in other fields has led to development of existing methods and introduced many new techniques. However most network methods assume static graphs where time plays no explicit role even if the underlying data is almost always evolving. Time can be incorporated into a network representation in two main ways. If we assign a single time to each edge we have a *Temporal Edge Network*. Such networks have received considerable attention (Holme & Saramäki, 2012). For instance they form a useful representation for the pattern of communications between individuals. Alternatively in *Temporal Vertex Networks* each node carries a single time. The citation network provides a natural example of the latter as each paper has its publication date. Here then we will focus on the analysis of this second type of temporal network, using the bibliometric context of citation networks to motivate our work.

The causal structure of citations plays a central role in bibliometric analyses. At the simplest level understanding the different time scales for citation patterns seen in different research fields is known to be essential. In Price's model (Price, 1965) vertices appear in a fixed order, reflecting the order of publication of real citation networks. Price's model captures the essential nature of a citation; they are always from newer to older papers. Applying Price's growing network model to other contexts where time plays a different role makes no sense e.g. links between web pages are not constrained by the age of a web site.

The constraints imposed by time are very different from the spatial constraints. Network science has few tools specifically developed to work with temporal vertex networks. However as part of our work we adapt results found in other areas: discrete mathematics, quantum gravity, and in computer science. Bibliometrics asks very different questions about such networks so applying these ideas is not always straightforward.

Our hypothesis is that existing network measures do not account for the constraint of time. So we have embarked on a programme to develop new temporally aware network measures and to prove their utility in the context of citation networks.

Methods and Data

Our networks are defined such that each node has a unique time. Edges can only exist from a younger to an older node, see Figure 1. Citations between academic papers are a good example, patents and court rulings have similar citation structures. All edges are directed, but the arrow of time also ensures that such networks will have no loops (acyclic) provided you follow the direction of the edges. The formal name for such a network is a *Directed Acyclic Graph* or *DAG* for short.

In practice, citation data is not exactly a DAG but we found that citations in the 'wrong' direction form less than 1% of our data so they should have a limited effect on any conclusions. We construct a true DAG by dropping any such acausal citations.

We have used a variety of data sets in our work (Clough et al., 2015, Clough & Evans, 2014). We have used citation information on the arXiv repository taken from two independent different sources. This allows us to check that our results are robust against any differences in citation extraction. First we use the KDD cup data (2003) which covers the first ten years of the hep-ph and hep-th sections (theoretical and phenomenological particle physics respectively). We have also looked at a separate version which covers all sections of arXiv up to 2013 which was derived from paperscape.org they also form a citation network.

We have also studied the citation network of around 4,000,000 US patents between 1975 and 1999 (Hall, Jaffe, & Trajtenberg, 2001). Finally we worked with the network defined by about 25,000 judgements of the US Supreme court 1754 to 2002 (Fowler & Jeon, 2008).

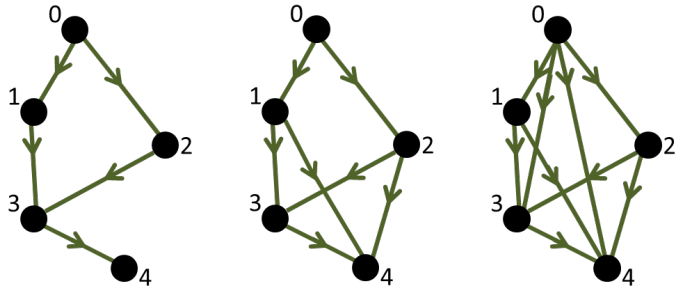

Figure 1 The unique transitively reduction (left) and transitive completion (right) of the citation network (a Directed Acylic Graph or DAG) shown in the centre. All casual relationships implied by an edge in the central network appear as an explicit edge in the right hand network. The edges in the left hand network are the least required to capture all these causal relationships.

Transitive Reduction (TR)

Our first example of a network operation, which takes account of the constraint of time, is Transitive Reduction (*TR*). In TR, links are removed provided that they leave the connectivity of every pair of nodes unchanged. That is if there was a path between a given pair of nodes (respecting the direction of the links) before TR, there will still be at least one such path after TR. This process can be defined on any network but for DAGs it is guaranteed to produce a unique result, see Figure 1. Algorithms for this procedure are well known in computer science but we found basic implementations in python were sufficient even for our largest networks (Clough et al., 2015)

Once we have this essential causal core of our citation network we illustrate our approach with two simple measures: the fraction of edges lost in the TR process and a comparison of the citation count of papers before and after TR.

Dimension

In bibliometrics, we often place papers in different fields as there is great interest in understanding the relationships between topics, as illustrated by maps-of-science (such as

Börner et al., 2012). It is natural to ask if we can assign a sense of dimension to such 'topic' spaces. A high dimension would indicate that researchers can develop work in several independent directions, a low dimension indicates that all the work in that field is tightly linked with little independence. There are some standard ways to assign an effective dimension to a network but these all assume that all directions are similar, just as moving left/right or forwards/backwards is the same for a ball on a flat table. Unfortunately, none of the measures used in the network science literature take account of time, which is a very different sort of dimension. Given that temporal information is an essential part of the definition of a citation network, we must work with a different type of measure. Our work (Clough & Evans, 2014) draws on inspiration from work in discrete mathematics on *posets* (partially ordered sets, e.g. Bollobás & Brightwell, 1991) and from the Causal Set programme of quantum gravity (e.g. Reid, 2003).

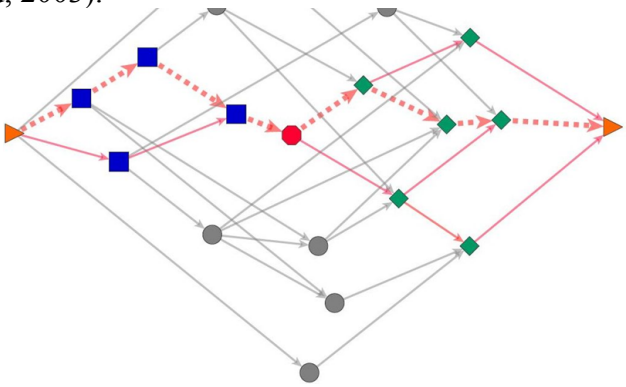

Figure 2 An illustration of the box counting method to find dimension. Here the source and the target papers (triangles at left and right respectively) define an interval of N=19 papers - the other vertices shown here. The edges represent the transitively reduced citation network of all twenty paper. The midpoint is shown as the red circle in the centre. It defines two sub-intervals N_1=4 (blue squares) on the left and N_1=6 on the right (green diamonds). This gives D=2.16 and D=1.61 as our dimension estimates. The example was generated by throwing points down with one space and one time coordinate chosen at random, i.e. D=2.

Our first approach is a simple box counting method (Reid, 2003). We first choose a pair of papers, the source and target nodes, at random. We then find the *interval* defined by the source and target nodes, which is the set of all N papers which lie on a path between source and target. As always our paths must respect the direction of time. Next we find the midpoint, a node chosen such that two sub-intervals defined by source and midpoint, and by midpoint and target nodes, are roughly equal size $N_1 \approx N_2$. It then follows that we should expect the 'length' scale of our two smaller intervals interval to be roughly half that of the large interval. Assuming papers are scattered at equal density in our data, we can use the number of points in an interval as a measure of the volume in the space-time. It then follows that the ratio of the number of points from small to large interval should scale as $N_1/N \approx N_2/N \approx 2^{-D}$. By analysing many intervals within one academic field the space-time dimension D (one time and $(D-1)$ topic space dimensions) of that field may be found.

The second method we use here is the Myrheim-Meyer dimension estimator (see Reid, 2003 for references). To do this we again pick a source and target paper. We then count the number causally connected pairs P in the interval defined by our source and sink which contains N nodes and these are related by $(P/N^2)=\Gamma(D+1)\,\Gamma(D/2)\,/\,(4\,\Gamma(3D/2))$ where $\Gamma(x)$ is the standard Gamma function. This formula is derived for a large N by assuming points are sprinkled at uniform density in Minkowskii space-time. We have also used the same approach

to show that in a different type of space, the cube box space of Bollobás & Brightwell (1991) the formula is simply $P=N(N-1)/2^D$.

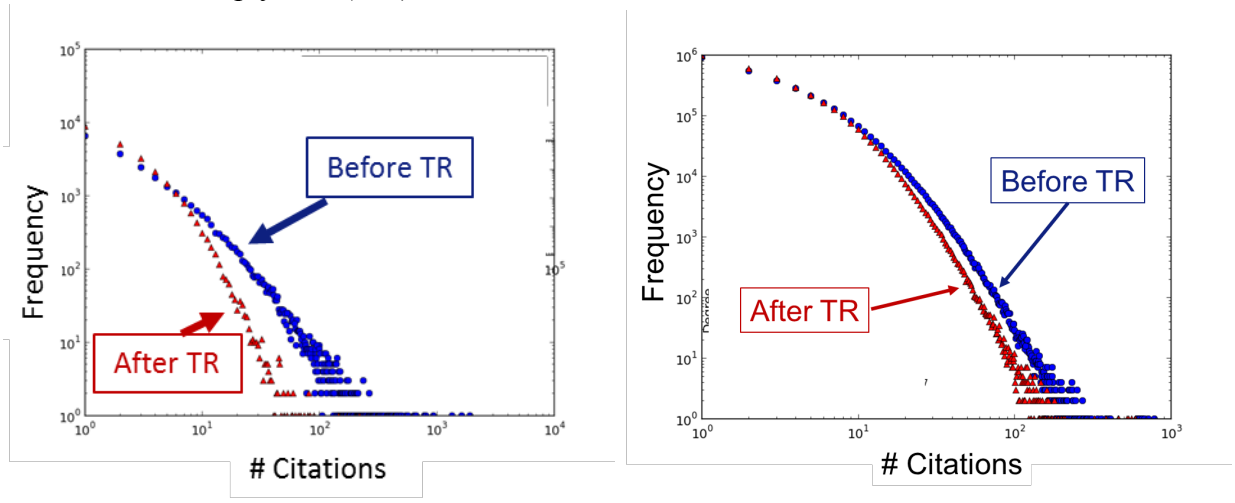

Figure 3 The citation count distribution before and after TR. On the left the results for the quant-ph section of arXiv (paperscape dataset) shows a significant change and an overall loss of around 80% of the edges. On the other hand, US patents shown on the right lose around 15% of edge and the citation distribution remains similar.

Findings

One of the most striking findings is that different types of citation network show very different behaviour under TR. All the citations networks of academic papers we have studied have shown a dramatic loss in the number of edges, typically around 70% to 80%. Further, it is the high cited papers which suffer the most as can be seen in Figure 3 for the hep-th arXiv where the citation distribution becomes noticeably steeper. On investigation it is clear that the edges which remain are those with the age difference between cited and citing papers. Interestingly citations in US supreme court judgements show a similar pattern (not shown) but US patents show only a moderate loss as shown in Figure 3.

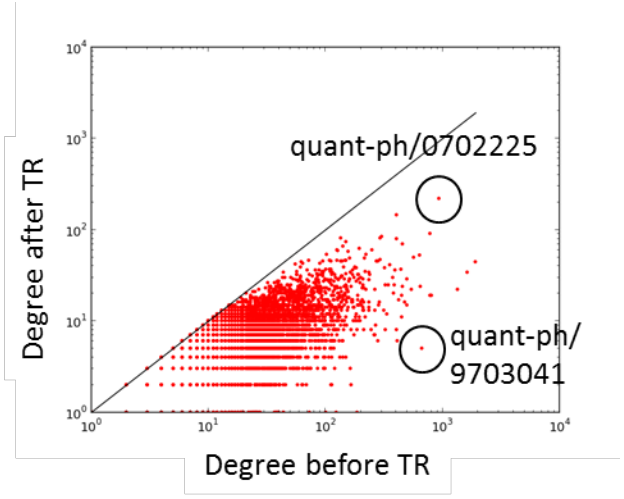

Figure 4 The citation count before and after TR for each paper in the quant-ph paperscape data.

Rather than looking at these bulk statistics we can look at the effect of TR on individual papers. Of course there are winners and losers. The example of the astro-ph arXiv section from paperscape.org highlights the different fates of two papers, see Figure 4. Paper quant-ph/9703041 (an older research paper on quantum entanglement) is one of the most highly cited papers with 664 citations yet TR shows that anyone using quant-ph/9703041 also took

information (directly or indirectly) from five other papers. On the other hand, paper quant-ph/0702225 (a more recent review of quantum entanglement) begins with a similar number of citations, 937, yet after TR it retains 219 of these.

We have also run our dimension measures on a variety of data sets. Our results are consistent whichever of the measures we use. What emerges is that we can generally give each field a well-defined dimension and that these are significantly different. For instance Figure 5 shows how papers in two parts of the arXiv repository have distinctive dimensions. For the arXiv we have found dimensions of about for hep-th (string theory), 3 for both hep-ph (particle physics) and quant-ph (quantum physics), and around 3.5 for while astro-ph (astrophysics).

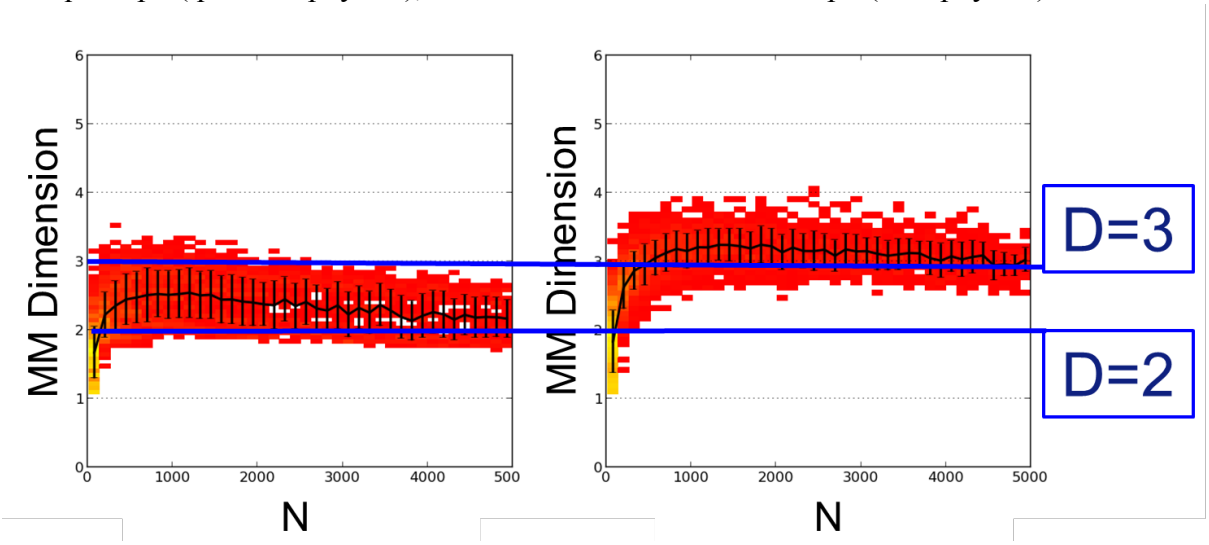

Figure 5 Dimension of two parts of the arXiv repository (KDD cup dataset) using the MM (Myrheim-Meyer) dimension estimator. Each point represents the dimension estimated from an number of intervals defined by two randomly chosen papers. On the left the hep-th section is seen to be of lower dimension than the hep-ph section shown on the right.

Discussion

For us TR captures the essential causal skeleton underlying the citation network. If information is flowing from older papers to newer papers and this is reflected in the bibliographies, then all the links in the transitively reduced network are the minimum needed for such a process. Of course in practice authors may use 'short cuts' and derive information directly from older papers, but equally such short cuts were not essential and therefore there is no reason to suppose they were important. We see TR as providing a lower bound on the actual route used by the flow of important information. To go beyond this, some sort of expensive semantic analysis is needed, be it via automatic methods or by hand.

In fact we believe the transitively reduced network may be much closer to the actual set of citations of direct relevance to a publication. We have found that around 80% of links between academic papers are removed by TR. Interestingly this matches the figure given by Simkin & Roychowdhury (2003, 2005) who suggest around 80% of citations are copied from intermediate works. Any citation which was copied will always be removed by TR.

Our suggestion is that TR could be an important way to reveal which papers were essential for the developments described in a new paper. Not surprisingly, these tend to be recent papers but it is still a surprise to find such a large fraction are removed. We have shown that there are big differences in the post-TR citation count of papers in similar fields with similar high citation counts. This could be a way to discriminate between papers and could provide an alternative basis for a recommendation system. For instance searches could be ordered by post-TR citation count. One hypothesis is that papers which retain a high citation count after

TR have been used across a wider range of topics. These are works which might be of more interest to researchers looking for papers outside their normal field of interest.

The behaviour of our patents and court citations also shows how TR can be a useful way to highlight different citation practices. The court data behaves in a way which is similar to that of academic papers with a large number of edges lost under TR. On the other hand, patents lose only a small fraction of their edges. The difference reflects the fact that for a patent, citations are a recognition of prior art, a legal necessity when writing a patent. However, as a patent is meant to be a novel development, they presumably try not to refer to earlier work so as to appear to be as different as possible from the literature. On the other hand, US Supreme Court judges seem to act like academic authors, citing older documents, which may have no direct relevance, along with the more recent documents, which have the latest distillation of this knowledge and are the real source of any innovation.

Our dimension measures again highlight difference between fields. We interpret the low dimension of the hep-th arXiv to suggest that string theory is a rather narrow field feeding off a few strands of research, at least when compared to hep-ph, quant-ph and astro-ph where research appears to be moving in a wider range of directions.

Conclusions

We have argued that citation networks require a new type of measure which takes account of the constraint imposed by time. We have given some examples of how this can be done and shown that they reveal some interesting features in real citation networks. We hope to add other measures and to improve the interpretation of our results by comparing them with non-network derived measures.

Acknowledgments

We would like to thank Damien George and Robert.Knegjens who provided us with access to their paperscape.org arXiv citation data. We also would like to acknowledge useful conversations with K.Christensen, J.Gollings, A.Hughes and T.Loach.

Abstract
This study investigates the relative power and characteristics of a set of social and epistemic terms to distinguish among disciplines of research article abstracts, using a corpus of 928,572 abstracts from 13 disciplines indexed by Web of Science in 2011. Applying the machine-learning approach to discourse epistemetrics using a sequential minimal optimization (SMO) algorithm, and a feature set of terms derived from Hyland's (2005) metadiscourse studies per Demarest and Sugimoto (2014), the current paper reports subsets of terms that best (and least) distinguish among disciplines, finding that the terms least able to distinguish among disciplines are rarely used and overwhelmingly adjectival or adverbial markers of authorial attitude, reflecting personal positioning, while terms best able to distinguish disciplines are mostly verbs frequently used as engagement markers, framing the generation of knowledge for the readership in ways that are standardized within disciplines (while varying among them). We plan to analyze the findings of the current research-in-progress from discipline-based as well as term-based perspectives, incorporating both into a two-mode network, as well as incorporating finer grained data for specific specializations to compare with the current higher-level disciplinary findings.

Conference Topic
Methods and techniques, altmetrics

Introduction
Understanding and depicting the relationships among different academic realms (whether disciplines, fields, specialisms, or a host of other divisions using some combination of social, epistemological, and institutional aspects) is a well-studied subarea of scientometric (Leydesdorff & Rafols, 2009). Initial forays into modeling disciplinary differences based on a core set of social and epistemic terms have yielded potentially promising results (Demarest & Sugimoto, 2013; Demarest & Sugimoto, 2014). However, no studies to date have used computational approaches to compare the abilities of specific social and epistemic terms to distinguish among disciplines. The current work-in-progress seeks to enact such a comparison, using a machine-learning approach to derive term differences between pairs of disciplines and by extension between a given discipline and all other disciplines under study. In finding the social and epistemic terms that best distinguish among academic disciplines, we hope to open new dimensions of analysis of the sciences through their texts.

Literature Review
There have been very few previous attempts to map the relatedness of academic disciplines based upon common social and epistemic terms. However, previous research of social and epistemic discourse usage in different academic disciplines as well as previous studies of document, journal, author, and discipline similarity or relatedness based on a variety of other measures guide the current study.

Differences in how academic disciplines employ language that positions the author in relation to the reader, the text itself, and previous scholars and works have been studied under various monikers, including stance (Biber & Finegan, 1989), metadiscourse (Hyland & Tse, 2004), appraisal (Martin & White, 2008), and attitude (Halliday, 1985). For the most part these differences have not been studied using automated quantitative methods (although cf. Argamon and Dodick, 2004), and in no cases have the resulting metrics been used as a basis for mapping the relatedness of disciplines. The current study draws upon Hyland's (2005) study of metadiscourse in a number of different disciplines, leveraging a set of words and phrases that Hyland (2005) found to be widely occurring in academic writing as our feature set for machine learning-based modeling of term differences among disciplines.

Previously, scholars have sought to map science based upon patterns of co-citation (Boyack, Klavans, & Börner, 2005) as well as topic, via ISI subject headings (e.g., Leydesdorff & Rafols, 2009). Other studies of similarity or relatedness have sought to compare multiple kinds of networks, including "bibliographic coupling, citation networks, cocitation networks, topical networks, coauthorship networks, and coword networks" (Yan & Ding, 2012, p. 1313). While the current work-in-progress focuses on a single type of similarity, it is with the intention of eventually adding to and comparing with these previously established measures of comparison. Furthermore, in order to create results that are comparable to previous work, we will also draw our data from the Web of Science, focusing specifically on the genre of scholarly articles, and use the high-level subject categories (although in future iterations of this study we hope to look at both higher and lower-level subject categories).

Methods

The current study analyzes all journal article abstracts from 13 disciplines contained in the Web of Science from 2011, totaling 928,572. Table 1 provides an overview of disciplines and counts of abstracts in the data corpus.

Table 1. Counts of abstracts by discipline.

Discipline	Abstracts
Engineering and Tech	172949
Biomedical Research	153166
Chemistry	129685
Physics	121702
Biology	93765
Earth and Space	70018
Mathematics	42685
Social Sciences	40463
Professional Fields	34590
Health	28343
Psychology	25802
Humanities	13673
Arts	1731
TOTAL	**928572**

For each abstract, relative frequencies were computed for 307 words or phrases taken from Hyland (2005). These terms fall into one or another of the following categories: hedges, boosters, attitude markers, engagement markers, and self-mentions. Hedges (e.g., "perhaps", "possible", "approximately") mitigate the certainty of an assertion, while boosters (e.g., "clearly", "obvious") amplify it. Attitude markers, such as "unexpectedly" or "unfortunately", frame assertions affectively, expressing the author's emotion regarding the

asserted facts, as distinct from their assurance of the facts' certainty. Engagement markers (such as "the reader" and "you", but also imperative verbs such as "consider" or "observe") address the reader explicitly or implicitly, and guide the reader to specific social and epistemic framing of an assertion (e.g., as an externally observable fact or as an idea intended for mental simulation). Finally, self-mentions, such as "I", "we", or "the author", serve as means for authors to insert themselves into the text, either as subjective actors or as social players (whether alone or as part of an authorial cohort).

After preparing the data, the Sequential Minimal Optimization algorithm (SMO) (Platt, 1998), a support-vector model classifier implemented in the WEKA v3.6.6 tool (Hall et al., 2009), was employed to create models distinguishing between each pair of disciplines based on the socio-epistemic features' relative frequencies. The resulting term weights for each model of discipline pairs were then normalized across the model, such that the absolute values of weights for a given discipline pair model would sum to 1. Model-normalized weights for each term were then averaged for each discipline across all discipline pairs for which the given discipline was a pair member. For the sake of standardization, negative term weights indicate a positive correlation with a given discipline (i.e., the more frequently the term appears in a text, the more likely this text belongs to the given discipline), while positive term weights indicate a negative correlation (i.e., the more frequently the term appears in the text, the less likely this text belongs to the given discipline).

Results

Due to space limitations, we eschew reporting the full 307 term set of results, focusing instead on the terms that most and least distinguish among disciplines. We discern these terms based upon the standard deviation of model-normalized average weights, as terms that discern well among disciplines will result in strong positive as well as negative weights, depending on which discipline is being modeled, while terms whose weights have small absolute values will in turn have smaller standard deviations, as all weights approach the 0 point.

Table 2 reports the 20 terms with the highest standard deviations of model-normalized average weights, as well as the 20 terms with the lowest standard deviations. While the results might at first blush suggest that the terms with the lowest standard deviations are part of a universal academic discourse, it is worth noting that many of the terms in the Bottom 20 list are exceedingly rare in the sample – out of 928,572 abstracts, "unbelievable" appears in 3 of them (although "shockingly" also appears in 3 abstracts; however, "unbelievable" is found in 2 engineering abstracts and one humanities abstract, suggesting that the scant data that exists shows no distinction between two otherwise fairly different disciplines). Also worth noting is that any terms that appeared in no abstracts at all are eschewed from the reported results.

However, the bottom 20 terms do provide some information about scholarly writing across the disciplines – the vast majority of these terms (19 out of 20) act as attitude markers; given the wide range of adjectives and adverbs available to describe the affective state of the author (and given that adjectives and adverbs are linguistic "open classes", i.e., new words can and are generated for these classes regularly), it is not surprising that such terms would be diffuse, rare, and not strongly indicative as individual terms.

Pivoting to consider the top 20 terms, the first notable characteristic is that where the bottom 20 terms tend toward adjectives and adverbs (as well as attitude markers), 19 of the top 20 terms are either self-mentions or engagement markers (and the latter for the most part are verbs). While nouns and verbs are also linguistic open classes, the use of verbs to describe the epistemic frame of scientific work here as well as the terms with which scientific authors refer to themselves can be seen to be more standardized within disciplinary communities, whereas the attitude markers of the bottom 20 terms are more personalized. The indicative

strength of self-mentions such as “we”, “my”, and “author”, as well as verbs like “argue” and “measure” also resonates with previous findings of Demarest and Sugimoto (2014), with “argue” and “my” serving as a strong indicator of philosophy and “measure” and “we” a better indicator of psychology and physics in dissertation abstracts as well.

Table 2. The top and bottom 20 social and epistemic terms for distinguishing among disciplines (ranked by standard deviation).

Top 20		Bottom 20	
Term	Standard Deviation	Term	Standard Deviation
we	0.009848	shockingly	0.0009166
argues	0.009686	view	0.0008793
prove	0.009614	disappointed	0.0008707
argue	0.009098	astonishingly	0.0008043
author	0.009063	!	0.0007801
showed	0.008494	incontestable	0.0007541
about	0.008138	knowledge	0.0007406
let	0.008044	incontrovertible	0.0007283
proved	0.008019	presumable	0.0007005
my	0.007908	unclearly	0.0006577
recall	0.007684	desirably	0.0006524
estimate	0.007646	amazed	0.0006068
review	0.007592	disappointingly	0.0006046
measure	0.007268	uncertainly	0.0004573
pay	0.007173	undisputedly	0.0003956
thought	0.007102	unbelievably	0.0003247
claims	0.006978	incontrovertibly	0.0002968
consider	0.006879	incontestably	0.0002821
shown	0.006687	astonished	0.0002649
set	0.006672	unbelievable	0.0001121

Another aspect of the findings to consider is that while the standard deviation values derive from the full set of model-normalized average weights, in some circumstances high standard deviation values can derive from a single outlier, while in others it derives from a more uniform spread of weights. Figure 1 depicts the model-normalized average weights for the top 20 terms ranked by standard deviation. Visual inspection reveals terms whose weights are more uniformly distributed (e.g., “author”), which suggest that they may serve as robust terms to distinguish among a variety of disciplines, while other terms (e.g. “let”, “prove”, and “proved”) serve as strong indicators of a single outlier discipline, with all other disciplines much more tightly clustered. As it happens, the terms “let”, “prove”, and “proved” provide a strong indication of mathematics as they occur more frequently in a text, in contrast to all other disciplines.

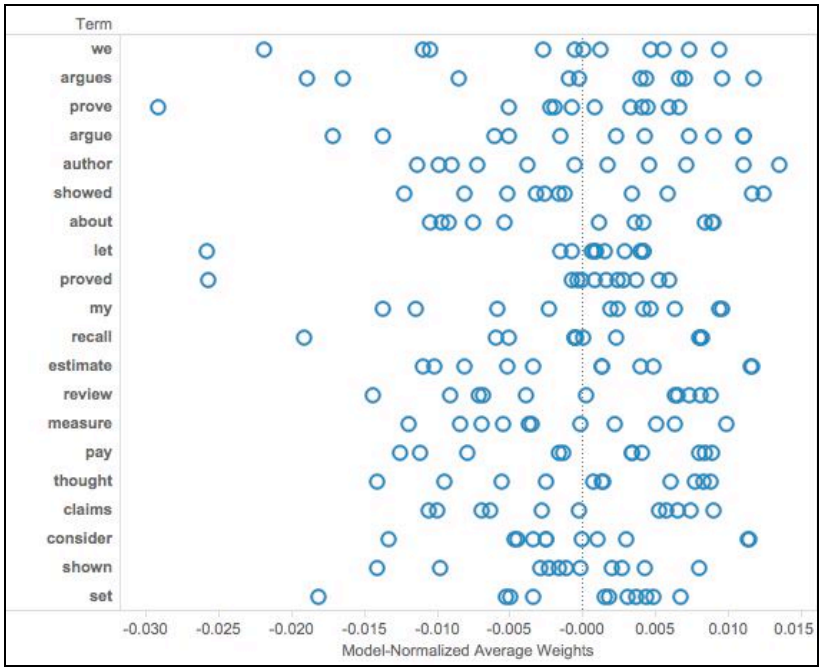

Figure 1. Model-normalized average weights (Top 20, ranked by standard deviation).

Future Directions

While the results of the current study-in-progress have focused on summary ranking and overall patterns of distribution of weights per term, our next goals in the near term are to more deeply tease apart trends as they appear for single disciplines as well as groups of disciplines, including the traditional groupings of soft vs. hard and pure vs. applied (Biglan, 1973). Further, we can derive overall measures of similarity among disciplines from the overall accuracy measures of the machine-learning models from which these terms are taken (per Demarest & Sugimoto, 2014), or more ambitiously we could seek to cast disciplines and terms in a bipartite network, to more fully grasp the interplay between different disciplinary communities and the words they use.

More distantly, we intend to use this same approach, in light of patterns and trends perceived at the current level of aggregations, to consider specializations, so that we may ask questions such as how broad the social and epistemic spread of specialized areas of study are within disciplines – are some disciplines more socially or epistemically diverse, and others more centralized? Do these degrees of variety reflect patterns of fragmentation and specialization in subject area? It is questions such as these that compels the current research-in-progress.

Abstract
Based on a dataset on Astronomy & Astrophysics a hybrid cluster analysis has been conducted. Hybrid clustering was based on a combination of bibliographic coupling and textual similarities using Louvain method at two resolution levels. The procedure resulted in seven and thirteen clusters, respectively. The statistics reflect a high quality of classification. For labelling and interpreting clusters, *core documents* are used. The results of these two scenarios are presented, discussed and compared with each other. The two scenarios clearly result in hierarchical structures that are analysed with the help of a concordance table. Furthermore, the core documents help depict the internal structure of the complete network and the clusters.
This work has been done as part of the international project 'Measuring the Diversity of Research' and in the framework a special workshop on the comparative analysis of algorithms for the identification of topics in science organised in Berlin in August 2014.

Conference Topic
Methods and techniques (special session on algorithms for topic detection)

Introduction
Within the framework of the event series on 'Measuring the Diversity of Research' a special workshop on the comparative analysis of algorithms for the identification of topics in science was organised in Berlin in August 2014. A dataset downloaded from Thomson Reuters Web of Science covering the annual volumes 2003–2010 was shared with all contributors in order to test the various algorithms and techniques and to compare the results of the different approaches. On the basis of the shared Astronomy & Astrophysics dataset the following analysis has been conducted at our institute. In particular, the topic structure of the subject defined by the set was analysed using two different but related techniques. A cluster analysis was based on bibliographic coupling and textual similarity. And *core documents* (Glänzel & Czerwon, 1996) defined on the same links were used to represent topics within the subject and to depict the internal structures of both subject and clusters (cf. Glänzel & Thijs, 2011). Main results are presented in the following, but changing parameters of the algorithm and of the combination of the components leads to further results.
Currently a new and more robust method for the measurement of textual similarities and thus for the revision of the lexical component is in development. A comparison of the results of the present study with those of the new algorithm is part of the ongoing project and will be presented on a later occasion, when available.

Methodological aspects
The advantage of using hybrid lexical–citation based methods, notably of combinations of term-frequency and bibliographic coupling, has already been discussed in previous studies (e.g., Glenisson et al., 2005; Boyack & Klavans, 2010). However, at this level of aggregation (topics within the same field or discipline) we have encountered several specific problems that have already been reported in earlier studies in the context of the detection of emerging topics (e.g., Glänzel & Thijs, 2012). Terms and phrases might become less specific since they express common knowledge base and vocabulary while others might gain more 'information

value'. The most important TF-IDF keywords and terms alone are often not specific enough for topic description and labelling. Thus a larger set of terms is needed to describe topics at this level. A possible solution has already be discussed already in earlier studies (e.g., Glänzel & This, 2011): On one hand, depending on the level of aggregation *and* the discipline under study, the weight of the two components can be adjusted and, on the other hand, instead of the best TF-IDF terms *core documents* can be used to describe and label clusters. In order to apply the hybrid clustering we have only vertices with *positive* degree (i.e., documents with at least one link) taken into account. Furthermore, we have removed all papers with publication years outside the period 2003–2010. Table 1 shows the description of the dataset.

Table 1. The input dataset.
[Data sourced from Thomson Reuters Web of Science Core Collection]

Data	Documents	Percentage
Original dataset	111514	100.00
Not present in ECOOM Database	103	0.09
Publications in 2003-2010	110412	99.01
Excluded from all analysis	1205	1.08

We applied Louvain method (Blondel et al., 2008) using Pajek (Batagelj & Mrvar, 2003) to this dataset. The reason for this choice was that hierarchical clustering with Ward used in previous projects (e.g., Thijs et al., 2013) often results in a heterogeneous "hotchpotch" cluster of objects that can otherwise not be assigned. Therefore we decided to apply Louvain method. We conducted a hybrid clustering with two components: *bibliographic coupling* (BC) and *textual similarity* (TS), where we used a weight of 0.75 for BC and 0.25 for TS according to the algorithm described in Glänzel & Thijs (2011). In particular, the underlying similarity measure r is defined as the cosine of the linear combination of the underlying angles between the vectors representing the corresponding documents in the vector space model, i.e.,

$$r = \cos\left(\lambda \cdot \arccos(\eta) + (1-\lambda) \cdot \arccos(\xi)\right), \quad \lambda \in [0,1],$$

where η is the similarity defined on bibliographic coupling and ξ the textual similarity. The λ parameter defines the convex combination, $\arccos(\eta)$ and $\arccos(\xi)$, respectively, denote the two underlying angles. Furthermore, we have conducted the clustering at two resolution levels, namely 0.7 and 1.4. The results of these two scenarios will be presented and briefly discussed in the following section.

Results

The results using both resolution levels are briefly summarised in Table 2. The number of documents, that could not been clustered, is marginal. The number of clusters has almost doubled (from 7 to 13) with growing resolution. The solutions for the two resolution levels are presented in Tables 3 and 4. Except for the tiny cluster (#13) on atmospheric turbulence in the second solution, all clusters are of reasonable size. This is expressed by the frequency, i.e., the number of documents per cluster (columns 2–4). The description of the clusters, shown in the last column of the tables, have been derived from the most important TF-IDF terms and the titles of the *core documents*, where the core documents have been determined according to see Glänzel (2012) on the basis of the *degree h-index* of the hybrid document network. In particular, core documents are represented by core nodes, which, in turn, are defined as nodes with at least h degrees each, where h is the h-index of the underlying graph. Or, to express this simpler, degrees of documents are ranked in descending order and the h-core is formed by the documents the degrees of which do not undercut their rank value. This method has proved

efficient in *local* clustering, that is, in clustering of fields or disciplines, where the network h-core usually represents the order of magnitude of 1% of the total document set (see Glänzel, 2012).

Table 5 lists the core documents of Cluster #5 of the first scenario with seven clusters as an example. The degrees given in the table also illustrates the role of core documents in the cluster: Core documents are by definition strongly interlinked with many other documents and therefore play a representative and central part in a network. And they are suited to depict the internal structure of the complete network, of a cluster or of parts of it. In this context Cluster #5 has not been chosen by chance. The core documents of this cluster form the centre of the structure. Links connecting core documents reveal the internal structure of both the field under study and the clusters as the links with other core documents of the same cluster as well as with those of other clusters are distinctly apparent. Beside this cluster, also cores documents of cluster 7 play a central part. This is shown in Figure 1. Core documents of cluster 5 are marked in pink, those of Cluster 7 in auburn.

By contrast, Figure 2 presents the concordance between the two scenarios. Indeed the two resolutions results in a different number of clusters as already have been shown in Tables 3 and 4. Now the question arises of whether the two approaches yield completely different structures or almost concordant hierarchic structures, where the choice of the resolution would go with merging and splitting clusters, respectively. The first case would, of course, be problematic and point to the possible inappropriateness of methodology, while latter case testifies consistency of the chosen method. Cluster concordance of the results of the two scenarios are visualised in Figure 2.

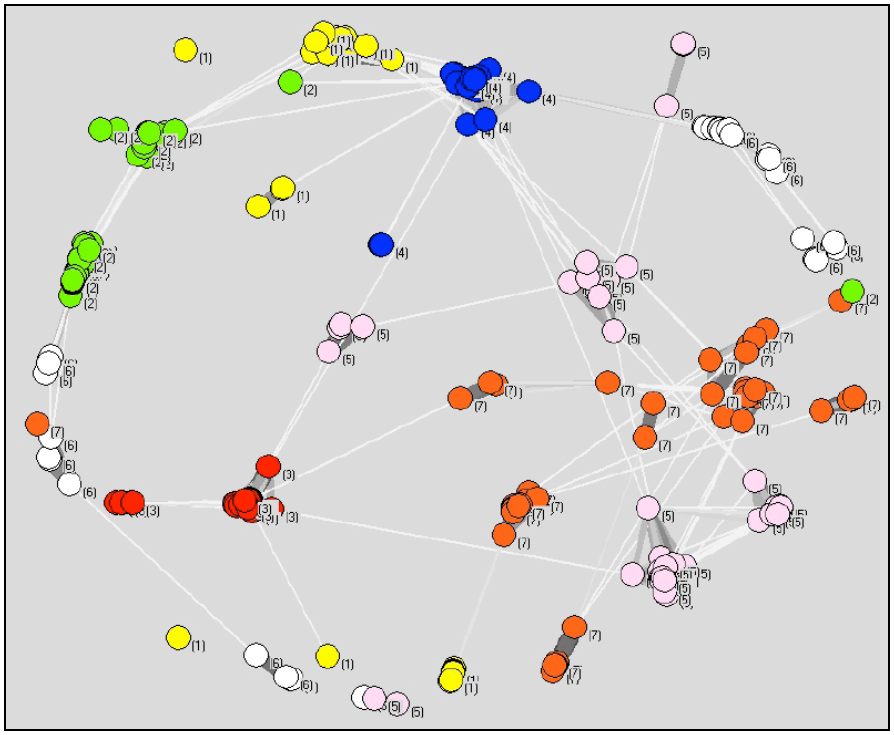

Figure 1. Structure of core documents in 7 clusters according to scenario 1 (Pajek with Fruchterman-Rheingold layout) [Data sourced from Thomson Reuters Web of Science Core Collection].

Hybrid Approach 13 Clusters \ Hybrid Approach 7 Clusters	1	2	3	4	5	6	7
1	94	0	0	5	0	1	0
2	96	1	0	2	0	1	0
3	1	95	3	1	0	0	0
4	1	0	91	0	0	7	0
5	1	0	0	86	2	1	10
6	0	0	0	100	0	0	0
7	0	0	0	2	98	0	0
8	2	0	0	4	0	94	0
9	0	0	0	0	97	0	2
10	1	3	1	1	42	51	0
11	1	2	0	1	0	95	0
12	0	0	0	1	2	1	95
13	5	61	24	0	2	0	7

Figure 2. Cluster concordance: scenario 1 – scenario 2 (overlap in %). [Data sourced from Thomson Reuters Web of Science Core Collection]

The document overlap in the corresponding clusters is expressed in per cents and, in order to facilitate interpretation, marked in different colours. Percentages sum up to 100% by rows. If one neglects the light-weight Cluster #13 in the second scenario, which actually represents just 0.4% of the total, one observes an almost perfect concordance of three clusters in scenarios 1 and 2 (#2 = #3, #3 = #4 and #7 = #12), one cluster splits up into two others (#4 = #5+#6) and finally two clusters split up into three clusters each, namely #5 = #7+#9+#10 and #6 = #8+#10+#11. Thus Cluster #10 in scenario 2 is the only one that breaches the strict hierarchy in the structures of the two scenarios. Its documents are almost equally distributed over Clusters #5 and #6 in scenario 1. The tiny one (#13) in the second

scenario can be considered a small sub-cluster of #2 in the first one, where it represents just slightly more than 2% of the documents of the total cluster.

Conclusions

Our main conclusions refer to two issues, firstly to the *clustering results* and secondly to the role of *core documents*. As to the clustering, both scenarios resulted in an almost perfect hierarchic structure. Cluster concordance and hierarchy was strong except for the cluster on 'Radio Pulsars' in the 13-cluster solution. This cluster was almost evenly spread over the clusters on 'Dark Energy' and 'Gamma Ray Burst' in the seven-cluster solution. Nevertheless, hierarchical assignment of 'Atmospheric Turbulence' in scenario 2 was also somewhat "fuzzy", but had a main concordance of more than 60% of documents with 'Coronal Loop' in the first scenario. In all other cases concordances were around or even above 90% document overlap.

The second group of remarkable observations refer to core documents. These documents represent the links across clusters as well as the internal topic structure of the clusters. In this context we have to repeat that core-document identification is in principle *independent* of clustering and thus does not require any cluster analysis or community detection, but it can be seamlessly integrated into clustering exercises, provided the same type of links, i.e., bibliographic coupling, co-citation, text similarity or hybrid, are used. Core documents reinforce the observation concerning centric results of the hybrid clustering. Core documents of the clusters on 'Dark Energy' and 'Neutrino' actually form the centre of the structure. The choice of the two resolution levels resulted in a hierarchic structure confirming the appropriateness of the applied method.

Acknowledgements

This work has been done as part of the international project 'Measuring the Diversity of Research' and in the framework a special workshop on the comparative analysis of algorithms for the identification of topics in science organised in Berlin in August 2014. The project and workshop series was jointly organised by the Humboldt Universität and Technische Universität Berlin. We would like to acknowledge their support of our study.

Introduction

The Open Access movement in scientific publishing and search engines like Google Scholar have made scientific articles more broadly accessible. During the last decade, the availability of scientific papers in full text has become more and more widespread thanks to the growing number of publications on online platforms such as ArXiv and CiteSeer (Wu, 2014). The efforts to provide articles in machine-readable formats and the rise of Open Access publishing have resulted in a number of standardized formats for scientific papers (such as NLM-JATS, TEI, DocBook).

Corpora

Different projects have been carried out to respond to the need of full-text datasets for research experiments (PubMed, JSTOR, etc.) and corpora.
E.g. the *iSearch* dataset was designed to facilitate research and experimentation in information retrieval, and specifically in aspects of task-based and integrated (a.k.a. aggregated) search. Its compressed size is about 46GB of documents in English from the physics domain that were collected from public libraries and open archive resources.

Semantic Web and Information Retrieval

Scientific papers are highly structured texts and display specific properties related to their references but also argumentative and rhetorical structure. Recent research in this field has concentrated on the construction of ontologies for citations and scientific articles.
CiTO (Shotton, 2010), the Citation Typing Ontology, is an ontology for the characterization of citations, both factually and rhetorically. It is part of SPAR, a suite of Semantic Publishing and Referencing Ontologies. Other SPAR ontologies are described at http://purl.org/spar/.

Statistical Analysis of Textual Data

Text Mining in R

Temis, an R Commander plugin (Bastin, 2013) provides integrated tools for text mining. Corpora can be imported in raw text. Another package is IRaMuTeQ (Ratinaud, 2009), a python application which uses the R libraries.

Correspondence Analysis

Correspondence analysis is a technical description of contingency tables and is mainly used in the field of text mining (Morin, 2006).
These tools could be very useful on the perspectives for the development of new text analytics approaches for bibliometrics.

Natural Language Processing Tools

Research in the field of Natural Language Processing (NLP) has provided a number of open source tools for versatile text processing.
The Apache *OpenNLP* library (Baldridge, 2005) is a machine learning based toolkit for the processing of natural language text. Written in Java, it is open source and platform-independent.
Stanford *CoreNLP* (Manning, 2014) integrates many NLP tools, including a part-of-speech (POS) tagger, a named entity recognizer (NER), a parser, a coreference resolution system, a sentiment analysis tool, and bootstrapped pattern learning tools. Stanford CoreNLP is written in Java and licensed under the GNU General Public License.
MALLET (McCallum, 2002) is a Java-based package for statistical NLP, document classification, clustering, topic modeling, information extraction, and other machine learning applications to text. It includes sophisticated tools for document classification: efficient routines for converting text to "features", a wide variety of algorithms (including Naïve Bayes, Maximum Entropy, and Decision Trees), and code for

evaluating classifier performance using several common metrics.

GATE (Cunningham, 2002) is open source free software for all types of computational tasks involving human language. It includes components for diverse NLP tasks, e.g. parsers, morphology, tagging, Information Retrieval tools, Information Extraction components for various languages.

CiteSpace (Chen, 2006) is a freely available Java application for visualizing and analyzing trends and patterns in scientific literature. It is designed to answer questions about a knowledge domain, which is a broadly defined concept that covers a scientific field, a research area, or a scientific discipline.

What is next?

Several studies examine the distribution of references in papers (Bertin, 2013). However, up to now full-text mining efforts are rarely used to provide data for bibliometric analyses. An example is the special issue on Combining Bibliometrics and Information Retrieval (Mayr, 2015). Novel approaches to full-text processing of scientific papers and linguistic analyses for Bibliometrics can provide insights into scientific writing and bring new perspectives to understand both the nature of citations and the nature of scientific articles. The possibility to enrich metadata by the full-text processing of papers offers new fields of application to bibliometrics studies like e.g. text reuse patterns in specific disciplines.

Working with full text allows us to go beyond metadata used in Bibliometrics. Full text offers a new field of investigation, where the major problems arise around the organization and structure of text, the extraction of information and its representation on the level of metadata. Unlike text-mining from titles and abstracts, full-text processing allows the extraction of rhetorical elements of scientific discourse, such as results, methodological descriptions, negative citations, discussions, etc. Scientific abstracts, by summarizing the text, provide only short, synthetic and thematic information.

Furthermore, the study of contexts around in-text citations offers new perspectives related to the semantic dimension of citations. The analyses of citation contexts and the semantic categorization of publications will allow us to rethink co-citation networks, bibliographic coupling and other bibliometric techniques.

Our aim is to stimulate research at the intersection of Bibliometrics and Computational Linguistics in order to study the ways Bibliometrics can benefit from large-scale text analytics and sense mining of scientific papers, thus exploring the interdisciplinarity of Bibliometrics and Natural Language Processing. Typical questions of this emerging field are: How can we enhance author network analysis and Bibliometrics using data obtained by text analytics? What insights can NLP provide on the structure of scientific writing, on citation networks, and on in-text citation analysis?

A Multi-Agent Model of Individual Cognitive Structures and Collaboration in Sciences

Bulent Ozel

ozel@uji.es
Universitat Jaume I, Department of Economy, Castellon De La Plana (Spain)

Motivation

This research takes a multi agent perspective while simulating knowledge diffusion mechanism in science. Multi agent systems are systems that are composed of a large number of autonomous agents that are capable of interacting with each other. The autonomous agents are not controlled by a central mechanism, instead, their decision taking logics are part of their actions and they are decentralized, hence, they are able to make decisions in order to accomplish individual tasks (Wooldridge, 2009). In this research, a scientist who is situated within a co-authorship network is considered as an individual autonomous agent. Her decision process at picking another scientist to co-author a paper and outcome of such an interaction builds up our multi-agent system.

In a science network, if two scientists work on the same paper, then they are considered connected. The social interaction linkage between them is a possible channel for knowledge diffusion. In our model, each author is considered as an agent that is capable of working with other authors, choosing whom to work with and what subject to work on. In order to set-up initial environment of our multi-agent system we need to identify initial co-authorship network, as well as, we need to represent knowledge space of each individual author in the network. In order to capture a representation of an individual's expertise a set of keywords, which is driven from publications of the author is used to form the node set of the semantic network of that very individual. The semantic relations, namely the links, in between the keywords in the set are established by their co-occurrence on a published article.

There are a number of challenges at designing interaction and evolution of such multi agent system. The challenges are (i) being able to incorporate a dynamic social network perspective while modelling interactions in between agents, (ii) designing, simulating and examining various knowledge creation and diffusion mechanisms as the outcomes of agent-agent interactions.

The first challenge addresses a problem within multi-agent modelling research area. Computational simulation of social systems falls short at covering dense and multitude interactions in between actors. Majority of agent-agent interactions are implicitly and limitedly modelled via agent-agent interactions using environmental variables. This limitation is partly due to complexities at agent-agent interactions and mainly due to lack of empirically validated interaction mechanisms. In this work, we borrow and adopt models from social network literature. More specifically, we examine co-authorship networks and empirically validated interaction models within the field.

In the second challenge, we take a socio-cognitive approach. We model and exploit cognitive structure of each agent both at the incentives of individuals to select other agents to collaborate and at modelling the outcome of resulting interactions. Namely, agents purposefully interact to create and transfer new knowledge.

In addition to challenges mentioned above there are several implementation challenges to be addressed for the simulation model. First of all, not all agents in the population interact with each other at each run and preferences of interaction cannot be uniformly random. In the model, those ones who decide to collaborate compute the set of candidate collaborators autonomously. An agent's current knowledge space, and his/her ego network are taken into consideration at incentives to collaborate. For instance, literature suggests that repetition of joint collaborations follows a power law distribution (Morris & Goldstein, 2007) mimicking power law distribution of individual publication productivity. Likewise, propensity to collaborate with collaborator of an existing co-author is incorporated adopting transitivity property of social ties (Wellman, 1988). Another empirically validated model of social tie formation mechanism that is adopted is "preferential attachment". It is known that in a complex social network probability of a node to have a new connection is proportional to the connections it already has (Barabasi, 2002). At each round of the simulation each agent independently determines a candidate set of collaborators. This candidate set is formed employing above-mentioned mechanisms.

A second implementation challenge is how to incorporate knowledge of individual agents. Dynamic social network mechanism does not take actual knowledge space of individual into consideration. In other words, knowledge space of individuals does not play a direct role on the interactions. Besides, while social interaction mechanisms hint whom to pick to collaborate it

does not explain outcome of interactions. It is necessary to come up with empirically validated and sound models to represent what knowledge will be exchanged as the outcome of such social interactions.

Literature suggests that there are two competing social mechanisms, which may help to consider cognitive structure of individuals on the preferences of collaborators. They are 'cognitive distinctiveness' and 'cognitive similarity'. Cognitive distinctiveness or cognitive similarity of two agents is measured by comparing their knowledge bases. For a pair of agents when the distinctiveness is high then there are more possibilities for them to learn from each other. If their knowledge bases overlaps widely, the knowledge they can get from each other is limited (Carley, 1991). However, it is known that people, in some cases, tend to interact with people they are similar to; a tendency, which is known as homophily (McPherson et al., 2001). The experiments are devised to observe impact of these two competing models.

Implementation

As we have mentioned above, each author is represented as an agent. Each agent has its own individual memory, where its knowledge base and its co-authorship history is kept and updated throughout the simulation. Knowledge base of an agent is formed by set of keywords based on agent's publication records. This set of keywords is interrelated to each other. It is represented by a symmetric matrix. The matrix is a representation of cognitive structure of an agent. The entries of the matrix encode co-occurrence frequency of respective keywords. Co-authorship memory of an agent is a set of authors with whom the agent worked with on a publication.

Set of all the keywords that are gathered from all of the publications is represented as a weighted graph. If two keywords belong to the same publication, then they have a connection and weight of the connection is the number of the times they are used together. When entire set of publications for all agents is considered, then this graph is the cognitive structure of the entire network and it will be represented as an environmental component in the simulation.

It is certain that real agents learn from each other via collaboration, but this is not the only way of learning new things. They also learn from their readings, the workshops they attend and many other resources, etc. In order to represent all such various source of knowledge accumulation by agents, knowledge injection method is used. At each simulation time point, which is set as a year, a set of new keywords is added to the cognitive structure of entire population. A probabilistic model is adopted to update cognitive structures after injection of new keywords to the set. Betweenness centrality of existing keywords is used. The higher betweenness of a keyword, the higher chance it receives a new link.

Initial Findings and Future Work

Results from our initial experiments hint that in scenarios where agents are inclined to collaborate with cognitively dissimilar agents, then resulting collaboration structure rather mimics co-authorship relations seen within a research center. On the other hand, when cognitive similarity leads the incentives to pick a collaborator, then resulting co-authorship rather mimics network structures observed within domain of a journal in a field.

A large set of experiments is to be conducted to fully verify and validate our initial results, as well as, to discuss challenges addressed above.

There are a number of additional implementation challenges, which will be addressed and attempted as part of this ongoing research. They are (i) how to model when and in what circumstances multiple co-authorship occurs; (ii) at each run, not only new knowledge pieces but also new agents will be injected to the simulation. Knowledge base of those new agents will be composed of partially by a subset of keywords that is already in the current set and partially by new keywords that is not in the set. This approach will mimic arrival of new scientists in a field.

Introduction

Every 20 minutes a new case of autism is diagnosed worldwide, which affects around 6% of the population of children. One of the major challenges in autism is how to reliably diagnose autism as early as possible so that early intervention can be imposed to dramatically change the whole situation, even lead to cure. Joint attention is among these early impairments that distinguish young kids with autism from normal kids. Joint attention is a transdisciplinary area which was studied in robotics, psychology, autism, and neuroscience. However, Due to the unaware of similar or related researches in different domains, researchers are unknowingly duplicating studies that have already been done elsewhere. On the other hand, due to the lack of domain knowledge in other domains, researchers can experience difficulties to understand the advances in other domains. To deal with this dilemma, generating hypotheses is considered a potentially effective way. It is a crucial initial step for scientific breakthroughs, and usually relies on prior knowledge, experience and deep thinking. Especially for transdisciplinary domains, generating hypothesis from literature in different but related disciplines can be exciting and highly demanded because it is no longer possible for domain experts in one domain to fully master the knowledge in another domain.

Although marked with several decades of research history, it is until recent years that hypotheses generating attracts more attention in transdisciplinary research domains. Swanson (1986) proposed ABC model to inference the literature-based hypotheses. Later on, Srinivasan (2004) presented open and closed text mining algorithms that are built within the discovery framework established by Swanson and Smallheiser. Their algorithms successfully generated ranked term lists where key terms representing novel relationships between topics are ranked high. Zhang et al. (2014) established the semantic Medline which biomedical entities and association are semantically annotated using concepts in UMLS. They assumed that the network motifs in the network can represent basic interrelationships among diseases, drugs and genes and reflect a framework in which novel associations can be derived as hypotheses to be further validated by domain experts. Spangler et al. (2014) presented a prototype system KnIT, which can mine the information contained in the scientific literature and represent it explicitly in a queriable network, and then further reason upon these data to generate novel and experimentally testable hypotheses. They applied their method to mine the publications related to p53 (a protein tumor suppressor) and are able to identify new protein kinases that phosphorylate p53. Malhotra et al. (2013) proposed a pattern matching approach for the detection of speculative statements in scientific text that uses a dictionary of speculative patterns to classify sentences as hypothetical. Their application on the domain of Alzheimer's disease showed that the automated approach captured a wide spectrum of scientific speculations and derived hypothetical knowledge leads to generation of a coherent overview on emerging knowledge niches. Song et al. (2007) constructed a Gene-Citation-Gene (GCG) network of gene pairs implicitly connected through citation and indicated that the GCG network can be useful for detecting gene interaction in an implicit manner. In this initiative, we use text mining approach to analyze related publications on joint attention from robotics, psychology, autism and neuroscience, to generate hypotheses which will be tested in the lab which collects eye contact and body movement sensor data. Here some preliminary results were reported and discussed.

Methodology

Due to the transdisciplinary character of "joint attention" research, we elaborately selected eight data sources (Wiley Online Library, ProQuest PsycINFO, Science Direct, Scopus, Web of Science, PubMed Central, Springer Link and Google Scholar) to maximize the coverage of the final dataset. The phrase "joint attention" is used to search separately on each data source.

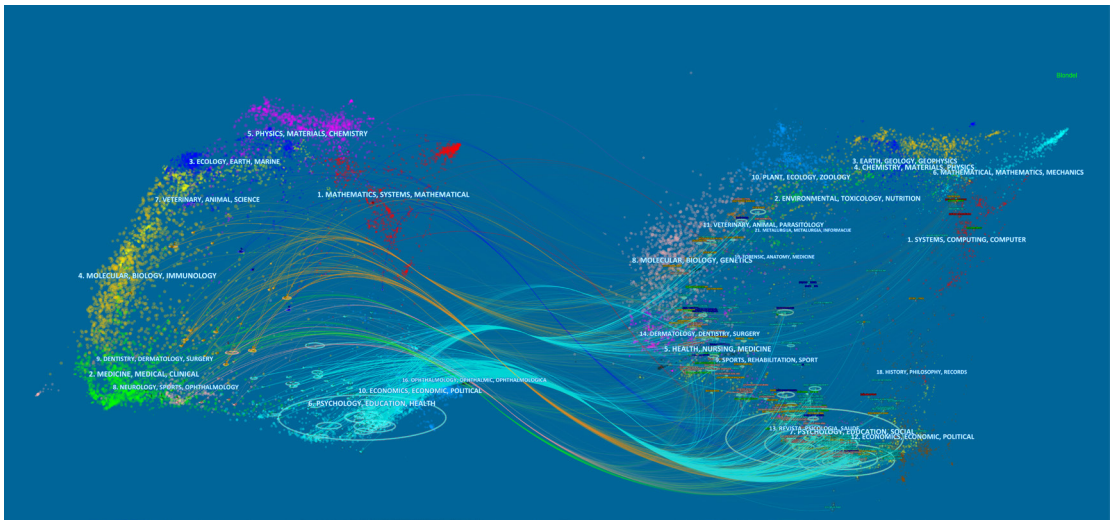

Figure 1. A dual-map overlay of "joint attention" search result from Web of Sciences.

Under the different download limitations, there are totally 39,845 records downloaded and 6,660 records left after remove duplicate records by the field "title". In the next step, keywords of each article in the dataset were extracted by using TF-IDF method. Then based on Keywords and other fields such as "journal name" and "citations", clustering were processed and relations among different clustering were analysed. By drawing the overall "research topic map", we can easily distinguish hot topics and their connections, and get to know their locations on the overall map. Then different dimensions (e.g., age, speech, language, and communication) were defined to analyse the distribution of current researches. Finally, from different dimension analysis aspects, research blind points were uncovered and new hypotheses were inferred, which will be tested in the lab.

Preliminary results

We tested a Web of Science query of "joint attention" (1,479 records) as a single dual-map overlay (Figure 1). Figure 1 shows the distribution of citing papers (left part) and cited papers (right part). Visualizations at this level are between journals, journal clusters, and overall maps. From the citation distribution and clustering results, we can identify the overall distribution of relevant sources and the most relevant targets (both ends with reference arcs). The label clustering result shows that the most popular domain discussing "joint attention" are Psychology, Education, Health, Medicine, Molecular, Economics, Mathematics, and Biology. It suggests that the Web of Science data is overwhelmingly dominated by a single journal *Journal of autism and developmental disorders*, with 169 papers. On the cited side, it is also the most cited journal in the dataset (6,640 citations). Other highly cited journals include *Child Development* (3,581 cites) and *Developmental Psychology* (2,328 cites).

Conclusions

This paper reports the ongoing effort on generating hypotheses in the transdisciplinary area of the joint attention research. We downloaded data from 8 separate data sources to maximize the coverage of "joint attention" related researches. Then text mining and visualization approaches were used to analyze related publications. Later stages of this research will generate hypotheses, which will be tested in the lab based on current research distributions on different predefined dimensions.

"What Came First – *Wellbeing* or *Sustainability*?" A Systematic Analysis of the Multi-dimensional Literature Using Advanced Topic Modelling Methods

Mubashir Qasim[1] and Les Oxley[1]

[1] *mq21@students.waikato.ac.nz,* [1]*loxley@waikato.ac.nz*

Introduction

Both sustainability and well-being (SaW) are inter-dependent, inter-disciplinary, multi-dimensional, and international subject areas. However, people tend to interpret the subjects significantly differently based on their professional affiliation, academic background, geographical location etc., (Brunn, 2014; Roberts et al., 2013). A search of the SaW literature, using any scholarly search engine, generates results ranging from the thousands to millions creating a challenge for the researcher in picking the right papers; constructing a reasonable structure and synthesizing the vast material in order to conduct a comprehensive review of the literature. The work presented here relates to the use of a sophisticated method to exploit the explanatory power of metadata, attached to the results of a search query, to identify hidden patterns in the universe of given articles. The methods and metadata used to conduct the systematic analysis are briefly discussed under following headings.

Components of systematic literature analysis

Acquisition of data

Our quest begins with the analysis of key characteristics of metadata obtained from JSTOR *Data for Research* (DFR), which enables exploration of >9.2 million articles. We collected and analysed the metadata for a sample of 68,817 papers from DFR which related to SaW for this exercise. Metadata were generated against four queries with different sets of keywords as listed in Table 1. Analysis of the metadata was conducted in three steps: Step 1., analysis of keywords, subject and subject groups, disciplines and discipline groups, journals, authors and trends of publications (as presented in a recent study by (Brunn, 2014) but with slightly different approach). In Step 2., we applied the Latent Dirichlet Allocation (LDA) to study language differentiation between SaW themes. The main aim of this exercise was to identify complex hidden patterns in the data and present them in easily understandable ways. In Step 3., we used a reference manager software package called *Qiqqa* to identify key themes in the personal library and to identify seminal and frontier studies within each theme using cross references in the collection.

Table 1: Detail of search queries.

Query	Results	Search keywords	Search in
A	4,903	wellbeing OR well-being	Abstract
B	57,681	sustainability OR sustainable development	Title
C	5,472	sustainability; sustainable development; wellbeing; well-being	Any
D	761	sustainability OR sustainable development; well-being OR wellbeing	Abstract

Analysis of keyterms

We sampled 300 top keywords appearing in the corpus of each query to represent the frequently used language patterns in the subjects of SaW. The results are presented in the form of word-clouds in which the terms with high frequencies of occurrence are represented by the larger size of the word. Each word in the cloud indicates a dimension or issue in a subject (Jaewoo & Woonsun, 2014). Broadly discussed dimensions in the well-being literature include income, health, relationships, family, child, psychology etc., are correctly identified in our word-clouds.

Type of journals and subject group

Inter-relatedness of the SaW literature is established by confirming the large number of journals shared by SaW papers as suggested by (Mimno, 2012). Here, we extracted the names of the top 20 journals by number of articles in each query. Our analysis validates the assumption that many journals include papers on both aspects of the SaW literature. The interdisciplinary nature of the SaW literature is further established by similar categorization of SaW papers with respect to different subject groups.

Trends in publications

Many modern databases are devoted to tracking publications e.g., as Google Scholar, ISI Web of Science, JSTOR, SCOPUS, etc., and enable

scholars to perform quick and broad browsing of the literature (Hood & Wilson, 2003). Their expansions or contractions over time can indicate the interest of scholars in an area and the evolution of novel approaches (Adam, 2002; Casagrandi & Guariso, 2009).

In our analysis, we find the first article related to Query A, appears in 1919 and the number of publications remains trivial until the 1970's. Thereafter, a huge influx of papers begins in the late 1970's with 30 papers per year, peaking at 311 papers in 2012. In contrast, papers related to sustainability in Query B started much earlier with the first paper published in 1800. This number reaches to 50 papers per year in the next 100 years and steadily increase thereafter for another 50 years to around 250 papers per year in 1950. Post-1950, the number of scholarly articles grew five fold over the next five decades and peaked in 2005 at 1304 papers per year. Articles related to both SaW in Query C emerge in the late 1970's and grow exponentially over the next 40 years. As Query D is a subset of Query C they exhibit similar trends. A comparison of these trends with the papers in the entire DRF corpus of 9.3 million articles indicates the level of interest of the scholars over different years.

Authors of publications and places

Another way to consider the SaW literature is to analyse the country of the main author(s) of an article in order to answer the key question "what countries are leading the SaW agenda?" We select the top 20 authors in each set of documents based on their number of publications. Their country is established from the place of their affiliation at the time of publication. Our results show 74 unique authors from 12 different countries wrote 1,869 SaW paper. Not unexpectedly, 9 of these countries are developed OECD countries with the United States the home of 61% of SaW authors and 29% of this literature is produced by people from Europe, Canada and South Africa and rest of them are from Australia, India and Botswana.

Differentiating language using LDA

Finally, we conducted probabilistic analysis of the SaW literature using Latent Dirichlet Allocation (LDA) in order to establish underlying topics within the corpus of documents in each query (a topic is a set of co-occurring words). Our analysis helps understanding what sort of language is used within and across disciplines; what clusters of words happen to occur together; and how the use of language changes overtime. Results are shown by java based interactive visuals made in the programing language R. Each topic provides a clear structure to build a paragraph in a literature review and the cluster of topics gives a clear indication of the categories/themes within each set of documents.

Identification of seminal and frontier studies

Most dominant papers in our set of documents are identified using in-bound references assuming that heavily cited and highly ranked articles are the key papers in each collection. Identification of these articles provides the best starting point to begin the traditional literature review with. We used network diagrams using a reference manager called Qiqqa to conduct this exercise.

Validation of results

The results are validated using the metadata from another widely used scholarly source called Web of Science. Most of our results exhibit the same characteristics as the results of DFR data.

Multi-Label Propagation for Overlapping Community Detection Based on Connecting Degree

Xiaolan Wu[1] and Chengzhi Zhang[2]

[1]*wuxiaolananhui@163.com*, [2]*zhangchz@istic.ac.cn*
Dept. of Information Management, Nanjing University of Science and Technology, Nanjing 210094 (China)

Introduction

With the growth of social media, social network analysis draws a great attention and becomes a hot research topic in the field of complex network, web mining, information retrieval, etc. An important aspect of social networks analysis is community structure (Newman, 2003).

In general, community detection methods are classified into two categories: overlapping methods (and non-overlapping methods (Hofman & Wiggins, 2008)). The former allows communities overlap, while the latter assumes that a network only contains disjoint communities. In this paper, we focus on the overlapping community detection. To find overlapping community, researchers use a wide variety of techniques, such as Clique Percolation Method, COPRA (Gregory, 2010), etc. COPRA is very fast, but the result of COPRA is nondeterministic, so we propose an improved COPRA with high determinacy in this paper.

An Improved COPRA Algorithm Based on Connecting Degree

To eliminate the nondeterministic of COPRA, we use Connecting Degree as definition 1.

Definition 1: Let v be a node on the undirected Graph $G(V;E)$, C is the set of overlapped communities on Graph, the connecting degree between node v and community $c(c \in C)$, denoted $C(v,c)$, be computed by the following formula (Duanbing, Mingsheng, Xia, 2013).:

$$C(v,c) = \frac{\sum_{u \in c} w_{vu}}{k_v} \qquad (1)$$

Where k_v is the degree of node v, w_{vu}=1 if there is an edge between node v and node u, zero otherwise. *

Connecting Degree can reflect the community tendency for a node to its neighbour communities, so we proposed a COPRA Based on Connecting Degree, named COPRA-CD. COPRA-CD works as follows: 1) To start, all nodes are initialized with a unique community identifier and a belonging coefficent setting to 1; 2) Each node updates its community identifier by the union of its neighbours labels, the corresponding belonging coefficient is obtained by normalizing the sum of the belonging coefficients of the communities over all neighbours. Then, comparing all the belonging coefficients and the parameter v, if all the belonging coefficients are less than v, calculating the connecting degree between node and its neighbour community, then only retain neighbour community with greatest connecting degree, else keeping these belonging coefficients that are more than v, then renormalize these belonging coefficients of remaining communities so that they sum to 1. After several iterations, if the stop criteria proposed by Gregory is satisfied, the propagation procedure stops; 3) Remove communities that are totally contained by others; 4) Split disconnected communities.

Experimental Results and Discussion

Test networks

At first, we do experiments on four real-world networks, whose information are shown in Table 1.

Table 1. General information of real networks

Networks	Description	Node&Edge
Karate	Zachary's karate club (Zachary, 1977)	34 &78
Dolphin	Lusseau's Dolphins (Lusseau, 2003)	62 & 159
Books	Books about US politics	105 & 441
Football	American College football union (Girvan, Newman, 2002)	115 & 616

Then we also test the performance of COPRA-CD on six LFR synthetic networks with various mixing parameter μ ranging from 0.1 to 0.6, the other standard configuration of LFR synthetic network used in this experiment is: n=1000, t_1=2, t_2=1, k=10, $\max k$=30, $\min c$=10, $\max c$=50, O_n=100, O_m=2.

Test metrics

To measure overlapping communities detection, Q_{ov} was be proposed by Nicosia et al (2009). The formulation of Q_{ov} as following:

$$Q_{ov} = \frac{1}{m} \sum_{c \in C} \sum_{i,j \in V} \left[\beta_{l(i,j),c} A_{ij} - \frac{\beta^{out}_{l(i,j),c} k_i^{out} \beta^{in}_{l(i,j),c} k_j^{in}}{m} \right] \qquad (2)$$

Where A_{ij} is the adjacency matrix of Direct Graph $G(E,V)$, C is the set of overlapped

* Corr. author: C. Zhang, Tel: +86-25-84315963.

communities, $l(i,j)$ is a link which starts at node i and ends at node j. $\beta_{l(i,j),c}$ is the belonging coefficient of $l(i,j)$ for community c, $\beta^{out}_{l(i,j),c}$ is the expected belonging coefficient of any possible link $l(i,j)$ starting from a node into community c, $\beta^{in}_{l(i,j),c}$ is the expected belonging coefficient of any link $l(i,j)$ pointing to a node going into community c. k_i^{out} is the out degree of node i, while k_j^{in} is the in degree of node j.

Test results and discussion

In order to show its performance, we compare three multi-label propagation algorithms, i.e., COPRA, COPRA-CD, and RC-COPRA. RC-COPRA stands for the version of COPRA with initialization using RC proposed by Wu et al. (2012). In our test, we run each algorithm 100 times on each network for the same value of parameter v. The average modularity result on real-world network was shown in Table 2, and the comparison performance on LFR synthetic networks was shown in Figure 1.

Table 2. Test Results on real-world Networks.

Networks	**COPRA (v=2)**	**COPRA-CD (v=2)**	**RC_COPRA (v=2)**
Karate	0.428	0.745	0.703
Dolphins	0.645	0.759	0.761
Books	0.826	0.815	0.830
Football	0.684	0.661	0.668
Networks	**COPRA (v=3)**	**COPRA-CD (v=3)**	**RC_COPRA (v=3)**
Karate	0.408	0.717	0.725
Dolphins	0.652	0.710	0.713
Books	0.830	0.822	0.827
Football	0.677	0.665	0.670

From Table 2, we find the modularity of CORPA is lower than that of other algorithms at the same v. At v =3, RC_COPRA algorithm gives better average modularity for every network, but at v=2, the modularity of RC_COPRA algorithm on Karate network is not better than that of COPRA-CD.

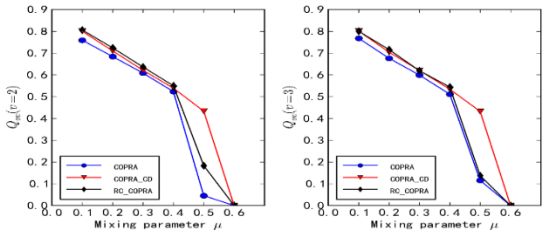

Figure 1. Experiment on synthetic networks.

As Figure 1 shows, when $\mu \leq 0.4$, all three algorithms show good performance. When $\mu =$ 0.5, LFR synthetic networks are very fuzzy, the overlapping community structure is not detected by COPRA and RC_COPRA, but detected by COPRA-CD, so we can conclude that for the given parameter, COPRA-CD is the most stable algorithm in these overlapping community detection algorithms.

Conclusions

In this paper, we propose COPRA-CD to uncover overlapping communities in social networks. Then we test it on four real-word networks and a group of synthetic networks. Experimental results show that both RC initialization and the connecting degree update strategy can bring improvements in quality, especially COPRA-CD has the best stability for fuzzy networks. In the future, COPRA-CD can be applied to analyze the community of co-author in paper.

Reproducibility, consensus and reliability in bibliometrics

Raul I. Mendez-Vasquez[1] and Eduard Suñen-Pinyol[2]

[1]raul.mendez@fundaciorecerca.cat, [2]eduard.sunen@fundaciorecerca.cat
Fundació Catalana per a la Recerca i la Innovació (FCRI), Bibliometrics. Pg. Lluís Companys, 23 E-08010 Barcelona (Spain)

Introduction

Bibliometrics, and scientometrics in general, have been enjoying what seems to be an endless party. Far from stopping, the demand for bibliometric indicators from governmental bodies, administrators and researchers, is continuously growing. During this "give me the indicators" phase several solutions have been provided by the community, let say new and more sophisticated indicators, which in turn geared the transition to the present "give me the indicators, but really?" phase. The impressive penetration of bibliometric indicators in decision making processes, some of which are crucial in the development of researchers' careers, has also brought the necessity for credibility on bibliometrics, and more specifically, on how it is practiced. Examples of improper use of bibliometric indicators have raised skepticism among users of bibliometric reports[1].

As a scientific discipline, bibliometrics is subject to the principle of replication and corroboration of results, just like any other discipline. Precisely, the credibility of scientists goes hand in hand with the reproducibility of their results.

The objective of this contribution is to bring attention to the importance of the reproducibility of the number of publications as an indicator of the quality of bibliometric reports.

Methods

We compared the numbers of publications estimated by three units following this schema: CTWS vs. BAC (us) and SCIMAGO vs. BAC. Sixteen universities reported in the CTWS Leiden Ranking 2011/2012, and 20 universities reported in the Iberoamerican Ranking SIR 2012 produced by SCIMAGO were selected for the study. Source, type of document, language and period were matched in each comparison. The numbers of publications produced by the BAC were sourced with the National Citation Report for Spain (NCR), an *ad hoc* database built in July 2012 as a live extraction from the Web of Science that compiles all the publications between 1970 and 2011, with at least one address in Spain. The unification was performed by hand based solely on the information contained in the address field of the NCR. Hierarchy relationships such as university campuses and institutes, affiliated hospitals, etc, were reconstructed in the system. All the addresses were also located to a specific administrative unit (a city in the majority of cases). Both, the information on the organizational hierarchy and location of the addresses were used to unify the name variants of subunits whenever mother organizations were not present in the addresses. Changes in the structure of the organizations within the analyzed period were recorded in the system. The unification terminated when a precision higher than 97% was achieved.

Results

A simple examination of the number of publications of a small set of universities revealed important reproducibility issues, even when controlling for source dataset, period of time and the document type (Table 1. several rows and columns were removed). A positive and statistically significant correlation ($p<0.01$) was observed between the numbers of publications produced by the three units (CTWS & BAC, *rho* 0.785; SCIMAGO & BAC, *rho* 0.860). The dispersion around the regression line was smaller in the comparison between SCIMAGO & BAC, than between CTWS & BAC, suggesting the presence of an outlier observation, whose removal increased the correlation between CTWS and BAC (*rho* 0.975, $p<0,001$). The concordance between the rankings produced by the three units was also positive and high, (CTWS & BAC, *tau* 0.733, $p<0.001$; SCIMAGO & BAC, *tau* 0.705, $p<0.001$). Removing the mentioned outlier observation increased the concordance between the CTWS and BAC (*tau* 0.905, $p<0.001$)

Discussion

These technical issues may explain the observed variability in the number of publications.

1) Completeness of the unification. The CTWS unit selected the universities with at least 500 publications per year and extended the unification to the name variants occurring at least five times in the source dataset. The BAC unit aims at attributing all variants to corresponding universities. However, mistakenly attributed name variants and non-identified variants were allowed to a maximum of 3%. The CTWS unit attributed the publications

[1]The title of a number of articles published in Nature in 2010 reflect this position: "Assessing assessment", "Do metrics matter?", "How to improve the use of metrics", "Let's make science metrics more scientific". Available at: http://www.nature.com/news/specials/metrics/index.html.

based on author names, a procedure not performed by the BAC. SCIMAGO provides no information on the unification in the website of the report.

A, data reported in the Leiden Ranking 2011/2012; **B**, number of publications estimated by BAC; **A-B**, magnitude of the difference between CTWS and BAC; (**A-B)/A**, percentage of change between CTWS and BAC; **C**, data reported in the Iberoamerican Ranking SIR 2012; **D**, number of publications estimated by BAC applying SCIMAGO criteria, but sourcing the analysis with the WOS; **C-D**; magnitude of the difference between SCIMAGO and BAC; (**C-D)/C**, percentage of change between SCIMAGO and BAC. 1; average; 2, standard deviation; 3, 95% confidence interval of the average. Acronyms: UB, Univ. de Barcelona; UAB, Univ. Autònoma de Barcelona; UCM, Univ. Complutense de Madrid; UPM, Univ. Politécnica de Madrid; UAM, Univ. Autónoma de Madrid; UV), Univ. de València; UGR, Univ. de Granada; USC, Univ. de Santiago de Compostela; US, Univ. de Sevilla; UPC, Univ. Politècnica de Catalunya; UZAR, Univ. de Zaragoza; EHU, Univ. del País Vasco.

2) Exactness of the unification. The CTWS unit estimated a 5% of false negative cases, while the BAC ensures a maximum percentage of error of 3%. SCIMAGO provides no information on this regard.

3) Proximity to the units under analysis. Two observations support the notion that local knowledge may explain a substantial part of the observed discrepancies: 1) the difference between SCIMAGO & BAC was smaller than between CTWS & BAC, and 2), SCIMAGO attributed more publications to their neighboring universities (UGR & US) than BAC, and vice versa in the case of the UB & UAB). A comparison of the number of publications of the Dutch universities between CTWS and BAC may shed some light on the effect that local knowledge or "regional peculiarities" (Moed, 1996) have on this indicator.

4) Delineation of the universities. The CTWS unit took into account "important university institutes" and changes in the structure of universities, while BAC took into account institutes, but also faculties, technical schools, locations, and structural changes. Failing to aggregate the publications of subunits could also explain the observed differences (de Mesnard, 2012).

5) Completeness and accuracy of the database (location of addresses). There is a difference between the sources used by the CTWS unit and BAC. The NCR may compile fewer records than the WOS, as addresses have to be located to Spain and errors are likely to happen during this process. This inconsistency may also play a lesser role in the comparison between CTWS and BAC.

Final considerations

Discrepancies in the number of publications of universities in the order of 10^2 or 10^3 are irrelevant when comparing the figures produced by different units. However, the magnitude of the difference might represent half of the output in some cases. Fortunately, the numbers of publications produced by the three units correlated pretty well, and the rankings were concordant. Technical issues can no longer be used as arguments to explain divergences of this magnitude, as none of the factors presented here are completely dependent on the technical capacity of a unit, rather than on procedural decisions: 1) completeness and 2) exactness of the unification, 3) knowledge of the surrounding environment, 4) completeness and accuracy of the source or 5) the type of document and period of time. The findings suggest that a consensus addressing these factors would do more in reaching a methodological "greatest common denominator" between the different units enabling improving the reproducibility of the indicators.

Semantometrics: Fulltext-based Measures for Analyzing Research Collaboration

Drahomira Herrmannova[1] and Petr Knoth[2]

[1] *d.herrmannova@open.ac.uk,* [2]*petr.knoth@open.ac.uk*

Introduction

The aim of this article is to demonstrate some of the possible uses of a novel set of metrics called *Semantometrics* in relation to the role of "bridges" in scholarly publication networks. In contrast to the existing metrics such as Bibliometrics, Altmetrics or Webometrics, which are based on measuring the number of interactions in the scholarly network, Semantometrics build on the premise that full-text is needed to understand scholarly publication networks and the value of publications.

Up to date many studies of scientific citation, collaboration and coauthorship networks have focused on the concept of cross-community ties (Shi et al., 2010; Guimerà et al., 2005; Silva et al., 2014). It has been observed that in citation networks, bridging or cross-community citation patterns are characteristic for high impact papers (Shi et al., 2010). This is likely due to the fact that such patterns have the potential of linking knowledge and people from different disciplines. Likewise, in collaboration and coauthorship networks, it has been shown that newcomers in a group of collaborators can increase the impact of the group (Guimerà et al., 2005).

The studies up to date have been focusing on analysing citation and collaboration networks without considering the content of the analysed publications. Our work has focused on analysing scholarly networks using semantic distance of the publications in order to gain insight into the characteristics of collaboration and communication within communities. Our hypothesis states that the information about the semantic distance of the communities will allow us to better understand the importance and the types of the cross-community ties (bridges).

More specifically, in order to gain insight into the type of collaboration between authors we are currently investigating the possibility of utilising semantic distance in a coauthorship network together with the concept of *research endogamy*. In social sciences, endogamy is the practice or tendency of marrying within a social group. This concept can be transferred to research as collaboration with the same authors or collaboration among a group of authors. The concept of research endogamy has been previously used to evaluate conferences (Montolio et al., 2013) as well as journals and patents (Silva et al., 2014).

Furthermore, in (Knoth & Herrmannova, 2014) we have introduced and tested the first Semantometric measure which we call *contribution(p)* and which can be used to estimate research publication contribution. Our results suggested that measuring semantic similarity of publications can be utilised to provide meaningful information about the value of a research publication, which is not captured by traditional bibliometric measures.

Types of research collaboration in a coauthorship network

We are currently investigating the possibility of combining semantic distance and research endogamy in the publication's collaboration network. The rationale behind this approach is based on how research collaboration happens. In case the authors of a publication come from different disciplines, their research is likely to link the two disciplines and to build a bridge between them. This bridge can help to provide vision and ideas otherwise unseen and help to transfer knowledge between the disciplines.

We propose to measure the semantic distance of coauthors of a publication based on semantic distance of all pairs of the coauthors, where the distance of a pair of authors can be expressed similarly as the *contribution(p)* measure (Knoth & Herrmannova, 2014). This situation is depicted in Figure 1, where the sets A and B correspond to the publication records of the two authors.

Table 1. Types of research collaboration based on semantic distance and research endogamy.

	High endogamy	**Low endogamy**
High distance	Established interdisciplinary collaboration	New interdisciplinary collaboration
Low distance	Expert group	New expert collaboration

In order to distinguish between emerging, short-term and established research collaboration, we propose to combine the semantic distance with research endogamy value of the publication as defined in (Silva et al., 2014). We assume that based on the combination of semantic distance and research endogamy the types of research

collaboration can be divided into four groups (Table 1).

We believe this classification is a useful tool in characterising the types of research collaboration that goes beyond the traditional understanding of the concept of bridges as used in scholarly communication networks. While semantic distance allows distinguishing between inter- and intra-disciplinary collaboration, research endogamy allows differentiating between emerging and established research collaborations.

Using semantic distance to measure research contribution in a citation network

A similar Semantometric approach based on the concept of semantic distance can be applied in citation networks. We have used this approach in (Knoth & Herrmannova, 2014) to develop a measure which we call *contribution(p)*. This measure is based on a hypothesis, which states that the added value of publication *p* can be estimated based on the semantic distance from the publications cited by *p* to the publications citing *p*. This situation is depicted in Figure 1.

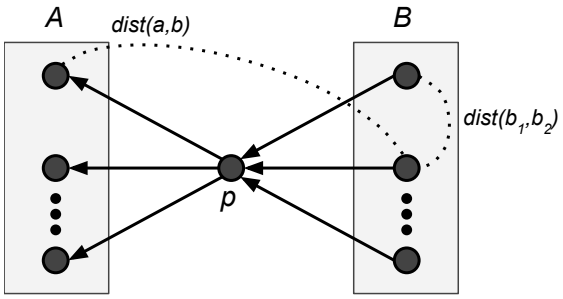

Figure 1. Explanation of contribution(p) calculation.

This hypothesis is based on the process of how research builds on the existing knowledge in order to create new knowledge on which others can build. A publication, which in this way creates a bridge between existing knowledge and something new, which will be developed based on this knowledge, brings a contribution to science. A publication has a high contribution if it connects more distant areas of science. Building on these ideas, we have developed a formula, which can be used for assessing research contribution of a publication. In order to adjust the contribution value to a particular domain and publication type, the metric uses a normalisation factor, which is based on the semantic distance of publications within the set of publications citing *p* and the publications cited by *p*. The measure and our experiments are in detail described in (Knoth & Herrmannova, 2014).

Conclusion

In this paper we proposed to apply the Semantometric idea of using full-texts to recognise types of scholarly collaboration in research coauthorship networks. We have applied semantic distance combined with research endogamy to classify research collaboration into four broad classes. This classification can be useful in research evaluation studies and analytics, e.g. to identify emerging research collaborations or established expert groups. Furthermore, we have presented another Semantometric measure, which we call *contribution(p)* and which is based on the idea of the importance of bridges in a citation network.

While bridges have been the concern of many research studies, their identification has been limited to the structure of the interaction networks. In contrast to these approaches, our approach takes into account both the interaction network (coauthorship, citations) as well as the semantic distance between research papers or communities. This provides additional qualitative information about the collaboration, which hasn't been previously considered.

Uncovering the Mechanisms of Co-authorship Network Evolution by Multirelations-based Link Prediction

Jinzhu Zhang, Chengzhi Zhang, Bikun Chen

{zhangjinzhu, zhangcz,chenbikun}@njust.edu.cn
Nanjing University of Science and Technology, Dept of Information Management, Xiaolinwei Str 200, Nanjing (China)

Introduction and literature review

Co-authorship network, a proxy of research collaboration, reveals the collaboration patterns and the determining factors through social network analysis perspective, with nodes representing authors and links representing co-authorships (Ortega, 2014; Yan & Ding, 2009). If we know what mechanisms push the evolution of co-authorship network, we could predict which authors may collaborate in future.

Most of the studies correlate co-authorship evolution mechanisms to similarity indicators which quantitatively compared by link prediction in homogeneous network (Lu & Zhou, 2010). In order to integrate multirelations between authors, path-based similarity indicators are proposed for co-authorship prediction in DBLP heterogeneous network (Sun et al., 2011; Sun & Han, 2013). However, what is the role of each mechanism plays and how to combine multiple mechanisms to suit the co-authorship network evolution need to be clarified, moreover, the method need to be verified in different domains.

Therefore, we integrate similarity indicators based on multirelations in heterogeneous network and quantitatively evaluate them by link prediction justly, to uncover and infer the mechanisms of co-authorship network evolution. Firstly, similarities between authors are represented by a matrix where the rows are multirelations and the columns are multirelations' measures. Secondly, the evaluation of similarities is processed based on link prediction, to reveal the importance of each mechanism which is the weight for combining multiple mechanisms. Finally, experiments are presented in the domain of Library and Information Science (LIS), which reveals the best appropriate mechanism, the significance of each mechanism and the combination strategy of different mechanisms.

Data and method

Data

We collect the data from the SCIE (Science Citation Index Expanded) databases in Thomson Reuters' Web of Science, using journal publications on subject category of LIS across 2000 to 2009.

We choose the authors that the frequency greater than or equal to five as the experiment data, which includes 669 authors, 3,948 articles, 6,476 keywords, 14 subject categories, 29 journals and 79,717 references.

We eliminate the subject categories because of too small numbers and references because of computing complexity. The co-author network has 1052 edges that indicate co-authorship, where we randomly choose 946 (90%) edges as training set and the remaining 106 edges as the testing set.

Multirelations-based link prediction

(1) Representation of co-authorships via multi-relations: Co-authorships via multirelations are systematically represented and extracted in a heterogeneous bibliographic network shown in Figure 1. Part of multirelations between authors could be represented in Table 1.

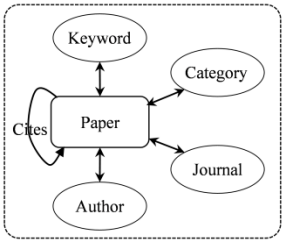

Figure 1. The nodes and relations in heterogeneous bibliographic network.

Table 1. Multirelations between authors.

Relations	*Description*
A-P-A-P-A	Common neighbours
A-P-A-P-A-P-A	Common neighbours' neighbours
A-P-J-P-A	Publish paper at the same journal
A-P-K-P-A	Authors have the same keyword
A-P-K-P-K-P-A	Authors' keywords co-word in same paper
A-P→P-A	Author x cite author y
A-P←P-A	Author x is cited by author y
A-P→P←P-A	Authors x and y cite the same paper
A-P←P→P-A	Authors x and y co-cited by same paper
A-P→P→P-A	Author x cite the paper that cite author y
A-P←P←P-A	The reverse relation of the above

(2) Measures of each relation: The four measures are the follows: path count (PC) is the number of

shortest path between two authors, normalized path count (NPC) is to discount PC by their overall connectivity, random walk (RW) and symmetric random walk (SRW) (Sun & Han, 2013).
(3) Evaluation of similarities based on link prediction: The relations and their measures combine the similarities, so there are 44 similarity indicators combined by 11 relations with four measures. We evaluate all the similarity indicators based on link prediction with precision and area under the curve (AUC).

Results

The three comparison perspectives are: (1) from the horizontal axis, compare which relation is best appropriate to the mechanism. (2) From the longitudinal axis, compare which measure is best to describe the mechanism. (3) Comparison between combined-relations-based and single-relation-based mechanisms.

The evolution mechanisms based on single-relation-based similarities

In Table 2 and Table 3, the entries emphasized in bold and italic corresponding to the highest accuracies from the horizontal axis.
In precision, the APAPA with NPC is the best appropriate and important mechanism in LIS where NPC plays the best in four measures, yet the APJPA with RW plays the worst. In AUC, the APAPA with SRW is the best mostly with little differences. There is lots of information loss in the projection from heterogeneous network to homogeneous network compared with CNs.

Table 2. The precision/AUC of single-relation-based similarities.

Relations	*PC(%)*	*NPC(%)*	*RW(%)*	*SRW(%)*
APAPA	38.4/87.5	***42.5***/87.5	31.7/87.7	41.4/***87.9***
APAPAPA	24.0/***86.2***	***32.9***/86	21.1/***86.2***	29.4/85.8
APJPA	3.2/76.8	***3.9***/77.2	0.9/76.7	2.6/***77.4***
APKPA	7.6/81.4	***20.4***/82.1	9.4/81.8	16.3/***82.3***
APKPKPA	2.2/70.8	***4.9/72.5***	2.5/70.9	4.3/72
CNs	23.4/84.1			

Comparison between combined-relations-based and single-relation-based mechanisms

The paper designs five combination strategies for comparison: (1) CR1: Combination of all relations without weights. (2) CR2: Combine all relations except APJPA. (3) CR3: Combination of all relations with weights denote by precision in Table 2. (4) CR4: the combination formed via just authors which is APAPA+APAPAPA. (5) CR5: the combination formed via just keywords, which is APKPA+APKPKPA. The precision and AUC are listed in Table 3.
In precision, the CR3 with NPC is the most appropriate and important mechanism in LIS where NPC plays the best in four measures, yet the CR5 with PC plays the worst. The AUC is consistent with the precision result mostly and others with little differences. The CR2 and CR3 with each measure are all outperformed the single-relation-based mechanisms. The CR4 performs much better than CR5 proves that in co-authorship formation the author is more important than research interest.

Table 3. The precision/AUC of different combinations of relations.

Relations	*PC(%)*	*NPC(%)*	*RW(%)*	*SRW(%)*
CR1	28.6/86.4	**40.8/88.6**	26.3/88.4	36/88.3
CR2	38.6/84.8	**43.7/87.4**	32.4/86.4	43.6/86.8
CR3	45.1/89.1	**49.2**/89.3	39.8/89.0	47.2/**89.5**
CR4	24.2/86	**38.6/86.4**	27.1/86.2	35.3/86.1
CR5	2.2/80.6	**16.7**/82.8	6.6/**83.1**	12/82.7

Conclusion and discussion

This paper uncovers the mechanisms of co-authorship network evolution by multirelations-based link prediction in LIS. In the next, we will consider other factors that influence research collaborations, all relations especially related to references to enhance the accuracy and validation in two or more different areas with different article types (e.g., journal and conference).

Citing e-prints on arXiv
A study of cited references in WoS-indexed journals from 1991-2013

Valeria Aman[1]

[1] *aman@forschungsinfo.de*
iFQ - Institute for Research Information and Quality Assurance, Schützenstraße 6a, 10117 Berlin (Germany)

Abstract

This study deals with the analysis of cited references in Web of Science (WoS) to e-prints on arXiv. Created in 1991, arXiv accelerated the scholarly communication and developed into a well-established e-print repository that functions as an essential access point to the latest research in physics, astrophysics, mathematics, computer science and related fields. Authors evidently rely on arXiv full texts and refer to them in their own research papers. These cited references to arXiv that represent the acceptance of e-prints in journals and series indexed in WoS are tackled in this paper. A total of 900,000 cited references to arXiv have been identified for the 1991-2013 period. Object of investigation is on the one hand the set of cited references to arXiv, and on the other hand the set of papers in WoS that cite arXiv. Among other things, the paper illustrates that citations to arXiv peak in the year after submission and drop rapidly. The geographical distribution of authorship citing arXiv in their papers shows that authors from the US, Germany, GB, France and Italy rely heavily on arXiv. The paper identifies "arXiv-friendly" journals where the majority of articles refer to arXiv.

Conference Topic
Journals, databases and electronic publications

Introduction

The arXiv is a convenient vehicle to disseminate research results prior to the publication of peer-reviewed articles. It is also common to submit postprints for reasons of wide availability and archiving. There is no doubt that e-prints are read by a wide community and are regarded to be of good quality. Thus, it is of interest to learn more about the perception of arXiv as a source of relevant information that supports researchers' ideas and discoveries. The study sets out to answer the following questions: 1) Do authors publishing in journals covered by Web of Science (WoS) cite e-prints on arXiv? 2) What characteristics in citations can be observed? 3) In which countries are authors situated that rely on e-prints in arXiv? 4) What are the journals that include the highest rate of articles with cited references to arXiv?

Background

The rise of preprints, e-prints and arXiv

There are several definitions for the term "preprint". Lim (1996) defines a "preprint" as a manuscript that has been reviewed and accepted for publication, a manuscript that has been submitted for publication, but for which a decision to publish has not been made yet, or a manuscript that is intended for publication, but is being circulated for comments among peers prior to journal submission. Electronic prints (e-prints) refer both to preprints and post-prints (peer-reviewed published papers), and other documents that are made available on the Internet. The "preprint culture" dates back to the 1960ies, when high-energy physicists were eager to disseminate their results by printing and mailing copies of their manuscripts simultaneously to journal submission (Goldschmidt-Clermont, 1965). The time consuming process of peer-review was hence effectively bypassed. With the advent of the World Wide Web in the early 1990ies, the emergence of new methods of scientific discourse were encouraged, altering the traditional channels of scholarly communication (Brown, 2001).

In summer 1991, Paul Ginsparg conceived the repository arXiv at the Los Alamos National Laboratoy (LANL) in New Mexico. Ginsparg (1994, p.157) stated that "the realization of arXiv was facilitated by a pre-existing 'preprint culture', in which the irrelevance of refereed journals to ongoing research has long been recognized". Ginsparg (1994, p.159) designed arXiv (formerly xxx.lanl.org) as a fully automated system, where users could maintain a database to disseminate information without outside intervention.

Originally, arXiv was intended for the High-Energy Physics (HEP) community, but expanded rapidly to cover all of Physics, Astrophysics, Mathematics and Computer Science. Since September 2003 arXiv covers Quantitative Biology. In April 2007 Statistics was included, followed by Quantitative Finance in December 2008. Today, arXiv is hosted at Cornell University in New York with seven mirror sites all over the world. It contains more than 1,000,000 full-text e-prints, receiving about 9,000 new submissions each month.[1] Researchers can check arXiv for new information, search for relevant papers, post their own papers and cite references by arXiv ID. It is a self-organizing publication mode that costs the users nothing (Langer, 2000). Another reason for arXiv's popularity is its democracy, because scientists "can post their research results without being hassled by grumpy editors and referees" (ibid., p.35). According to Ginsparg (1994, p.157) physicists have learned to determine from the author, title and abstract whether to read a paper "rather than rely on the alleged verification of overworked or otherwise careless referees".

Nowadays, researchers still regard it as valuable to publish their work in peer-reviewed journals. Prior to formal publication, the findings may be spread as conference proceedings, reports, working papers or preprints. As Heuer, Holtkamp and Mele (2008, p.2) point out "scientists expect unrestricted access to comprehensive scientific information in their field, state-of-the-art information venues to optimize their research workflow and quality assurance at the parallel existence of traditional peer-review and the immediacy of dissemination and feedback". A publication delay of several months between the completion of a work and its appearance in a peer-reviewed journal is simply a "negative phenomenon in scientific information dissemination" (Amat, 2008, p.379). Amat (ibid.) found that the publication delay depends primarily on the peer-review process (see also Luwel, 1998). ArXiv serves to overcome this delay and helps to circulate results upon realization.

Previous work

The citation behaviour of e-prints available through arXiv has been studied extensively. Youngen (1998) identified the growing importance of e-prints in the published literature. He found that e-prints became the first choice among physicists and astronomers for finding current research and keeping up with colleagues and competitors at other institutions. Brown (2001) studied citations of e-prints on arXiv in astronomy and physics journals from 1998 to 1999. The citation analysis showed that the peak of citations to e-prints is reached after three years, which is comparable to papers in print journals. Garner, Horwood & Sullivan (2001) determined the place of e-prints in the scholarly information delivery, concluding that rapid dissemination of results in form of preprints establishes priority and enables rapid feedback. Brown (2003) asked for the opinion of chemists about citing e-prints in the articles they author. Fifty-two percent said they would cite e-prints whenever possible, whereas 48% stated that they would not. Reasons for avoiding to cite the Chemistry Preprint Server (CPS) are the lack of relevant articles, the lack of customary to cite, and the lacking awareness of CPS (ibid., p.365). The study of infiltration of CPS e-prints into the literature of chemistry revealed that "no citations to e-prints were found in the journal literature using ISI's Web of Science from 2000 to 2001" (ibid., p.366). Prakasan & Kalyane (2004) focused on the

[1] http://arxiv.org/stats/monthly_submissions / [Last visited January 06, 2015]

citations in Science Citation Index to e-prints on arXiv, submitted under the four categories hep-ex, hep-lat, hep-ph and hep-th[2], providing a broad insight into citation habits.

Several studies focused on the citation impact of e-prints on arXiv, also within the Open Access debate (see Harnad & Brody, 2004; Antelman, 2004). Schwarz & Kennicutt (2004) analyzed articles published in the Astrophysical Journal in 1999 and 2002 and reported that papers posted to the astro-ph-section on arXiv were cited more than twice as often as those without a version on arXiv. In accordance, Metcalfes (2005) findings show that astronomy papers in the highly-cited journals Science and Nature received higher citation rates when their authors posted their papers on arXiv's astro-ph. Metcalfe (2006) studied the field of solar physics with the result that papers posted to arXiv are on average 2.6 times as often cited as papers not being posted. He concludes that higher citation rates are not a result of self-selection of outstanding papers, since conference proceedings reveal the same result. Moed (2007) analyzed how the citation impact of articles deposited in the Condensed Matter section in arXiv and subsequently published in a journal compares to that of articles not deposited on arXiv. He concluded that arXiv accelerates citations, because it makes papers earlier available. Davis & Fromerth (2007) examined whether mathematics journals from 1997 to 2005 with a previous preprint version on arXiv receive more citations than non-deposited. Their findings show that articles in arXiv receive on average 35% more citations, which translates to 1.1 citations per article. They explain the citation advantage with the Open Access, the Early View, and the Quality postulates, which are non-exclusive.

Henneken et al. (2007) analyzed whether e-prints on arXiv are preferred over the journal articles in four core journals in astrophysics. They found that as soon as an article is published, the community prefers to read and cite it, so that the usage in the NASA Astrophysics Data System (e-print system) drops to zero. They also showed that the half-life (the time at which the use of an article is half the use of a newly published article) for an e-print is shorter than for a journal article. Gentil-Beccot, Mele & Brooks (2009) investigate whether HEP scientists still read journals or rather prefer digital repositories. Their citation analysis shows that free and immediate dissemination of preprints results in a citation advantage for HEP journals. Furthermore, their analysis of clickstreams reveals that high-energy physicists prefer preprints and seldom read journals.

Some of the studies suggest that articles with a previous preprint on arXiv receive more citations than articles without. Other studies report no such effect. Gentil-Beccot, Mele & Brooks (2009) did not detect any citation advantage from publishing in Open Access HEP journals. Their finding is similar to that of Moed (2007) in Condensed Matter, Davis (2007) in Mathematics and Kurtz & Henneken in Astrophysics (2007).

Brody, Harnad & Carr (2006) examined the correlation of the number of article downloads and the number of citations. On the basis of arXiv they show that the short-term Web usage impact of e-prints predicts a medium-term citation impact of the final article. Haque and Ginsparg (2009; 2010) found that e-prints posted to arXiv at the beginning and end of a day reach a wider readership and receive higher citation rates over the course of ensuing years than posting in the middle of day. Shuai, Pepe & Bollen (2012) analyzed the online response to preprint publications on arXiv, studying the delay of article downloads and Twitter mentions following submission.

Larivière et al. (2014) analyzed the proportion of papers across all disciplines on arXiv for the 1991-2012 period, just as the proportion of arXiv papers that are published in WoS-indexed journals. They determine the time between arXiv submission and journal publication, ageing characteristics and impact of arXiv e-prints and their published alter ego. They also focus on

[2] High energy physics - experiment (hep-ex), high energy physics - lattice (hep-lat), high energy physics - phenomenology (hep-ph), and high energy physics - theory (hep-th).

the proportion of cited references in WoS to arXiv e-prints by discipline. Working with percentages, they quantify that journals in nuclear and particle physics have 6.6% of their references to arXiv e-prints, whereas in mathematics this share is below 1.5% (ibid., p.1163). Stimulated by the work of Larivière et al. (2014), this study sets out to quantify the number of cited references in WoS to arXiv manuscripts, and to provide a broader view on characteristics of cited references and the papers that include them.

Data and methods

Database

The study builds upon the bibliometric database at the "Competence Center for Bibliometrics for the German Science System" that is hosted at the iFQ.[3] It consists of data from Thomson Reuter's Web of Science. Peer-reviewed journal articles are the primary mode of communication of scientific research. Researchers write reviews or articles with discoveries, theories and results. To relate their work they cite other articles if they know the article and believe it to be relevant to their own work. They might also provide negative citations in order to disagree or to say that a paper has flaws (see Brody, Harnad & Carr, 2006). Citations can be therefore used as a measure of influence and importance of preceding articles.

The identification of references to arXiv depends on the quality of the bibliographic information (e.g. the presence of the reference to arXiv) and the extent to which WoS was able to parse the references of the citing articles. Identifying cited references to arXiv can lead to false positives, when a reference looks like an arXiv identifier but is actually not, or where authors make mistakes. A linking by bibliographic data is more precise as it builds upon author names, journal title, volume, page number, year of publication etc.

Data collection

Different from Youngen (1998), who analyzed those cited references that state explicitly "preprint" in ISI's SciSearch (p.451), this study also includes postprints. Hence, all manuscripts on arXiv are in the following referred to as "e-prints". The e-print identifier assigned by arXiv provides a standardized number that allows each e-print to be uniquely identified. This uniqueness is required for correct citing of the work. ArXiv has established a subject grouping and numbering system for submitted e-prints. Examples are Astrophysics (astro-ph), Condensed Matter (cond-mat), High-Energy Physics-Theory (hep-th) or Nuclear-Experiment (nucl-ex), followed by a numerical string, indicating the year and month of submission, and an increasing accession number. A typical example is quant-ph/95002, where quant-ph stands for Quantum Physics, "95" for the year 1995 and "002" for the accession number. Up to March 2007 this ID enabled a broad subject categorization. In April 2007, the arXiv-ID was changed and no longer contains subject categories. It consists of eight digits, of which the first four represent the year and month of submission. Divided by a period, they are followed by a four-digit long accession number, e.g.: arXiv: 0705.0002. We can infer that this e-print was loaded in May 2007. Since the accession number will soon reach its capacity, the length of the accession number has been extended by one digit in January 2015.[4]

The search for arXiv e-prints in the cited reference field in WoS was approached in several steps. E-prints up to 2007 were identified on the basis of an alphanumeric string that contains the subject category followed by the year of submission and the accession number.[5] E-prints published in 2007 or later were identified by the string "arXiv" followed by a numerical string. This led to an overall satisfying result, since the string "arXiv" is unique and causes

[4] http://arxiv.org/new#dec19_2014 [Last visited January 06, 2015]
[5] The categories in bold print were used for the matching: http://arxiv.org/ [Last visited January 06, 2015]

almost no confusion. A low number of false positives cited references were deleted manually. Only one in four cited references had a publication year assigned, which is indeed not necessary, since it is part of the arXiv ID. With the application of Regular Expressions in SQL the year of e-print publication was deduced for more than 99% of cited references. A publication year was not deducible, where authors cited arXiv simply in this fashion: "arXiv". The search strategy may not include citations to works that technically have to be considered as arXiv e-prints. According to Youngen (1998, p.451) authors may have cited preprints as "submitted to...", "to be published in...", "in press" or "unpublished", depending on their state in the publication cycle. Thus, in reality, the number of citations to e-prints on arXiv may be much higher than presented here.

Data corpus[6]

With the search strategy described, 892,867 cited references to arXiv were identified for the 1991-2013 period, of which 357,557 have a distinct character string. Due to multiple subject categorizations in arXiv, author typos, or erroneous data parsing in WoS, one and the same e-print can be referred to in different spelling variants. Hence, the actual number of arXiv e-prints cited in the 1991-2013 period by papers in WoS is lower. At the same time 289,145 distinct papers were identified in WoS that constitute these 892,867 cited references. To relate these figures, Brown (2001) found 35,928 citations to arXiv e-prints (posted between 1991 and 1999) in astronomy and physics journals published in 1998-1999. In the following, analyses are based on the cited references to arXiv and the WoS-papers that include them.

Results and discussion

Figure 1 provides an overview of the data collected. The number of e-prints submitted to arXiv has been gradually rising from 303 in 1991 to 92,641 in 2013.[7] The number of papers in WoS citing at least one e-print on arXiv has steadily increased and comprises around 28,000 papers in 2013. In addition, we can see the number of cited references to e-prints on arXiv with the publication year of the citing paper as indicated on the x-axis. We can derive that a paper citing arXiv includes on average more than one citation to e-prints on arXiv. Most of the citations to e-prints were provided in 2012 (ca. 76,000).

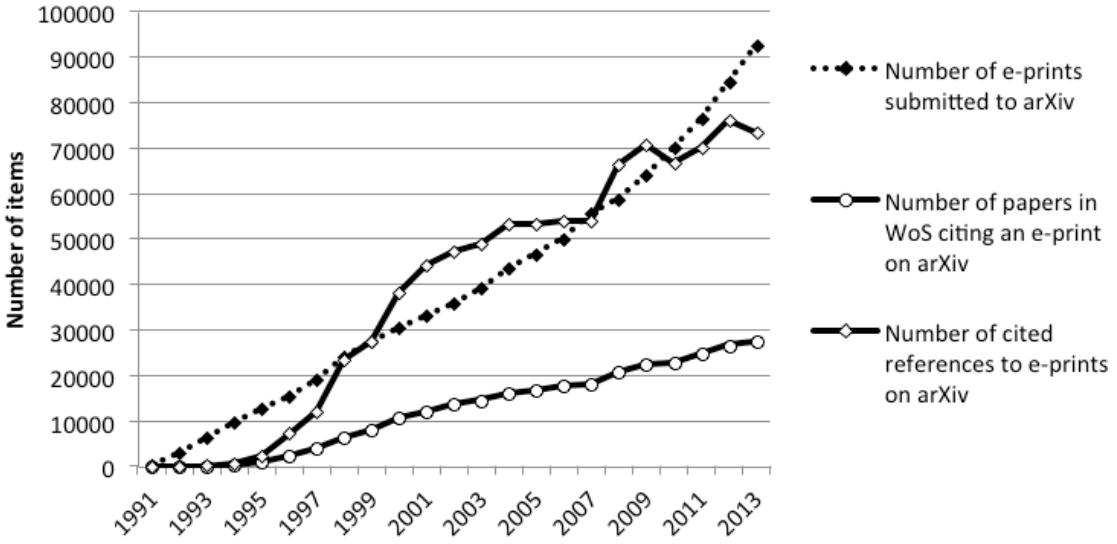

Figure 1. Overview of the yearly growth of submissions to arXiv, the number of papers in WoS citing arXiv e-prints according to their publication year, and the number of cited references.

[7] http://arxiv.org/stats/monthly_submissions [Last visited January 06, 2015]

The analysis of document types shows that articles rank first with 96.0% of all WoS documents from 1991-2013 that cite arXiv. Reviews (3.2%) refer to arXiv as well, in order to provide a broad or up-to-date state of research. Editorials, Letters, Corrections and Notes also reference arXiv.

In the following, it does make a difference whether cited references are analysed or the WoS-papers that include those. Due to different citation habits, even within a broad field such as physics, it appears more suitable to consider primarily the citing papers. Table 1 provides an overview of the subject areas that constitute most of the citations to arXiv. The first column lists the Subject Categories[8] (SC) in WoS in a descendant order, regarding the number of arXiv citing papers assigned to this SC. We can see that Particle Physics ranks first (21%), followed by Astronomy and Astrophysics. In total, these 12 SC cover more than 90% of all citing papers that refer to arXiv between 1991 and 2013. The percentages and order of the SC changes when we have a look on the number of cited references to arXiv. Particle Physics still ranks first, claiming almost one-third of all cited references to arXiv. The results suggests that papers in Particle Physics have on average a higher number of cited references to arXiv than those in other SC.

Table 1. Overview of Subject Categories in WoS that contribute to the majority of papers that cite arXiv and their number of cited references. The data is based on 289,145 arXiv-citing papers in WoS that provide 892,867 cited references in 1991-2013.

Subject Category	No. of papers citing arXiv	Share in %	No. of cited references	Share in %
Physics, Particles & Fields	88,757	21.0	398,022	30.5
Physics, Multidisciplinary	70,383	16.7	248,091	19.0
Astronomy & Astrophysics	68,805	16.3	225,326	17.3
Physics, Mathematical	28,073	6.7	82,490	6.3
Physics, Condensed Matter	25,658	6.1	49,852	3.8
Mathematics	23,894	5.7	46,952	3.6
Physics, Nuclear	22,838	5.4	83,712	6.4
Optics	13,602	3.2	27,414	2.1
Physics, Atomic, Molecular & Chemical	12,754	3.0	25,625	2.0
Mathematics, Applied	10,976	2.6	20,169	1.5
Physics, Applied	9,223	2.2	17,099	1.3
Physics, Fluids & Plasmas	5,704	1.4	9,488	0.7

This leads us to the analysis of the distribution of cited references among the papers in WoS that cite arXiv. Table 2 illustrates the frequency of citing papers in WoS that include as many cited references as stated in the left column. We can see that six papers in WoS have more than 200 references to arXiv in their list of references. Every eleventh paper, out of the set of arXiv citing papers, includes 6 to 10 references to arXiv. Nevertheless, around 46% of citing papers provide a single reference to arXiv. A closer look on the paper with the highest number of cited references to arXiv shows that it is a review article from 2000 on String Theory and Gravity, where a link to arXiv was set additionally to the journal article reference. This brings us to the analysis of characteristics in citations to arXiv. Are e-prints on arXiv immediately cited when there is no corresponding journal article or are they also used in future and even preferred over the corresponding journal article?

[8] The 260 SC in WoS are assigned to journals on the basis of their scope and citation links.

Table 2. Distribution of cited references among WoS-papers that cite e-prints on arXiv.

Number of references to arXiv in a single paper	Number of papers citing arXiv	%
more than 200	6	0.00
151 to 200	8	0.00
101 to 150	29	0.01
51 to 100	222	0.08
21 to 50	2,567	0.89
11 to 20	9,375	3.24
6 to 10	25,859	8.94
5	12,544	4.34
4	18,939	6.55
3	30,969	10.71
2	56,204	19.44
1	132,423	45.80
Total	289,145	100.00

Figure 2 shows on the one hand the line graph of all citations to e-prints on arXiv up to 2013. Different from Figure 1 the x-axis signifies the year of e-print publication. Thus, the sudden decrease of cited e-prints from 2008 on is due to the fact that they had less time to be referenced than those posted in earlier years. In addition, Figure 2 provides bars indicating the years in which these e-prints were cited by WoS papers. Each bar represents the number of cited references to arXiv in the same year as the e-print was published, the subsequent year and two and three years respectively after publication of the e-print. The space between the line graph and the bars represents the cited references to e-prints that were provided more than three years after e-print publication. Since e-prints from recent years did not have much time to be cited, the bars coincide with the line graph of the total number of cited e-prints.

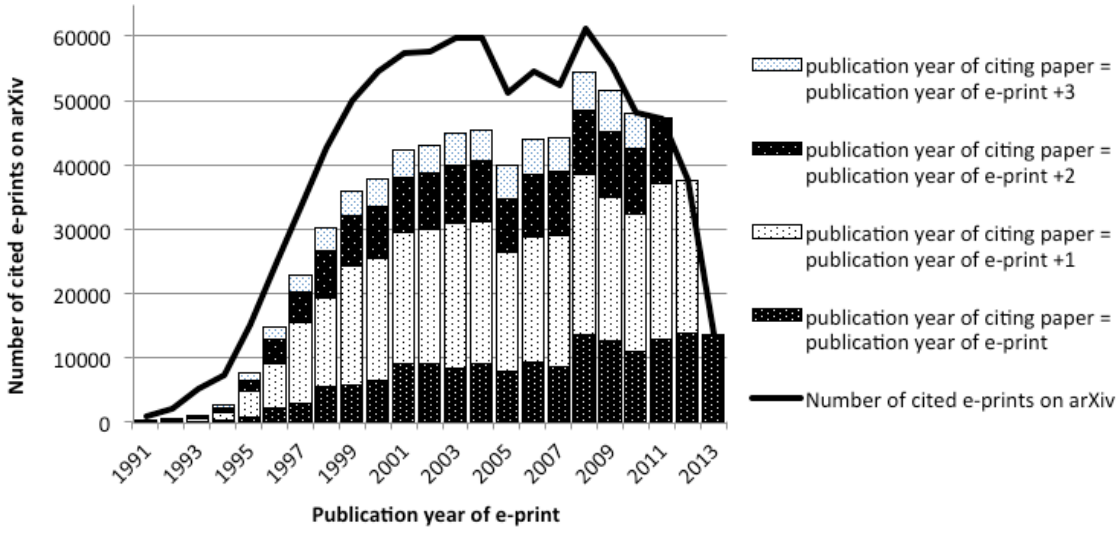

Figure 2. Time series of citation distribution. Illustrated are citations that equal the year of e-print submission, citations to e-prints that are one year old, up to the age of three years. The line graph signifies the total number of e-prints cited, published in the year as indicated.

It becomes evident that e-prints on arXiv are mostly cited in the subsequent year of e-print post. Almost half of all cited references in a year relate to e-prints that were placed on arXiv the preceding year. This is in accordance with Larivière et al. (2014, p.1166), who found that citations to e-prints on arXiv peak the year following submission. The figure also indicates that e-prints are cited immediately in the same year of posting. Only a small share of cited

references points to three-year old e-prints. On the contrary, Brown's (2011) analysis in astronomy and physics showed that the peak of citations to e-prints is reached after three years. The results in Figure 2 are in little accordance with Henneken et al. (2007, p.19) who showed that the usage of e-prints drops to zero as soon as the journal article has appeared, suggesting that authors have access to subscribed journals and prefer to cite the refereed version. Garner, Horwood & Sullivan (2001, p.251) quantified that 90% of papers on arXiv are later published in journals so that a corresponding article can be found and cited properly.

Nevertheless, there are many reasons that underscore the high citation rates of e-prints. Davis & Fromerth (2007) write that the arXiv copy is sufficient for the purpose of citing it in one's own work. They found that articles that are also accessible on arXiv receive 23% fewer downloads from the publisher's web site two years after publication (ibid., p.23). Gentil-Beccot, Mele & Brooks (2009) found that citations start before publication, because scientists in HEP do not wait for an article to be published. Even in the first few months after journal publication authors read and cite the preprint (ibid., p.6). According to Moed (2007) colleagues start to read a paper and cite it in their own articles earlier if it is deposited on arXiv. The following Figure 3 illustrates the relation between the publication year of a WoS-paper citing arXiv, and the publication year of the cited e-print. The whole bar in each year (y-axis) represents the total number of cited references to e-prints on arXiv from this year (cf. Figure 1). The cited references from each year are grouped by the publication year of the cited e-print. Each bar indicates the share of e-prints, according to their year of publication. For the year 2013 we can see that 13,000 cited references (top black part of the 2013-bar) refer to e-prints published in the same year. The lion's share of cited references in 2013 (24,000) is to e-prints published in 2012. In general, we can conclude from Figure 3 that the majority of references in each year points to e-prints published in the preceding year.

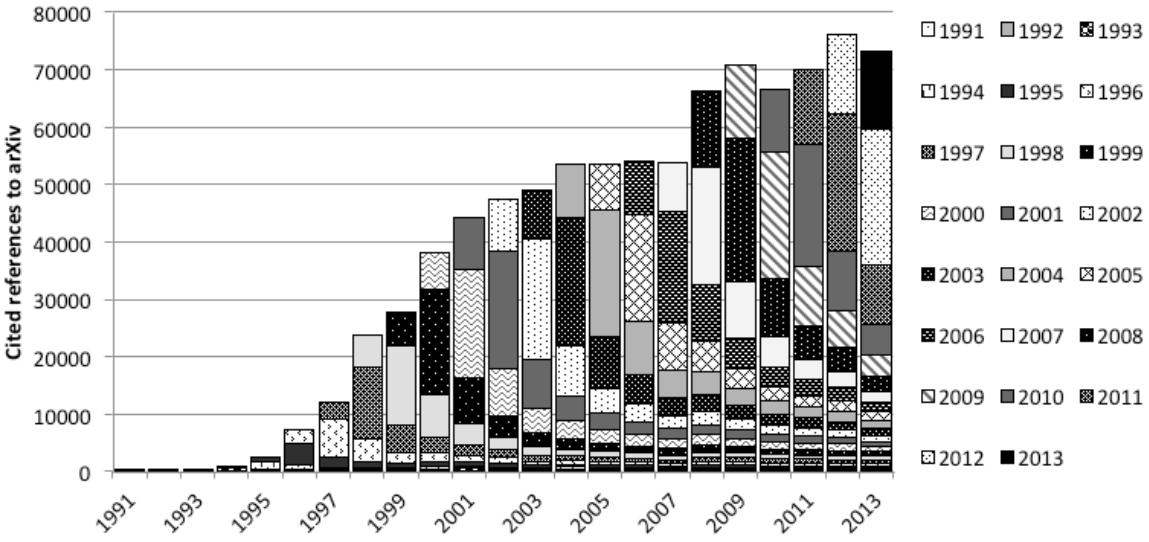

Figure 3. Time series of cited references to e-prints on arXiv. The x-axis represents the publication years of WoS-paper citing an e-print, whereas each bar represents the share of the years a cited e-print was published in.

To see where the authors that frequently cite arXiv are from, Table **3** provides a ranking of countries according to the highest number of papers in WoS with at least one cited reference to arXiv. USA rank first with one-third of all papers that cite arXiv. They are followed by Germany and Great Britain. Note that the percentages do not add up to 100, since co-authored papers can be attributed to multiple countries.

Table 3. Overview of countries that most frequently cite arXiv e-prints. The percentages are calculated on the basis of the total number of citing papers (289,145).

Rank	Country	No. of WoS-papers citing e-prints	%	Rank	Country	No. of WoS-papers citing e-prints	%
1	USA	97,085	33.6	11	Switzerland	14,489	5.0
2	Germany	45,842	15.9	12	India	11,764	4.1
3	GB	30,776	10.6	13	Poland	9,332	3.2
4	France	28,159	9.7	14	Brazil	9,004	3.1
5	Italy	27,896	9.6	15	Netherlands	8,361	2.9
6	China	25,467	8.8	16	South Korea	8,271	2.8
7	Japan	25,196	8.7	17	Australia	7,296	2.5
8	Russia	22,772	7.9	18	Israel	7,019	2.4
9	Spain	15,902	5.5	19	Sweden	5,402	1.9
10	Canada	14,879	5.1	20	Belgium	4,709	1.6

The journals whose articles most often cite e-prints on arXiv are identified in Table 4. On the left of the table, journals are ranked according to their number of citing papers in the 1991-2013 period. On the right of the table journals are ranked according to their number of cited references to arXiv. Evidently, most of the journals carry a majority of HEP content. Among these are *Physical Review D*, *Journal of High Energy Physics* (JHEP), *Physics Letters B* and *Nuclear Physics B*. Striking are also the astrophysical journals, among which we can find the *Astrophysical Journal, Monthly Notices of the Royal Astronomical Society* and *Journal of Cosmology and Astrophysical Physics*.

Table 4. Overview of journals in WoS with the highest number of papers citing arXiv and journals with most of the cited references to arXiv in the 1991-2013 period.

Journal	Citing papers	%	Journal	Cited ref.	%
Physical Review D	30,287	10.5	Physical Review D	112,261	12.6
Physical Review B	15,080	5.2	Journal of High Energy Physics	77,431	8.7
Journal of High Energy Physics	14,881	5.1	Physical Review B	66,750	7.5
Physical Review Letters	13,816	4.8	Nuclear Physics B	50,757	5.7
Physics Letters B	13,707	4.7	Physics Letters B	29,195	3.3
Physical Review A	9,599	3.3	Physical Review Letters	28,873	3.2
Astrophysical Journal	8,428	2.9	Classical and Quantum Gravity	22,969	2.6
Nuclear Physics B	8,033	2.8	Physical Review A	20,480	2.3
Monthly Notices of the Royal Astronomical Society	6,256	2.2	Journal of Cosmology and Astrophysical Physics	19,559	2.2
Physical Review E	5,081	1.8	International Journal of Modern Physics A	18,685	2.1
Sum	125,168	43.3	Sum	446,960	50.1

Youngen (1998) could not find firm rules for citing preprints, with the exception of the Astrophysical Journal, which stated that "References to private communications, papers in preparation, preprints, or other sources generally not available to readers should be avoided" (p.453). Nevertheless, it ranks seventh among the most active journals citing e-prints on arXiv. This restriction must have been eased over the years, as can be seen in Figure 4. Depicted are time series of percentages of papers in a journal that cite arXiv, for the ten

journals with the highest number of arXiv-citing papers (see Table 4). We can observe that up to 1997 the *Astrophysical Journal* had less than 10% of their papers citing e-prints on arXiv. This share was growing in the following years to reach approx. 25%.

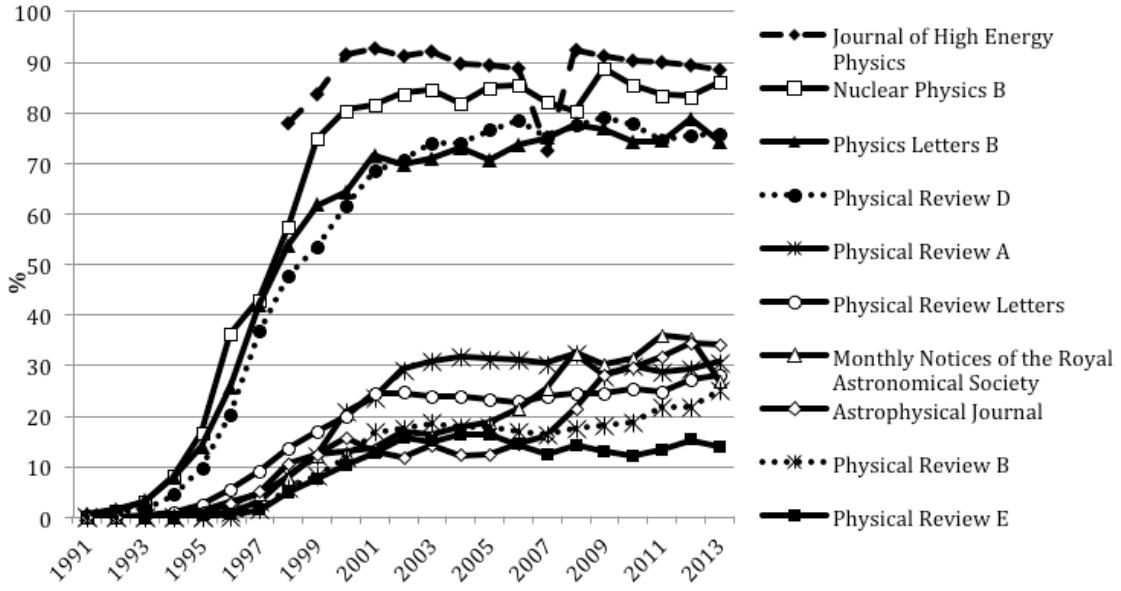

Figure 4: Time series of the percentages of papers in a journal that cite arXiv. Displayed are the 10 journals that most actively cite arXiv.

Striking is the decline of the share of papers in JHEP with references to arXiv in 2007, for which no explanation can be given. Overall, the shape of the line graphs suggests a rapid growth of arXiv's acceptance in the 1990ies and a constant reliance on arXiv in the past 15 years. The following table identifies other "arXiv-friendly" journals, where the majority of papers rely on arXiv. Since the number of papers published in a journal can differ immensely, Table 5 indicates percentages of the number of a journal's papers that cite arXiv. To provide an up-to-date view, only papers published between 2004 and 2013 are considered.

Table 5: Journals in WoS with the highest share of papers citing arXiv. Analyzed are only citing papers that were published between 2004 and 2013.

Journal	%	Journal	%
Journal of Cosmology and Astroparticle Physics	89.9	Journal of Physics G-Nuclear and Particle Physics	59.0
Advances in Theoretical and Mathematical Physics	81.7	International Journal of Modern Physics A	59.0
Annual Review of Nuclear and Particle Science	80.7	International Journal of Modern Physics D	57.5
Communications in Number Theory and Physics	79.8	Progress of Theoretical and Experimental Physics	56.2
European Physical Journal C	70.9	Physics Reports-Review Section of Physics Letters	55.5
Fortschritte der Physik-Progress of Physics	70.4	General Relativity and Gravitation	54.0
Quantum Information & Computation	69.3	Gravitation & Cosmology	54.0

Modern Physics Letters A	62.3	Journal of Sympletic Geometry	53.6
Progress in Particle and Nuclear Physics	61.5	Reviews of Modern Physics	52.8
Acta Physica Hungarica A-Heavy Ion Physics	60.4	Algebraic and Geometric Topology	52.2
Geometry & Topology	60.3	Progress of Theoretical Physics	51.7
Classical and Quantum Gravity	60.0	Astroparticle Physics	51.2

Ranking the journals on the basis of percentages instead of absolute numbers enables us to spot mathematics journals. The 24 journals listed prove that the circle of users coincides with the target group of arXiv that consists mainly of high-energy physicists. In HEP it is usual practice to submit papers to arXiv prior to journal submission. According to Gentil-Beccot, Mele & Brooks (2009) the arXiv often presents a version very similar to the published one. Finally, the arXiv version is freely available, while the journal versions require subscription.

Conclusions

The rapid dissemination of research results enabled by arXiv has accelerated the read-and-cite process (see Brody, Harnad & Carr, 2006). The identified number of cited references to arXiv and the rapid citation of e-prints in WoS-indexed journals indicate that e-prints are accepted within certain communities as well as among journal editors. Taking citation counts as a proxy for quality, e-prints on arXiv can be regarded as of good quality. They are valued, read and used within the scientific community, mainly because they present results upon finalization, circumventing the publication delay. To refer to these most up-to-date findings, authors evidently do not hesitate to cite arXiv e-prints in their research papers. The high number of cited references presented in this study suggests the usage of e-prints over the journal articles, as it was also found by Davis & Fromerth (2007). One reason for the preference of arXiv e-prints is the free availability of full text, especially if readers do not have access to the journal. Besides, the arXiv version is often similar to the formal journal article and can be easily cited by ID. An obvious reason to cite arXiv full texts even years after publication might be simply that the e-print does not have a published alter ego to be cited. Furthermore, the results showed that citations to e-prints peak in the year after publication and drop rapidly in the following years. Authors may still rely on the e-print but cite the formal publication, so the decline in citations does not necessarily indicate a decline in use. This could be proved in a future study with download data of arXiv e-prints over time.

Whereas this initial study is mostly exploratory, future work will link arXiv data to the data in WoS to examine, whether the cited e-prints have a journal version or not. So far, Larivière et al. (2014, p.1161) found that 64% of all arXiv e-prints are published in a WoS-indexed journal. An improved unification in our bibliometric database of institution names will allow analysing reasons why certain institutions rely on arXiv. Is it due to the presence of large physics departments, research centres, outstanding and highly-active researchers, collaboration or cutting-edge research? Moreover, a qualitative study of authors and their reasons to cite arXiv instead of the journal article would provide valuable information on the recent scholarly communication process.

Abstract
The research area of scientometrics began during the second half of the 19th century. After decades of growth, the international field of scientometrics has become increasingly mature. The present study intends to understand the evolution of the collaboration network in *Scientometrics*. The growth of the discipline is divided into three stages: the first time period (1978-1990), the second period (1991-2002), and the third period (2003-2014). Both macro-level and micro-level network measures between the studied time periods were compared. Macro-level analyses show that the degree distribution of the collaboration in each timespan are consistent with power-law, and both the average degree and average distance steadily increase with time. Micro-level structure analyses illustrate the authors with high performance in raw degree measure, degree centrality measure, and betweenness measure are dynamic in different timespans. From three dimensions (raw degree, degree centrality, and betweenness centrality), the collaboration dominators are identified in each time span. In addition, the visualization methods are applied to display the evolution of the collaboration networks for each of the three stages of scientometrics' development.

Conference Topic
Journals, databases and electronic publications

Introduction
Scientometrics is an interdisciplinary field that uses mathematical, statistical, and data-analytical methods and techniques to perform a variety of quantitative studies of science and technology (Chen, Börner, & Fang, 2013). In short, it can be defined as the science of science. The term "Scientometrics" has been first used as a translation of the Russian term "naukometriya" (measurement of science) coined by Nalimov and Mulchenko (1969). The research area of scientometrics began during the second half of the 19th century. This paper proposed a macro- and micro-level overview of the author collaboration patterns in journal *Scientometrics* to study the evolution of the field of scientometrics. The present study intends to understand the evolution of the collaboration network in *Scientometrics*. In this study, social network analysis methods are employed to describe the evolution of scientometrics over nearly 40 years after entering the development stage of this field. Both macro-level and micro-level network measures between the studied time periods were compared. Then, visualization methods were applied to display the evolution of the collaboration networks in three periods: the first time period (1978-1990), the second period (1991-2002), and the third period (2003-2014).

Related Works and Research Questions
Scientometrics has been studied for more than 100 years. Over the past years, scientists' studies of scientometrics shifted from the unconscious to consciousness, from qualitative research to quantitative research, and from external description to detailed study revealing the inherent properties of scientific production. Previous scholars (Pang, 2002; Yuan, 2010) tend to divide the development of scientometrics into three stages: embryonic period (from the

second half of the 19th century to early 20th century), the founding period (from the beginning of the 20th century to the 1960s), and development period (after the 1970s). In order to study the development period of scientometrics, Schubert (2002) indicated that as the representative communication channel of its field, the journal *Scientometrics* reflects the characteristic trends and patterns of the past decades in scientometric research. Therefore, in this study, we employed the publications in *Scientometrics* over the past 37 years to detect the evolution of the scientific collaboration networks in this field.

Previous research has provided some insight into the author collaboration network analysis in different disciplines. Barabasi et al. (2002) investigated the collaboration network in mathematics and neuroscience articles published between 1991 and 1998. Newman (2001) compared the co-authorship networks of in physics, biomedical research, and computer science, and found the differences of the collaboration networks between experimental and theoretical disciplines. By using the bibliometric methods, Ardanuy (2012) analyzed the level of co-authorship of Spanish research in Library and Information Science (LIS) until 2009, and found a significant increase in international collaboration. Given the advanced visualization techniques, Franceschet (2011) represented a collaboration picture of computer science collaboration including all papers published in the field since 1936.

These studies have investigated the collaboration networks in different disciplines and compared their differences. However, few studies investigated the field of scientometrics over the past 37 years. There is a need for researchers to identify and compare both the macro-level and micro-level characteristics of the scientific collaboration network in *Scientometrics* through different time periods.

This paper intended to address the following two research questions:

RQ1. What are the macro-level features of the collaboration networks in *Scientometrics* in each time period?

RQ2. What are the micro-level features of the collaboration networks in *Scientometrics* in each time period?

Method

Data collection

For the development period of scientometrics, the foundation of the journal *Scientometrics* (in September, 1978) is a landmark event. Following some of the predecessors (Schoepflin & Glänzel, 2001; Hou, 2006), this study used the journal as a representative model of scientometrics research. The research data involves 3627 documents published in *Scientometrics* during 1987 to 2014 retrieved from the Web of Science on December 10th, 2014, and the other 347 articles published from 1978 to 1986 retrieved on April 20th, 2013. The total of 37 years were divided into three periods: the first time period (1978-1990), the second period (1991-2002), and the third period (2003-2014).

The raw data extracted from Web of Science database that consisted of the bibliometric information of each paper. Microsoft Excel was applied to build the 2-mode author-to-paper matrices for each time period. In order to produce the collaboration networks, the 2-mode author-to-paper matrices were transferred to 1-mode author-to-author matrices based on the formula proposed by Breiger (1974): $P=A(A^T)$. In this case, the matrix A was the 2-mode author-to-paper matrix and the matrix AT was the transposition of the matrix A, and the 1-mode author-to-author matrix was generated by multiplying these two 2-mode matrices. In the produced author-to-author matrix, each row and column represented an author, the intersection cells contained the cumulative number of the co-authored papers by two authors, and the diagonal cells demonstrated the total number of papers written by each author.

Data analysis

Two social network analysis software packages (Ucinet and Netdraw) (Borgatti, Everett, & Freeman, 2002) were adopted in the data analysis to calculate the network measures and draw the networks. Ucinet is a software package which mainly deals with the social network analysis, and Netdraw, the network visualization tool, can be used to display the networks generated by Ucinet.

Results and Discussion

An overview

Over the 37 years, a total of 4,211 authors published 3,974 papers in *Scientometrics*. Figure 1 indicates the distribution of the number of articles and the number of scholars in each time period. In Figure 1, the *X*-axial represented the 3 time periods, and the *Y*-axial represented the frequencies, and the 2 bars in each period showed the number of authors and articles separately, and the line showed the trend of the differences between the two bars. Separately, 626 papers were contributed to by 435 authors from 1978 to 1990, 1,106 papers were published by 1,029 authors from 1997 to 2005, and 2,242 papers were written by 3,102 authors from 2006 to 2014. Based on Figure 1, both the number of articles and the number of authors increased over the three time spans. When we compared the two frequencies in each period, the number of articles was greater than the number of authors at the first two stages, but the number of authors boomed at the third stage which resulted in the number of authors being much greater than that of the authors. The increases of the total number of articles and authors suggested the rises of the collaboration opportunities through the three time periods.

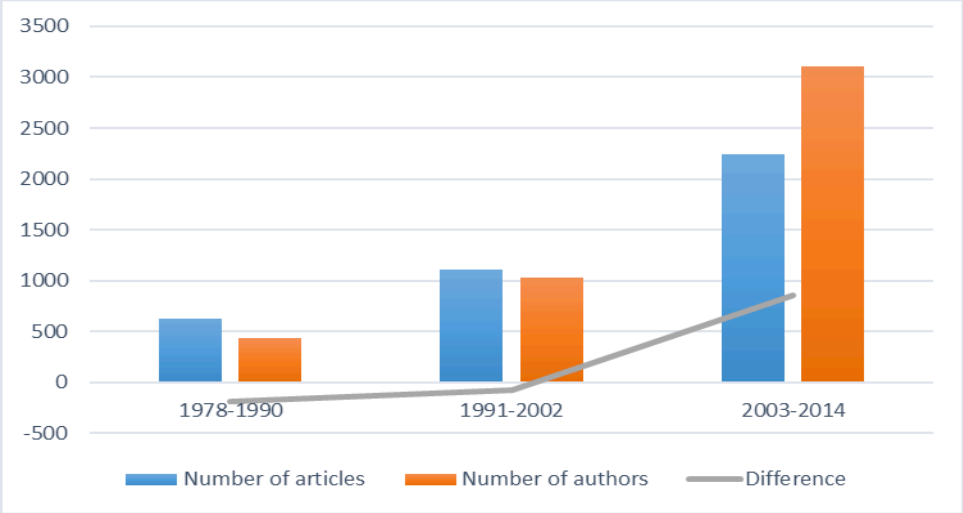

Figure 1. Distribution of the number of articles and authors in three time periods.

Macro-level structure analysis

In order to study the evolution of the scientific collaborations through three time periods, three 1-mode author-to-author matrices were plugged in Ucinet to calculate a variety of network measurements. There are a number of measures which can be used to evaluate the structure of a network. In this study, we will mainly focus on four elements to approach: degree distribution, average degree, average distance, and cluster coefficient.

The number of collaborators that each author has in a collaboration network is the degree of a node (Ding, Rousseau, & Wolfram, 2014). In Figure 2, three lines illustrated the distributions

of the node degree in each time span, respectively. The *X*-axial represented the number of authors, and the *Y*-axial represented the degree of the authors. From Figure 2, it can be seen that most authors held the low degree in all three periods. Based on the locations of three distribution lines, more authors tended to join more collaborations from 1978 to 2014 with the increase of the number of total authors published on the journal.

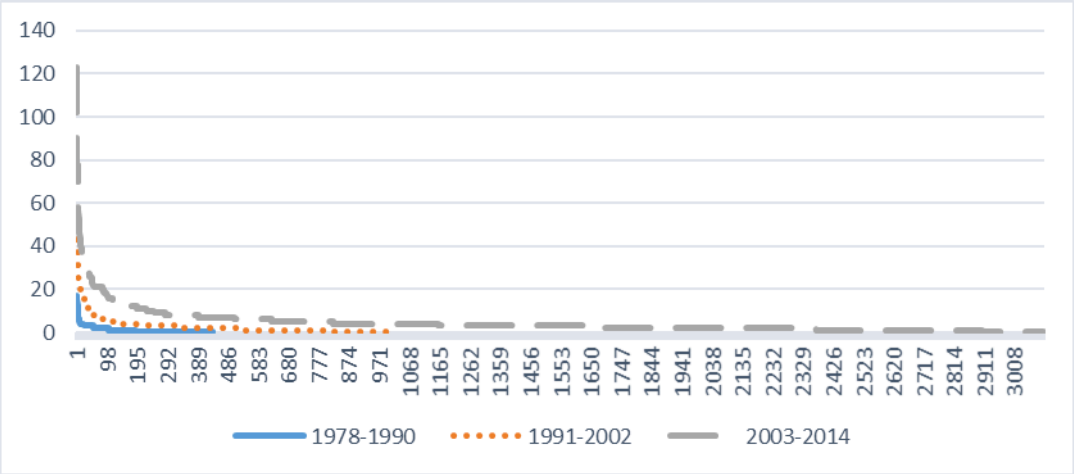

Figure 2. Degree distribution for authors in three time periods.

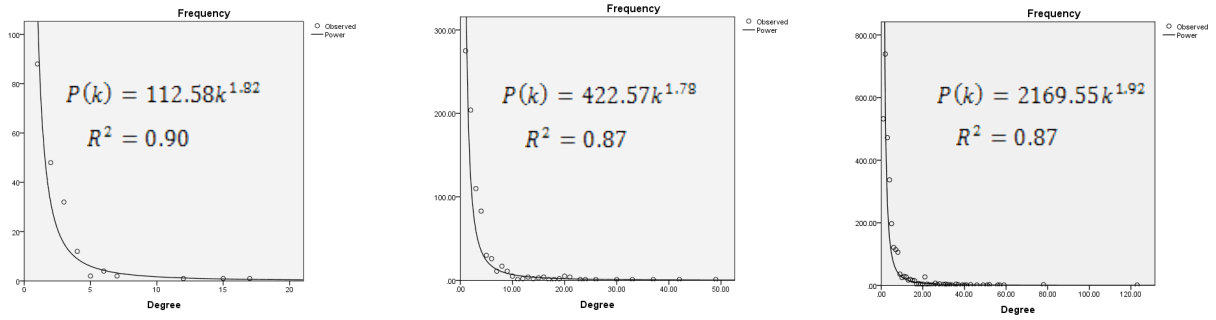
The degree distribution characterizes the spread of the edges each node has in a network. Although the degree distribution of a random graph is a Poisson distribution, Albert and Barabási (2002) have discovered that, for most large networks, the degree distribution has a power-law tail: $P(k) \sim k^{-\gamma}$, where $P(k)$ is the distribution function. In this study, the distributions of the collaboration network in each period were calculated and drawn in Figure 3. Power-law regression model was used to detect the degree distribution patterns in different timespans (Albert & Barabási 2002). Figure 3 illustrated the modeling results for the three periods, and the x-axis plots low degree nodes on the left and high degree nodes on the right; the y-axis indicates their probability. In both cases, power-law model performed the good fits to the observed data. In relationship between the degree of the authors and the corresponding frequencies can be estimated by: $P(k) = 112.58k^{1.82}$ with $R^2 = 0.90$ in 1978-1990, $P(k) = 422.57k^{1.78}$ with $R^2 = 0.87$ in 1991-2002, and $P(k) = 2169.55k^{1.92}$ with $R^2 = 0.87$ in 2003-2014. As discussed by Albert and Barabási (2002), the degree distribution of the collaboration network of high-energy physicists reach the almost perfect power-law



1978-1990 1991-2002 2003-2014

Figure 3. Degree distribution plots for collaboration networks.

with an exponent of 1.2, while the collaboration networks of mathematicians and neuroscientists between 1991 and 1998 held the degree exponents 2.1 and 2.5 (Barabasi et al., 2002). Comparing with those previous studies in different disciplines, the degree distribution of the collaboration of *Sicentometrics* in each timespan were consistent with power-law with degree exponents 1.82, 1.78, and 1.92, respectively. In addition to degree distribution, previous studies proved that there were several other useful indicators to feature a social network. Table 1 represented the four key measures for each time periods. Figure 3 describes the changes of each measure between 1978 and 2014.

Table 1. Four key measures of the collaboration networks in each time periods.

	1978-1990	*1991-2002*	*2003-2014*
Average Degree	0.794	2.101	3.435
Average Distance	1.412	4.673	7.106
Clustering Coefficient	0.941	0.873	9.014
Components	309	420	701
Diameter	4	11	19

Average degree is calculated by counting the average number of links per author (Barabasi et al., 2002). In the collaboration network, the average degree characterizes the interconnectedness between authors. Yin, Kretschmer, Hanneman, and Liu (2006) identified that the higher the average degree, the tighter the network. From Table 1, we can see that the average degree steadily increased with time, which demonstrated that authors cooperated more often. This results confirmed Barabasi et al.'s (2002) observations in Mathematics and Neuroscience. One possible reason might be the sharp increase of the total number of authors led to more possible connections between the new authors and also between the new authors and the existing authors.

The distance between two nodes is measured by the length of the shortest path between those two nodes. Average distance in a network is calculated by the average length of the geodesic paths between all reachable pairs of nodes (Borgatti, Everett, & Freeman, 2002). From Table 1, the average distance of the collaboration networks started form 1.412 (in 1978-1990), grew to 4.673 (in 1991-2002), and finally reached 7.106 (in 2003-2014). Watts and Strogatz (1998) examined that many social networks show a “small world” phenomenon that have small characteristic path lengths. According to Yin et al. (2006), short average distance allows authors to share information more rapidly. In this case, the average distance of the collaboration network enlarged with time, but actors were still able to reach the others within short paths in all periods. The cluster coefficient for the co-authorship network in *Scientometrics* appeared to have increased sharply: rising from 0.941 in 1978-1990 to 9.014 in 2003-2014.

Micro-level structure analysis

Micro-level structure analysis was adopted to measure the individual authors. One of the main purpose of social network analysis is to identify the core actors in a network. We applied four measures (raw degree, degree centrality, betweenness centrality, and closeness centrality) to investigate the structural characteristics of each author in each timespan.

Table 2 summarized the top 10 authors with highest degrees in each time period. Freeman (1978) defined the degree of a point as the number of other points to which a given point is adjacent. In the collaboration networks, the degree of an author represents the number of authors a given author co-authored with before. Schubert A held the highest degree with 17 in the first period, which showed he cooperated with 17 authors between 1978 and 1990. In both

second and third timespan, Glänzel W. achieved the first place with 49 and 123 collaborators in 1991-2002 and 2003-2014, respectively.

Table 2. Raw degree (top 10 authors) in each time period.

Apart from the raw degree of the actors, the centrality is one of the most important structural attributes of social networks (Freeman, 1978). Over the past years, a number of centrality measures have been proposed by sociologists. In the case of co-authorship network, each centrality measure demonstrate special characteristics of the author cooperation. The centrality indicators are designed to identify the "core" authors from different perspectives. The degree centrality can be seen as an index of its potential communication activity. For the co-authorship network, the authors with high degree centrality may result in the status of "elite" (Yin et al., 2006). Freeman's (1978) betweenness centrality is based upon the frequency with which a point falls between pairs of other points on the shortest or geodesic paths connecting them. Regarding to the collaboration, betweenness centrality can be used to assess the potential of an author for control of communication in the knowledge flow network. Tables 3 and 4 summarized the top 10 authors with the highest degree and betweenness centralities in each time period, respectively.

From Table 3, we can see that authors with high degree centrality were dynamic in different timespans. New authors arrived in a field and gathered more collaborations, whereas the existing authors decayed, to some extent, with time. No author ranked in the top 10 in all three time periods. From the perspective of potential communication ability, the "star" of the collaboration networks changed over time. When it comes to the betweenness centrality, Glänzel W was no doubt the core author in both the second and third time periods. Interestingly, from both dimensions (degree centrality and betweenness centrality), Glänzel W occupied the genuine dominator (or "star") position from 2003 to 2014, which suggests that he possesses potential communication ability as well as the possible ability to control the communication between other authors in recent years.

Collaboration network visualization

Figures 4 to 6 present the evolution of the collaboration network in the three stages. Clearly, both the number of the authors and the collaborations boosted, which also illustrated the expansion of this field. With the time advanced, the collaborations between authors were strengthened. To highlight the changes in collaboration, we removed removed isolated nodes in the network in both Figures and displayed only the collaborating authors and their connections. The size of both the nodes and the labels indicated the degree of the authors. The strength of the collaboration was shown by the thickness of the ties between nodes. The authors with high degree in Table 2 were outstanding in the networks.

Conclusion

This paper approached the evolution of the scientific collaboration networks of scientometrics based on the publications in *Scientometrics*. The past 37 years were divided into three timespans: the first time period (1978-1990), the second period (1991-2002), and the third period (2003-2014). Based on the macro-level structure analyses, the degree distribution of the collaboration of *Scientometrics* in each timespan were consistent with power-law, and both the average degree and average distance steadily increased with time, which

demonstrated that the cooperation between authors was getting more frequent. Micro-level structure analyses illustrated the authors with high performance in raw degree measure, degree centrality measure, and betweenness measure were dynamic in different timespans. Interestingly, on each dimension, Glänzel W became the genuine dominator (or "star") in the most recent period: 2003-2014. Finally, the visualization of the evolution of the collaboration network in three stages was presented, and the boosts of the number of authors and their collaborators were displayed in the network graphs.

Abstract
This paper describes the analysis of open access (OA) publishing in the Netherlands in an international comparison. As OA publishing is now actively stimulated by Dutch science policy, similar to the UK, a bibliometric baseline measurement is conducted to assess the current situation, to be able to measure developments over time. For the study we collected data from various sources, and for three different smaller European countries (the Netherlands, Denmark, and Switzerland). Not all of the analyses for this baseline measurement are included here; the analysis presented in this paper mainly focuses on the various ways OA can be defined while using Web of Science, and the problems with interpreting these results. From the data we collected, we can conclude that the way OA is currently registered in various electronic bibliographic databases is quite unclear, and various methods applied deliver results that are different, although the impact scores point in the same direction.

Conference Topic
Journals, databases, and electronic publications

Introduction
Acceleration of open access goals in the Netherlands coincides with implementation of new current research information systems (CRIS) at Dutch universities and research institutes. This deployment of institutional CRIS systems provides an opportunity for national level tracking of open access through coordinated metadata schemes and common registration practices. As open access is notoriously difficult to measure, contemporary analyses often employ random sampling techniques (Archambault et al., 2014; Björk et al., 2010). All publication records in a given sample are tested to determine the proportion of full texts that are open access publications. National level coordination of research information provides an opportunity for improved, more precise assessment of open access publishing. In this study we use bibliographic data to establish a baseline analysis of the proportion of open access publishing in the Netherlands.

Assessment of open access publishing is complicated by a growing diversity of what counts as open access, the copyright restrictions for when a publication can be made openly accessible, and the lack of clear and consistent identification of open access publications in bibliographic data. To examine these challenges we begin with a definition from the Budapest open access Initiative (BOAI):

> Free availability on the public internet, permitting any users to read, download, copy, distribute, print, search, or link to the full texts of these articles, crawl them for indexing, pass them as data to software, or use them for any other lawful purpose, without financial, legal, or technical barriers other than those inseparable from gaining access to the internet itself. The only constraint on reproduction and distribution, and the only role for copyright in this domain, should be to give authors control over the integrity of their work and the right to be properly acknowledged and cited. (BOAI 2002)

This definition highlights two distinct channels of access: (1) human access to read, download, and reuse the full text of published articles; and (2) machine access to crawl, index, or analyze the content of articles. The BOAI also proposes two operational paths to access through open access journals and self-archiving in repositories, subsequently referred to as

Gold open access and Green open access (Bailey, 2005). Hybrid open access generally refers to the situation whereby authors can pay to make their articles in subscription journals openly accessible on the Web (Björk, 2012).

In addition to the broad categories of Gold, Green, and Hybrid modes of open access, multiple versions of a manuscript may exist due to variations in publishers' licensing agreements. These agreements typically specify how, when, and under which conditions a manuscript may be openly accessible on the web. For example, a publisher may allow Green open access through self-archiving in an institutional repository. However, publishers' copyright restrictions differ on the stage of manuscript development that may be openly accessible, thus assigning different rights to different versions of the text. Commonly specified version types include the submitted manuscript (before peer review), the accepted manuscript (peer-reviewed but not formatted), and an exact copy of the published manuscript (Björk et al., 2013). This creates the possibility that the open access version of a manuscript is substantively different from the published version. In such instances, it is unclear whether the open access version has been sufficiently validated through the quality control measures such as peer review.

Another variation is delayed access, which is applied as an embargo period, after which a copy of the publication may be self-archived or the publisher may remove access restrictions on the journal website. Embargo periods are generally specified as a delay of 6, 12, 18, or 24 months after publication, with 12 months being the most common embargo period (Laakso & Björk, 2013). For Green open access, it is thus left to authors and institutions to track and manage a variety of self-archiving policies, which in itself has been shown to be a barrier to open access (Davis & Connolly, 2007). However, this kind of administrative overhead is largely absent from subscription journals that convert articles to open access after a specified delay (e.g. 12 months). In addition, a bibliometric analysis of 'delayed access' journals found journal and article impact factors higher than comparable averages from both subscription journals and direct (no delay) open access journals (Laakso & Björk, 2013).

A common refrain among proponents of open access is that open access publishing yields increased citation impact. While there are conflicting reports regarding an open access citation advantage (OACA), heightened attention to this issue has increased our understanding about citation behaviour more generally. Numerous bibliometric studies claim that open access publishing results in a significant increase in citations. In these studies the size of advantage varies widely based on a variety of issues, such as disciplinary differences, methodological approaches, variation in how open access is defined, and difficulty in determining when an article is made openly accessible (Swan, 2010). In addition, a number of confounding factors have been shown to influence citation frequency such as early exposure to draft versions of a manuscript (Moed, 2007), self-selection bias whereby an author may choose open access for only her best publications (Kurtz et al., 2007), the availability at multiple access points (Xia, Myers & Wilhoite, 2011), and physical proximity of researchers (Lee et al., 2010).

To control for these factors, Davis et al. (2008) employ randomized controlled trial methods, whereby randomly selected articles in subscription based journals are switched to open access. The resulting configuration is similar to hybrid open access, such that the article is made to be openly accessible and is listed among the non-open access articles on the journal's website. In the Davis et al. (2008) study a citation advantage was not present. However, the research design used to control for confounding variables (randomized controlled trial) also limited applicability of the findings to the hybrid model of open access. More recently, Archambault et al. (2014) show variation in the accumulation of citations associated with the different modes of open access. The authors find a citation *advantage* most prominently associated with the self-archiving mode of open access (Green OA) and a citation

disadvantage associated with full and immediate open access journals (Gold OA). This study also establishes a general ranking of citation accumulation on the bases of open access, listed in order of most to least: Green OA, Other OA, Not OA, and Gold OA." (Archambault et al., 2014, pp. 20, 24)

To address the variability of circumstances associated with open access publishing, recent studies invert the research design from top-down queries of bibliometric datasets to bottom-up testing whether a publication is an open access publication. This approach involves random sampling of a given publishing domain, harvesting full-texts from the Internet, and analysis of available metadata from harvested manuscripts (Björk et al., 2010). While this approach circumvents much of the variability noted above, it is nevertheless dependent on the presence and quality of metadata. (The potential for improved metadata practices is addressed in the discussion section below.)

The objective of our analysis is to show the challenges of bibliometrically analysing OA publications and associated impact scores. We use Web of Science (WoS) data, either directly retrieved from the database, or combined with article-level data extracted from journals listed in the Directory of Open Access Journals (DOAJ). As both data sources are incomplete with respect to open access publications, the analysis is focused on comparison of relative output and relative impact among three European countries of similar size and scientific production: the Netherlands, Denmark, and Switzerland, in order to show developments in time, as well as differences resulting from both approaches. It is important to note that Green OA articles are excluded from our analysis. While the Netherlands maintains a robust national repository for Green OA (NARCIS), there is not yet a reliable system of identifying the self-archived state of publications within bibliometric datasets. As such, the proportion of open access and associated impact comparisons are limited to the available data on Gold OA.

Data collection

In the study we make use of data from various sources. The Web of Science (WoS) database is used in its internet version, available to most Dutch researchers. We also used the CWTS version of the WoS, a tailor-made database based upon state-of-the-art bibliometric techniques and indicators. In this version, the functionality to search for OA output is not yet available. Finally, we make use of the journals and the publications listed in the Directory of Open Access Journals (DOAJ). From this data source, we will further focus on the digital object identifiers (DOIs), while leaving out other elements (such as the license types, as this information is unclearly defined as well as unclearly linked to the publications).

Method I: The first way of data collection from WoS starts from the desktop interface of the WoS database. The functionality to collect this information is not yet available in the in-house WoS database at CWTS, so therefore we had to collect these data from the internet version directly. This approach involved the following steps:

1) Collect the output of one of the selected countries for a particular year;
2) Within that set, further distinguish the OA part of that selected output;
3) Download these publications from the WoS database (including the so-called UT-code, a unique identifier within WoS that allows for linking to the CWTS WoS database);
4) Select within the CWTS database the output for the three countries;
5) Match the selected output from the Internet version of the WoS with the in-house CWTS version;
6) Create two sets within the CWTS database, an OA formatted set of publications, and a non OA formatted set of publications.

These steps were taken for all three countries, collecting publications from 2000-2013.

The definition of how the publications were defined as OA is based upon the following statement on the WoS database' website: "The Thomson Reuters Links open access Journal

Title List includes free journal content that are available for linking from the Web of Science."

Method II: The second method started from the Directory of Open Access Journals (DOAJ). This list contains journals that have implemented the Gold open access business model. CWTS has downloaded the complete list, and all publications published in the journals on the DOAJ list. By making use of this dataset, we could use a second approach to the OA output of the three countries taking the following steps:

1) First select within the CWTS database the output for the three countries;
2) Collect their Digital Object Identifiers (doi);
3) Match these with the doi's of the publications downloaded from the DOAJ list;
4) Create two sets within the CWTS database, an OA formatted set of publications, and a non OA formatted set of publications.

We focused on articles, letters and reviews only, excluding other types of documents such as editorials, meeting abstracts, book reviews, etc. The choice for these types is based upon the importance of these three types in communicating scientific findings among peers, and their relative homogeneity within the system.

Methods

In the study we present a number of indicators. In cases we present numbers of publications, this is indicated with a P. In case citation data are presented, we use MNCS (Mean Normalized Citation Score), as well as the MNJS, the field normalized journal impact indicator, to indicate the normalized impact scores in the study (Waltman et al., 2011a; Waltman et al., 2011b). While the output indicator can be used for the various electronic systems we use in the study, and P can relate to various document types analysed, the citation impact indicators are used only within the context of the WoS database. In case of the impact indicators, the length of the citation window is one year longer than the presented year block (so in case of the last block, 2009-2012, the citation impact is measured up until 2013, currently the last year fully covered in the CWTS WoS database).

Results

First we present the results from Method I, described above. The output numbers of the three countries according to the methodology I are found in Table 1 along with the two separate parts of the output, distinguished by openness. The analysis covers the period 2000 up until 2012 for publication data, and up until 2013 for citation impact data. In this analysis we use moving publication year windows, in order to create more solid and stable trend lines, as we are more interested in the trends than in variation from year to year.

The data presented in Table 1 clearly show that OA publishing is becoming increasingly important, in all three selected countries. The Netherlands is lagging somewhat behind Denmark and Switzerland, albeit with only a small part of the total output.

In Figure 1, we have distinguished between the open access format output of the three countries (indicated by the 'Ex OA' label to the country names). What we observe are increasing trends for the parts of the output not published in OA format, which is also visible for the OA format of the output of these three countries, and as shown above in Table 1, increases somewhat faster for Denmark and Switzerland as compared to the Netherlands.

Table 1. Output (P) of Denmark, the Netherlands, and Switzerland, distinguishing OA and non-OA output, 2000-2012.

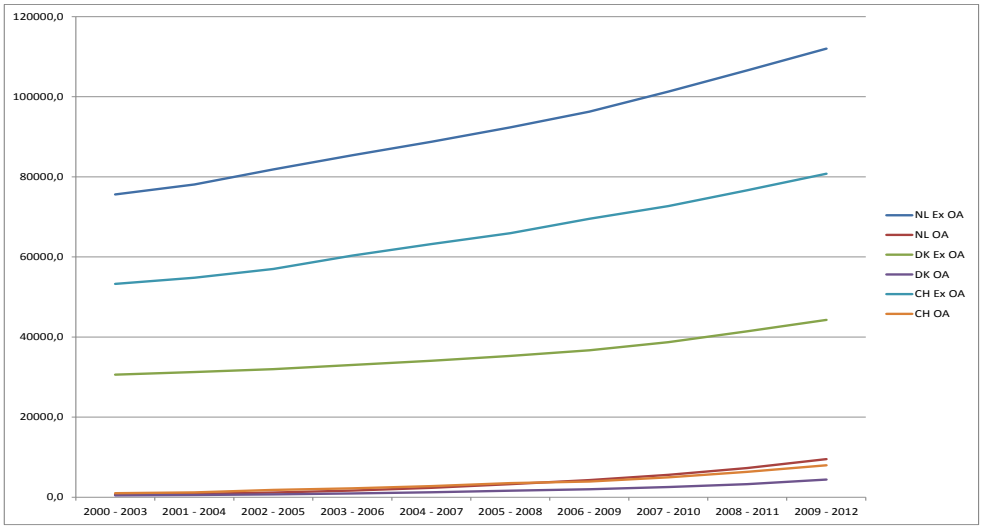

Figure 1. Output development (P) of Denmark, the Netherlands, and Switzerland, 2000-2012/2013.

In Table 2, we present the citation impact scores as represented by the MNCS indicator, the field normalized impact of the outputs of the three countries, again separated by the two types of publication output: open access and non-open access publications.

Figure 2 shows that for all three countries the non-OA part of the output has a citation impact well above world average, with Switzerland topping the other two countries, which have a nearly equal field normalized impact score. The impact of OA publications is lower for all three countries. The impact of the OA part of the national outputs of Denmark and Switzerland were initially well above world average. This is also the case for Swiss publications, as the OA format published output is lower on MNCS only from 2007-2010/2011 onwards. In case of Denmark, this drop started somewhat earlier, while in the case of the Netherlands, the OA output never got an impact higher than that of the non-OA format output. Another interesting phenomenon is the increase of the gap between the impact of OA and non-OA output. This is particularly the case for Switzerland and Denmark, where we observe a clear drop of the impact of OA format output compared to their non-OA formatted output, and to a lesser extent for the Netherlands, where the two impact lines are more slowly diverging.

Table 2. Citation impact (MNCS) of Denmark, the Netherlands, and Switzerland, distinguishing OA and non-OA output, 2000-2012.

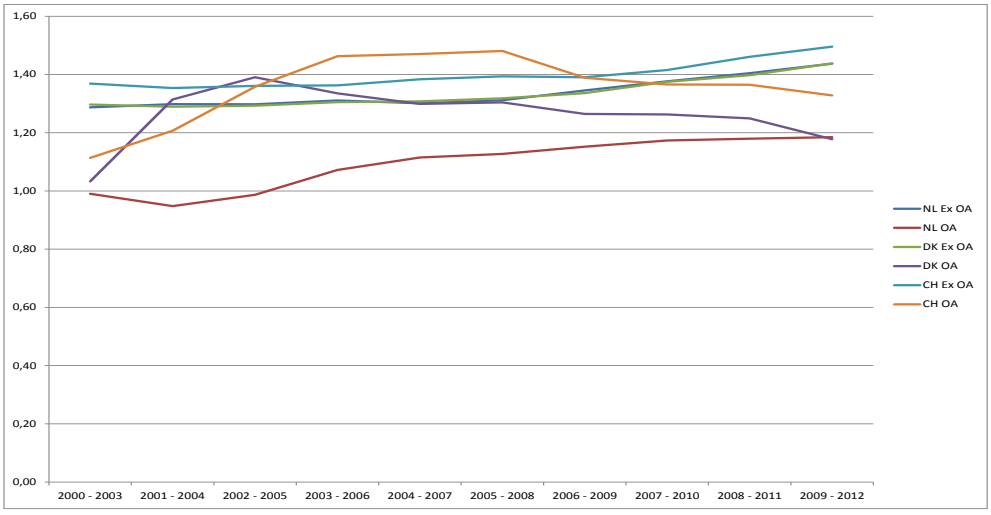

Figure 2. Impact development (MNCS) of Denmark, the Netherlands, and Switzerland, 2000-2012/2013.

If we shift our focus towards the journal impact analysis (see Table 3 and Figure 3), for which we use the indicator MNJS, we see an even more interesting phenomenon. While the output in non-OA format published journals shows a choice for journals with increasing impact scores, the OA format published outputs end up in journals with decreasing field normalized impact scores. We even notice a diverging trend in these two clusters of trend lines: non-OA format published journals tend to show increasing impact scores, while OA format published journals show decreasing impact trends. This is striking since these are three of the 'scientifically stronger' nations, as far as can be measured with bibliometric instruments.

Here we start with the results from methodology II. The results of the output analysis are shown in Table 4, which again covers a similar distinction between OA and non-OA format output, but now according to the definition described above under Method II. We combined the DOIs of journals on the DOAJ list with the DOIs available in the WoS. From the total set of 787,611 DOIs in the DOAJ list, we matched 226,641 publications in WoS on the basis of available DOIs. The reason for this seemingly low recall is twofold. In the first place, not all journals covered by the DOAJ list are processed for the WoS database, and secondly, not all publications in journals covered in WoS do contain DOIs. This means that for some journals that are both covered in the DOAJ list as well as in WoS, a match is impossible, particularly

for the earlier years in the analysis. Like the first methodology we followed, we separated the OA format published output from the Netherlands, Denmark, and Switzerland from the total set of publications for the three countries under study.

Table 3. Journal-to-field citation impact (MNJS) of Denmark, the Netherlands, and Switzerland, distinguishing OA and non-OA output, 2000-2012

	NL Ex OA	NL OA	DK Ex OA	DK OA	CH Ex OA	CH OA

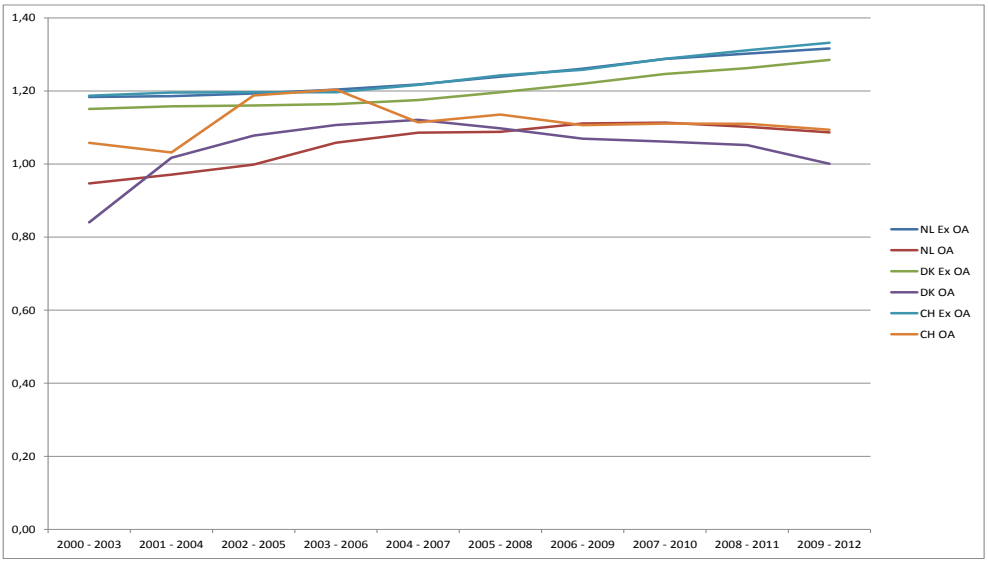

Figure 3: Journal impact development (MNJS) of Denmark, the Netherlands, and Switzerland, 2000-2012/2013.

First of all, we observe that the overlap between the DOAJ list/WoS combinations with Dutch/Danish/Swiss publications in WoS is much smaller compared to the previous analysis on Dutch/Danish/Swiss output in OA format, which is most likely the result of the missing DOIs in the WoS database. If we compare the results of Table 1 with those presented in Table 4, we find much lower shares of OA output compared to the overall output of the three countries. This is further underlined by Figure 4, in which the OA format output of the three countries is at the low end of the graph, while we simultaneously observe a strong increase in the output of the non-OA format output of the three countries.

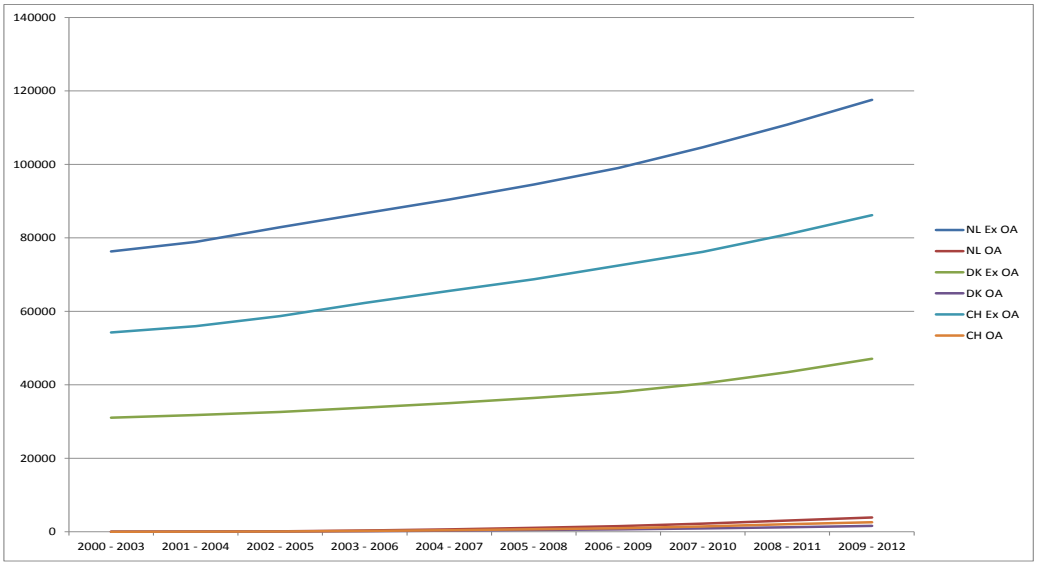

Figure 4. Output development (P) of Denmark, the Netherlands, and Switzerland, based on matching of DOI's, 2000-2012/2013.

In Table 5, we present the impact scores of the three countries, again distinguishing OA format output and non-OA format output. Again we observe lower impact scores for the OA format output of the three countries, except for the starting block of the analysis (please note that the output numbers are extremely low in this part of the analysis for the Netherlands and Denmark, respectively 10 and 4 papers). From the second year block onwards, we observe increasing trends in the impact of the OA format of the three countries, although we must stress that this is also the case for the non-OA format output of the three countries.

Figure 5 shows this stable development of both sets of publications in time, whereby the impact scores are increasing on both sets, although the 'difference' remains more or less the same between the two sets of scores.

In Table 6 we present the outcomes of the analysis on the journal impact scores, based upon methodology II. Here we observe, similar to the previous outcomes, fluctuations in the initials years of the analysis for the OA format output, followed by a more stable situation from 2005-2008 onwards. This finding is even more visible in the graphical representation of Table 6, as in Figure 6.

Conclusion and Discussion

In this final part of the paper, we will summarize the main bibliometric findings, and then move towards limitations in the ways OA is now disclosed in electronic systems supporting bibliometric analyses. Finally, we will discuss the need to improve identification of open access publications and the use of bibliometric techniques to measure OA.

Please note that our conclusions are mainly related to the domains in which journal publishing is the dominant way of communication (the natural, life and medical sciences, and to a lesser extent the social sciences and humanities (van Leeuwen, 2013). We observe for the three countries that the share in output in OA journals is lagging behind as compared to the journals that maintain the non-OA format. We observe a divergence in the development of citation impact for (Gold) OA and non-OA publications with consistently lower impact for the OA publications.

Second, we observe that OA journals have lower journal impact scores than non-OA journals. This may mean that they still struggle to find their position within the total 'reputational hierarchy' of the domain, and as such also within the WoS database. This is a common problem for new journals, and OA journals are no exception. It should be noted however, that our findings associated with OA impact are consistent with what others have found: Gold OA is associated with no citation advantage or a disadvantage (e.g. Archambault et al., 2014). With the inclusion of the various forms of Green OA, we would expect to find a larger proportion of open access articles and a more nuanced outcome related to impact. That Green OA has been found to have increased accumulation of citations (Archambault et al., 2014), may be associated with the circumstances identified above as confounding factors (e.g. early exposure, multiple access points, and proximity of researchers).

Third, we may need to worry about the role of peer review in the journals that are part of the expansion of the WoS database in the last couple of years, many of which are in the OA segment of the database. The Institute for Scientific Information, the predecessor of the current owner of the WoS database Thomson Reuters, always clearly indicated that a properly functioning peer review system within a journal was one of the conditions for a journal to be included in the system (next to other criteria, such as international focus, regular appearance,

preferably in the English language, etc.). We do not know whether this is still such a strong criterion, particularly given the fact that so many new journals appeared around the OA development.

A fourth conclusion relates to the messy situation around the various manners by which open access is defined in electronic databases. The two different ways open access can be operationalized within the world of WoS is an example of this unclear and somewhat messy situation. The fact that the Scopus database did not have the functionality to clearly define open access for users of the system is another instance of the situation around open access. Further examples of this lack of clarity are the various ways open access is operationalized by the publishing industry. There is no clear way of operationalizing in the larger databases of the various business models (such as Gold, Green, and Hybrid open access). Yet another example relates to the various license types related to open access.

A recently published metadata standard for open access holds some promise for improving both human and machine identification of open access publications (Carpenter, 2013). Here, too, stakeholders involved in the new standard were unable to agree on a precise definition of open access. Instead, the standard specifies metadata elements for *free to read* and *license reference*, the latter of which should point to copyright information publicly accessible on the Web (NISO 2015). Increased attention to national research assessment and increased use of institutional CRIS systems together provide a potentially welcoming context for implementing new metadata practices. This would ideally include the possibility of tracking open access among the diversity of research outputs maintained by CRIS systems and considered in assessment events. In this context, it becomes important to assign openly accessible, persistent identifiers to all research objects (Tatum & Wouters 2014). This would increase the potential use of institutional research information for tracking open access as part of regular research assessment practices, rather than relying solely on estimation derived from random sampling of commercial datasets.

Abstract
A journal's impact and similarity with rivals is closely related to its competitive intensity. A subject area can be considered as an ecological system of journals, and can then be measured using the competitive intensity concept from plant systems. Based on Journal Citation Reports data from 1997, 2000, 2005, 2010, and 2013, we calculated the mutual citation, cosine similarity, and competitive relationship matrices for mycology journals. We derived the mutual citation network for mycology according to Journal Citation Reports data from 2013. We calculated each journal's competitive pressure, and the competitive intensity for the subject. We found that competitive pressures are very variable among journals. Differences between a journal's absolute and relative influence are related to the competitive pressure. A more powerful journal has lower competitive pressure. New journals have more competitive pressure. If there are no other influences, the competition intensity of a subject will continue to increase. Furthermore, we found that if a subject has more journals, its competitive intensity decreases.

Conference Topic
Journals, databases, electronic publications

Introduction
Scientific and technical (S&T) journals have an important role in science and knowledge dissemination. Journals that are focussed on the same subject are at competition with each other. We must build a favourable competitive environment to realize the optimal allocation of limited resources. At the same time, the "survival of the fittest" mechanism boosts the development of S&T journals.

To build a sustainable environment and competition mechanism, we must analyse and measure the present environment of S&T journals, especially in terms of competition. Many researchers have investigated the competitive environment of S&T journals.

Reaching a consensus on the relationship between the journal environment and competition

Scholars began to study the competitive relationship of journals in the 1920s. Competition is mainly related to the resources of subeditors, editors, and authors. Studies found that competitive power is related to a journals' impact factor (IF) (Campanario 1996). Zhu (1999) discussed the relationship between an S&T journal's quality and competitive spirit. A few years later, scholars proposed that competition is a basic attribute of science and noted the differences between different journals' abilities to secure resources. Powerful journals typically attract more attention, which results in a Matthew effect on the journal's development. Scholars have attempted to measure competition between journals using quantitative indexes (Manfred & Scharnhorst, 2001). Researchers have generally accepted that S&T journals develop within a competitive environment. They have explored definitions of the competition between S&T journals (Cai, 2003), how to increase a journal's core competitive strength (Chen 2005), and how to take advantage of market competition (Gao,

2004). Recently, Leydesdorff, Wagner and Bornmann (2014) focused on competition between highly cited journals dependent on the proportions of most-frequently cited publications in the European Union, China, and the United States, which are represented differently because they use different databases.

Determining the competitive relationship between journals using quantitative methods

Leydesdorff noted that Pearson correlations could be used as similarity measures for citation patterns based on bi-connected graphs (Leydesdorff, 2004). He then used principal component analysis and factor analysis to design indicators for the position of the cited journals in the dimensions of the database (Leydesdorff, 2006). Yang analysed the relationship between a journal's value chain and competitive edge using value chain theory (Yang, 2006). As a whole, these ideas and methods for quantitatively measuring a journal's competitive relationship have not been generally accepted, and are not fully developed.

Applying research ideas from ecological competition

Recently, ideas related to competition and competitive intensity in ecology have been applied to research related to S&T journals. Scholars such as Tao, Daoping and Gaoming (2007) have attempted to consider the survival and development of S&T journals from an ecological perspective. Xinyan (2008) researched the concentration ratio of an S&T journal's market share and its competition. She also analysed the index model of competitive intensity in ecology, and applied it to measure a journal's competitive intensity (CI). This was a meaningful exploration, but did not result in a proper index for measuring a journal's distance in terms of the ecological system of S&T journals (Xinyan, 2008).

The competitive environment of S&T journals has been extensively analysed. Progress has been made in terms of the quantitative analysis. Although the CI concept from ecology is useful, we do not know how to define and measure the "distance" between journals. The institute of Scientific and Technical Information of China has measured journal similarity using the mutual citation matrix and cosine similarity method since 2011 (ISTIC, 2011). This provides a measurement of the distance between journals.

In this study, we considered a journal's absolute impact value and similarity as parameters based on the *Journal Citation Reports*. We measured the competitive pressures of mycology journals and the CI for the entire subject using scientometrics and the CI.

Methodology

In this study, we used the concept of CI from the field of ecological research to define the "competitive pressure" among S&T journals. The following design scheme illustrates how we calculate the relevant values.

Main factors that influence the competitive relationship between S&T journals

In a relatively closed ecological environment, the CI mainly depends on the differences between plant diameters and the distance between plants. In this closed environment, the competitive relationships between plants can indicate the strength of the overall competition within the ecological environment.

If we consider journals that focus on one subject, we are investigating a relatively closed ecological environment. Then, all the individual journals can be viewed as separate plants. As shown in Figure 1, the respective "diameters" (D_i and D_j) of journals i and j, and the "distance" (L_{ij}) between them are the major factors of the competitive relationship.

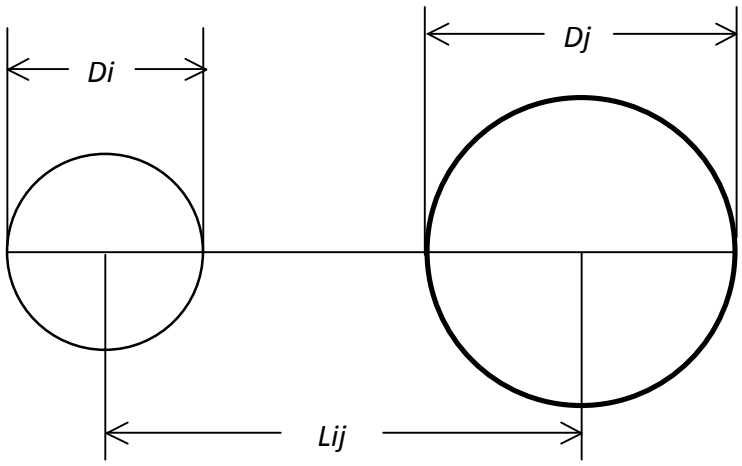

Figure 1. Main factors influencing the competitive relationship between S&T journals.

The number of total citations can be used as an alternative indicator to reflect the influence of the journal

The absolute influence of the journal can be seen as the plant thickness (diameter). Typically, a thicker plant is more capable of competing for resources and fighting rivals. Similarly, more influential journals are generally stronger in terms of their access to excellent manuscripts, funding, and attention. Journals with weaker influences are under more pressure from competitors.

The absolute influence of journals can be quantified using three main indicators: total citations (TC), IF, and the number of published papers.

Among these indicators, the IF is more likely to fluctuate. The number of papers is more vulnerable to subjective factors and can sometimes change dramatically. For example, a change to the journal's publishing cycle from bimonthly to monthly will lead to a sudden increase in the number of papers, and an accordingly sharp drop in the IF (because of a doubled denominator). Compared with the IF and paper number, the total citation indicator is relatively more stable and objective. It visually reflects the influence of journals, is less effected by other factors, and has a distinct advantage in terms of long term monitoring.

Additionally, the IF depends on the average number of citations of paper in a journal, so the total citation is equal to the IF multiplied by the number of papers. From this point of view, the total citation is monotonic in the mathematical sense.

Considering the above discussion, the total citation can be used as an alternative indicator of the influence of a journal. Therefore, in this study, we use the total citation as the diameter (D_i) of journal *i*. That is,

$$D_i = TC_i, \tag{1}$$

where TC_i is the total citation of journal *i.*

The similarity of two journals can be compared using the "distance" between them

It is widely accepted within the ecological community that competition is most intense when the same species live in the same environment (Clements, 1905). The similarity between two journals is also an important factor in their competitive relationship. In other words, a greater similarity between two journals leads to more intense competition. The similarity between two journals can be compared using the "distance" between them (L_{ij}).

Zheng, Na & Guozhen (2012) calculated a citation matrix for a sample of Chinese journals, which is classified into 61 subjects. They calculated the similarities for each journal in a specific subject area, and then constructed the similarity matrix for the journals. We used the same definition, and calculated the distance between periodicals using

$$\mathrm{Lij} = \frac{1}{Sij} - 1, \quad (2)$$

where S_{ij} is the cosine similarity indicator between i and j. S_{ij} is in the range of [0,1], and l_{ij} is in the range of [0,∞]. A S_{ij} value that is closer to 1 means that journals i and j are more similar. Accordingly, the distance L_{ij} is closer to zero. Conversely, if S_{ij} is closer to zero, i and j are less similar and the distance L_{ij} is closer to infinity.

Calculating the competition pressure between S&T journals

We used Hegyi's quantitative measurement for plant competition in ecology (Hegyi, 1974). Suppose that there are n journals for a subject, the target journal is called i and is set as the "basic journal", and the other is called j and considered a "rival journal". Then, $CRij$ is the competitive pressure on journal i from rival j. It is calculated using

$$\mathrm{CRij} = \frac{Dj}{Di \cdot Lij}. \quad (3)$$

We can assume that the competitive pressure on i from j is inversely proportional to the absolute influence of i, is directly proportional to the absolute influence of the rival, and is inversely proportional to the distance between the journals. This assumption is consistent with an intuitive understanding of the competitive relationship.

Combining Equations (1), (2), and (3), we get

$$\mathrm{CRij} = \frac{TCj}{TCi \cdot \left(\frac{1}{Sij} - 1\right)}, \quad (4)$$

where TC_i and TC_j represent the TC for i and j, and S_{ij} is the cosine similarity between periodicals.

CR_{ij} and CR_{ji} represent the competitive relationship between i and j. The cosine similarity S_{ij} measures the angular distance between a journal and its rival, so S_{ij} and S_{ji} are equal. However, CR_{ij} and CR_{ji} are not equal if TC_i is not equal to TC_j. Equation (4) implies that C_{ij} and C_{ji} have a mutually reciprocal relationship.

We can conclude from the definition that the basic journal is under less competitive pressure if it has a higher total citation value than its competitor, and vice versa. The more similar the journals are, the greater the competitive pressure. A journal does not compete with itself, so CR_{ii} is zero.

Calculating the competitive pressure on basic journal i

Suppose that, within its discipline, basic journal i has n-1 rival journals. Then, CI_i is the total competitive pressure on journal i from all of its rivals,

$$\mathrm{CIi} = \sum_{n}^{j=1} CRij. \quad (5)$$

Overall competitive strength for a specific subject

The number of competing journals depends on the subject classification. To compare disciplines, we define the overall competitive strength as CIS. It is the average competitive pressure for all journals, i.e.,

$$\mathrm{CIS} = \frac{1}{n}\sum_{n}^{i=1} CIi. \quad (6)$$

Analysis and Results

We calculated the mutual citation, similarity, competitive relationship, and competitive pressure matrices for the journals, and the CI for mycology using Journal Citation Reports (*JCR*) data from 1997, 2000, 2005, 2010, and 2003.

The inter-citation matrices for the target subject, and the similarity and competitive relationships

We used journals focussed on mycology to demonstrate how to calculate and analyse inter-citations within the target subject, and the similarities and competitive relationships between journals.

There are 23 journals indexed in the *JCR 2013* for mycology (*n=23*). The inter-citation matrix (*C*) was constructed by calculating the inter-citations of each pair of journals. We used the cosine similarity method to transform the inter-citation matrix to the similarity matrix, *R*. The cosine similarity is calculated using

$$\text{Cosine}(x,y) = \frac{\sum_{i=1}^{n} x_i\, y_i}{\sqrt{\sum_{i=1}^{n} x_i^2}\sqrt{\sum_{i=1}^{n} y_i^2}}. \quad (7)$$

We transformed *R* into a net document and used Pajek to produce Figure 2, which shows the mutual citation network for mycology according to *JCR 2013*. Each node represents a journal, and a node's area represents the journal's TC. The location of the journal and the thickness of the link represent its similarity with its rivals.

From another perspective, we considered the whole subject area as an ecological space. Then, the 23 journals are independent plants. Figure 2 can be regarded as an ecological system with 23 plants, as viewed from above. The differences between the plant diameters and distances between plants determine the CI and the state of the journals.

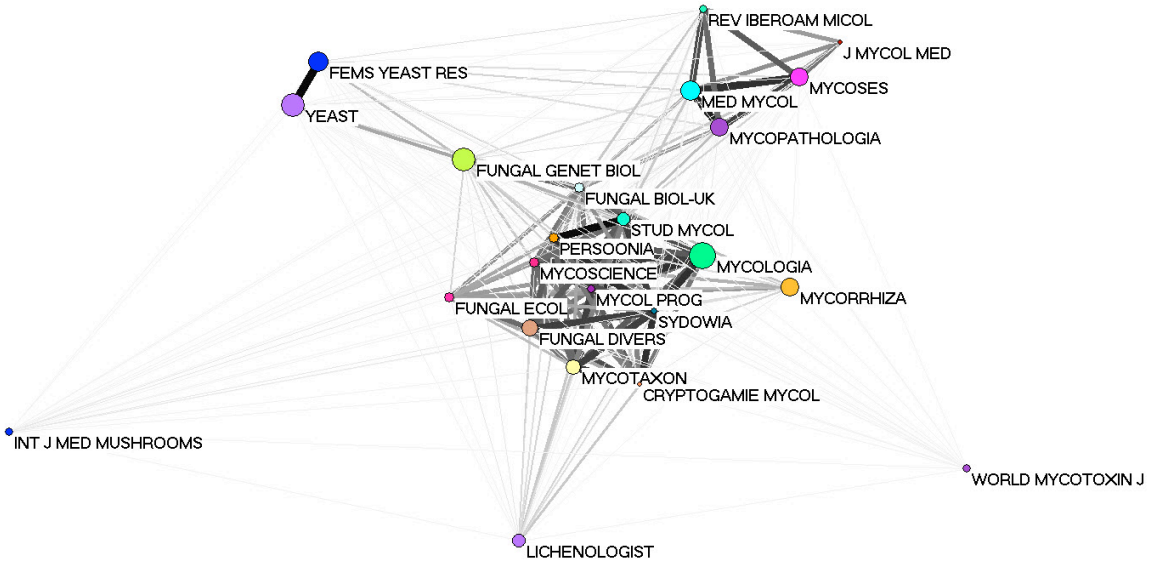

Figure 2. Mutual citation network of journal focussed on mycology, according to *JCR 2013.*

We applied Equation (4) to construct the competitive pressure matrix (*CR*) for the 23 journals, by considering each journal's TC and the cosine similarities between each journal pair.

Competitive pressure for a journal (CI)

Equation (5) shows that the CI of a journal is a combination of the competitive pressure from all of each rivals. We measured the competitive pressure of the all journals using competitive relationship matrices for mycology at five time points.

Table 1 shows that there were large differences in the competitive pressures of the rival journals. The maximum was 408.198 and the minimum was 0.022. In *JCR 2013,* two journals had competitive pressures over 100, 15 were between 10 and 100, and six were under 10.

Table 2 shows the competitive intensities compared with the IF and TC, for mycology journals in 2013. The rankings based on the IF and TC is different from the CI rankings. Some journals are ranked in the top 10 in terms of TC and IF but have low CIs, and some are ranked in the bottom five in terms of TC and IF but have higher CI*s*. Therefore, a more powerful journal has lower competitive pressure. We have only listed the results based on the 2013 data, but they were similar for 1997, 2000, 2005, and 2010. The difference between a journals' absolute and relative influence is related to its competitive pressure.

There are certainly some exceptions. Journals that are extremely similar have a significant influence on the competitive pressure. For example, some journals have TCs that are greater than one thousand and are very similar to other journals with the same mass influence, so they also have high competitive pressures. However, some journals are focused on narrow fields and have distinctive characteristics, and therefore do not have much competition because there are not many similar journals, although their TC may be high.

Figure 3 shows the difference between the CI rankings for a set of journals between 1997 and 2000, and a second set of journals between 2005 and 2013. For the first set, the CI rankings for most of the 14 journals decreased from 1997 to 2013, and only four were in the top ten. This typically means that the competitive pressures of traditional journals (with a longer publishing history) were declining. At the same time, most of the second set started in a high competitive pressure situation, and approximately half of them remained in the top ten of the CI ranking. This means these new journals had to face more challenges.

Competitive intensity for a subject

Equation (6) shows that the CI for a subject is the average competitive pressure of all the journals. We calculated the CIs for mycology in 1997, 2000, 2005, 2010, and 2013.

Table 3 shows that the competitive intensity for a subject (CIS) increased from 1997 to 2005, but the number of journals only increased from 15 to 17. We can see that the CIS decreased between 2005 and 2010 because the number of journals increased from 17 to 23 (by approximately 35%). By analysing the relationship between the subject's scale and CIS, we can see that more journals correspond to low CIs. From 2010 to 2013, the number of journals was stable at 23 so the CIS increased. In the absence of any other influences, the CIS will continue to increase.

By analysing the competitive pressure on each journal and the CIS, we can determine the state of the competitive environment using a quantitative method, and compare the competitive

relationships of different journals and subjects. Through a comparative analysis, we can research reasons for any differences and provide S&T publications with scientific data and tools. Additionally, the data can be used to monitor the S&T journals environment at a macro level, and help decision makers with regard to administration.

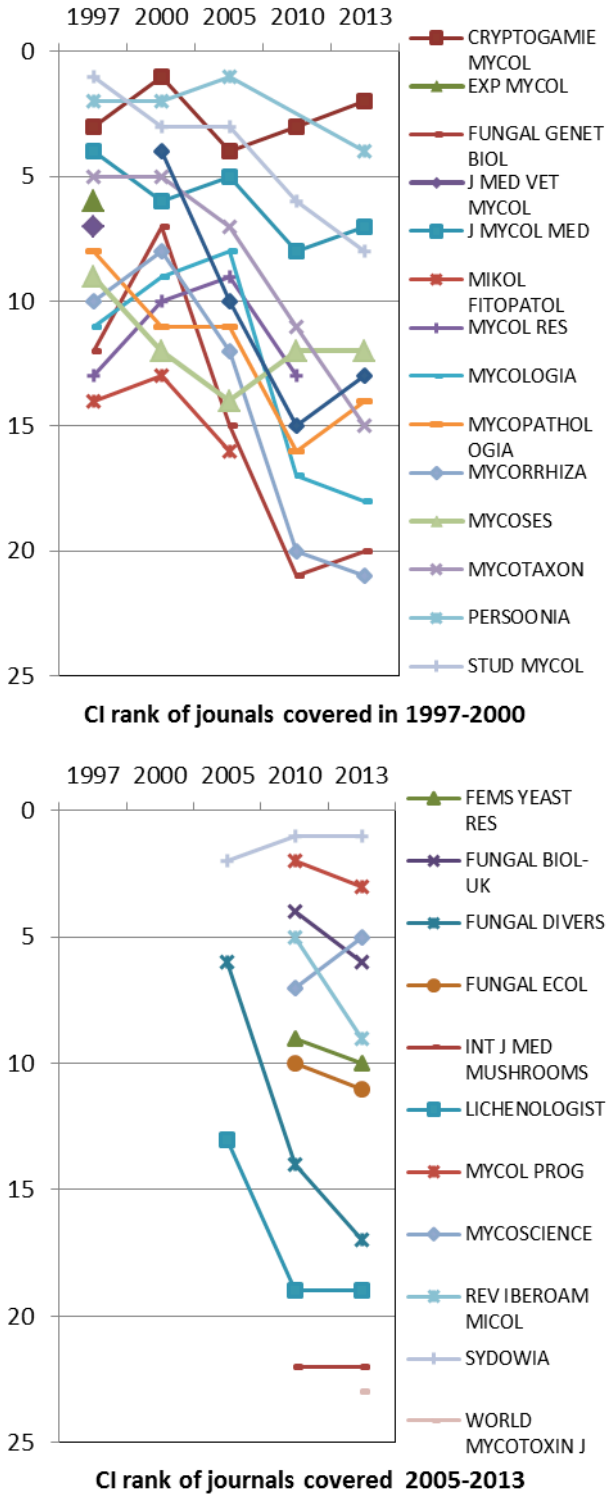

Figure 3. Relationship between competitive intensity (CI) and time.

Table 3. Competition intensity (CI) and number of journals for mycology

CIS	29.489	39.110	43.726	38.500	41.361

Conclusions

There is vast difference in the CIs between subjects and competition pressures between journals.

We have measured journals' competition pressures and the CIS using quantitative methods. The differences between journals' competitive environments may be caused by many related factors. Different journal attributes are related to competitive pressure. For example, the competitive environment and resources vary among multidisciplinary, ordinary professional, and specialized professional journals. Fundamental research or academic journals and engineering or application journals have different competitive features. Chinese journals are obviously different to English language journals. So the factors that influence competitive pressure and intensity, measurements of these related factors, and mechanisms that influence journals' competitive environments must be studied further.

The competitive pressure from a powerful rival may be equal to the pressure from several weakly similar journals.

The ecological concept of CI is a combination of all kinds of competitive pressure. So the competitive pressure on a journal is a combination of the competitive pressure from all of its rivals. The competitive pressure from a powerful rival may be equal to the pressure from several weakly similar journals. The combination of competitive pressure for each journal may be different, which can lead to a high competitive pressure and number of rivals. It can be used as reference when analysing a target journal's competition.

A journal's homogeneity is important when developing S&T journals. Using our quantitative method, we found that homogeneity is obvious in some fields, especially journals that lack "personality". Such journals have higher competitive pressures. The homogeneity of a journal increases its competitive pressure, and the homogeneity of a subject hinders a favourable competitive environment. There is typically fierce competition between two journals that are very similar. Abnormal cooperative relationships exist between some journals, who adopt inter-citation journal group models. These very similar journals pursue high IFs and cited rates. The academic misconduct phenomenon is one problem that results from a journal's homogeneity.

More study is required for multidisciplinary or interdisciplinary journals.

In our method, each journal only belongs to one subject. However, developments in science and technology have led to fusions and evolutions in subject areas. Most articles belong to more than one subject area. At the same time, some journals are multidisciplinary, so it can be difficult to define their subject. We measured a journal's competitive pressure in terms of only one subject. Future research is required to determine how to measure and compare competitive pressure and similarities for multidisciplinary or interdisciplinary subjects.

A favourable competitive environment is only possible at the proper scale

The scale of the subject (number of journals) is related to its competitive pressure and intensity. A favourable competitive environment is only possible at the proper scale. If there

are too many or too few journals the CI decreases. In S&T journal administration, the distribution and trends of the CIs can be used as a reference to promote the development of favourable and sustainable environments.

The research findings in this study can be used as a reference for a new journal when choosing a subject and field.

In management science, there are "red ocean" and "blue ocean" strategies when facing competitive environments. The red ocean strategy directly reacts to competition, whereas the blue ocean strategy avoids direct competition and exploits new markets (Chan & Mauborgne, 2005). When facing competition from rivals, S&T journals must choose an optimal path based on the current environment and future positioning. Journals with relative advantages tend to use red ocean strategies, proactively consolidating and extending their advantages. Relatively weak journals use blue ocean strategies, seeking paths that reduce homogeneity problems and competitive pressures. The findings of this study can be used as a reference for a new journal when choosing a subject and field. In a fiercely competitive fields, it is difficult to successfully launch a new journal without obvious diversity.

Abstract
In this study we compare the visibility and performance of Latin American and Caribbean (LAC) Science in terms of its presence in the core collection indexes included in the *Web of Science* (WoS) —*Science Citation Index Expanded*, *Social Sciences Citation Index*, and *Arts & Humanities Citation Index*—and the *Scielo Citation Index* (SciELO CI)—which was recently integrated into the WoS platform. The purpose of this comparison is to provide some inputs to reconstruct the role of SciELO as a communication platform for science produced in Latin America and the Caribbean, and to provide some reflections on the potential impacts—in terms of a better understanding of the global scientific scenery—of the articulation of SciELO CI into WoS: Are there significant differences in the region´s scientific results when studied from publications included in SciELO CI versus those included in the traditional core collection of the WoS? Are regional exercises, such as SciELO, successful in enhancing the visibility of regional scientific production?

Conference Topic

Journals, databases and electronic publications

Introduction

Although the participation of Latin American and Caribbean (LAC)-edited journals in WoS has increased over time, this growth is not comparable to the growth in the participation of scientific articles with at least one author affiliated to an institution in LAC. This increase in participation has been interpreted as a successful integration of LAC science into the world repertoires despite a persistent and notorious gap in the making of good scientific journals (Meneghini, Mugnaini & Packer, 2006). The difference in the nature and characteristics of the journals considered and included in each of the indices justifies our expectation of finding significant differences in the science produced in LAC and communicated through WoS or SciELO CI indexed journals: while the inclusion policy of WoS targets the top quality journals by discipline, the program SciELO has had an inclusive policy aimed at increasing visibility and circulation of LAC journals and their content.[1]

[1] SciELO (Scientific Library on Line) was a program that was initiated in Brazil in 1997 with the purpose of offering a core of Brazilian scientific journals in an open access mode through internet. The program had a successful expansion in the region and now includes, in addition to Brazilian, journals from Chile, Cuba, Spain, Venezuela, Colombia, Argentina, Costa Rica, Mexico, Portugal, Peru, and Uruguay. It is important to note that the SciELO program transcends the SciELO citation index which is the subject of this study. Not all the scientific journals that belong to the SciELO collection and whose content has been made available through SciELO´s program belong to ScieLO´s citation index.

Another difference in the origins of SciELO and WoS that might be helpful in explaining the differences in regional scientific communication is related to the disciplinary context of each of the indexes. A lot has been written about the "natural" or hard sciences origin of WoS, which derived from the Science Citation Index (Garfielfd, 1971), but was expanded to include a broader range of journals and then accompanied by the Social Science Citation Index and later on by the Arts & Humanities Citation Index. The three indexes have been operative since 1978. SciELO, on the other hand, resulted from cooperation of the Fundacao de Amparo a Pesquisa do Estado do Sao Paulo (FASPEP) and the Latin American and Caribbean Center for Health Sciences Information (Bireme) of Panamerican and World Health Organization (PHO/WHO).

We believe that SciELO´s contribution to global science relies on its impact in the circulation of LAC scientific production and therefore the visibility of this production. In the last 15 years, SciELO played an important role in the development of capabilities in LAC to produce world-class scientific results, particularly though the consolidation of a regional base of high-quality scientific journals. The financial requirements to maintain such an exercise updated, expanding and relevant (Aguillo, 2014), together with the potential of SciELO indexed journals to provide a representation of LAC science, might explain the interest behind the inclusion of the regional exercise in the Thomson Reuters owned databases.

The inclusion of SciELO into WoS has had a mixed reception in the LAC scientific community. In 2007, an alliance between Scopus and SciELO raised expectations of all SciELO information to be included in Scopus (Elsevier, 2007). The potential impacts of the inclusion of the journals, and the ambiguity of whether all SciELO journals would be included in Scopus raised some concerns in the LAC scientific community. The negotiations behind SciELO´s inclusion either in Scopus or WoS, was perceived by some editors of LAC journals as a "sell-out" of SciELO´s principles and allowed uncertainty in the future of the regional journal structure that SciELO had aimed to consolidate.

With this paper we expect to contribute on the relevance of both indexes and the complementarities between them as they represent different styles of scientific communication that transcend the center-periphery debate on scientific production. This section is followed by a section in which we introduce the data and methods employed for this study. The results section will focus on the differences between the indices; specifically in the geographical, collaborative aspects, and cognitive characteristics of the communications in each. We finish this contribution with some reflections on the challenges and opportunities of the integration of SciELO into WoS.

Data and Methods

We downloaded all the bibliographical information from the core collection of the WoS (SCI expanded, SSCI, A&HCI) for 79,924 documents that responded to the search query for affiliation country to any LAC countries AND publication year 2012. The same information was downloaded for 30,518 documents that responded to the same search query in the SciELO CI available through WoS. While participation of LAC authors explains 73% of the total publications in SciELO CI, in WoS, this participation is lower than 5%.[2] The organization of the information into relational databases was possible through dedicated routines available at http://www.leydesdorff.net/scielo and http://www.leydesdorff.net/software/isi/index.htm.

[2]In January 2015, a total of 1,899,805 documents were included in WoS with publication year 2012, and 41,621 in SciELO CI.

In order to assess some of the differences in the sets of data considered in this analysis, we provide some descriptive statistics in Table 1. We include the mean and the standard deviation to provide some order of magnitude and dispersion among attributes.

From Table 1, differences among the types of communications included in each set are evident. The mean (μ), represents the average number of authors, addresses, citations, cited references and subject categories per document and the standard deviation (σ) is included to illustrate dispersion in these data. The documents in journals indexed in WoS have more citations, and more frequently result from collaborations among larger number of authors in European or American institutions. These documents are more codified (in terms of the cited references used) as well, and, in general, have a significantly larger impact (in terms of citations received). The mean and standard deviation of the journals are included to represent the average number of LAC documents per journal. Although fewer journals concentrate LAC scientific production in SciELO CI than that in WoS, dispersion among different titles is greater; as can be expected, SciELO CI indexed journals have a larger participation of LAC authors compared with authors from other countries. A total of 163 journals are indexed in both WoS and SciELO CI.

Table 1. Differences in the sets of LAC publications from SciELO CI and WoS Core collection.

LAC publications	**SciELO CI**			**WoS Core Collection**		
Records	30,518			79,924		
Statistics	**N**	**μ**	**σ**	**N**	**μ**	**σ**
Authors	91,269	3.8	2.4	306,560	14	144,3
Addresses	11,858	2.3	1.5	168,390	3.9	14.3
Times cited	7,733	0.3	0.7	274,225	3.4	18.6
Cited references	681,151	26.2	19.1	1,969,653	37	29
Subject Categories	186	1.2	0.7	246	1.5	0.8
Journals	750	40.7	44.5	7,268	10.9	28.0

We use the Overlay maps Toolkit available at http://www.leydesdorff.net/overlaytoolkit (Rafols, Porter & Leydesdorff, 2012) to provide the different visualizations of the relations among disciplines in each of the document sets (SciELO CI and WoS core collection). We rely on these visualizations to suggest disciplinary differences in each of the sets of documents. We expect some of these differences to reflect on diverse goals and interests in the management of each of the indices and which were shortly introduced above.

To reflect upon the distinctions in the collaborative nature of the communications in each index, we build a collaboration network between countries using Pajek.

Results

In this section we provide some results on the differences between communications in the Core Collection of WoS and the recently integrated SciELO CI, focusing on the regional, collaborative and cognitive aspects underlying these communications. In Table 2, we provide the number of records in each of the sets by country of origin of the authors. To normalize for documents with a high number of co-authorships we include a fractional counting of documents considering the total number of signing authors.

The divergence in the countries' participation in the scientific production of LAC can result from (a) the degree in which the specific country has become articulated in the SciELO program and the efforts in increasing the SciELO journal list of each country. As can be expected, the most important SciELO journal collection is from Brazil and it includes 337 journal titles, Colombia follows with a total of 184 journal titles, Mexico has 149, Argentina

and Chile 107 and 106 journal titles each. Another explanation is (b) the specific country´s treatment and importance of national scientific journals.

The policy effort supporting national scientific journals varies in the region where some countries privilege international publication while others aim at balancing international visibility with support to local journals and local publishers (Vessuri, Guédon & Cetto, 2014). Different publication strategies are also evident from Table 2 where the effect of fractional counting seems to be more drastic for communications in journals indexed in WoS Core collection than in SciELO CI. Colombia, for example, has relied on collaborating with international peers to increase their participation in international journals and databases (Lucio-Arias, 2013).

Table 2. Regional distribution of papers in WoS Core collection and SciELO CI.

Country	SciELO CI		WoS	
	Records	Fractional	Records	Fractional
Brazil	19,537	11,929.5	44,812	21,844.1
Colombia	3,065	2,312.2	4,007	1,734.9
Chile	2,409	1,754.3	7,277	3,562.0
Mexico	2,336	1,529.2	13,041	5,879.3
Cuba	1,979	1,053.5	966	320.8
Argentina	1,625	1,223.8	9,975	4,953.8
Venezuela	526	340.8	1,240	543.9

Honduras	3	1.0	25	2.8
Dominica	1	0.2	2	0.4
Dominican Republic	1	0.2	33	4.4

The alliances and collaborations reflect important differences in the networks of collaboration that emerge from LAC scientific communications in each of the indices considered (See Figures 1 and 2).

Collaborations in WoS suggest the importance of North America and Europe as allies in the production of scientific knowledge in the region. Collaboration of LAC countries with peers "from the north" dominates scientific communications where LAC participate. Regional collaboration seems not very relevant and in fact not as important as collaboration with Asia, Africa and Oceania. South-South collaboration has received a lot of attention (Arunachalam & Doss, 2000; Chandiwana & Ornbjerg, 2003) and has become an important issue in the

development policy agenda.[3] We believe, nevertheless, that South-South collaboration depicted in Figure 1 is mostly mediated by developed countries and does not represent necessarily a transfer and exchange of resources and knowledge.

The resulting map of collaborations in LAC scientific communications in journals indexed in SciELO CI, suggest a more pronounced strategy based on the regional conjugation of research efforts. Collaboration with Europe is mainly oriented towards Spain and Portugal, suggesting language and cultural similarities as a strong motivation to collaborate. Collaboration with North America and particularly with the United States might rely on geographic proximity as this is stronger in the case of Mexico.

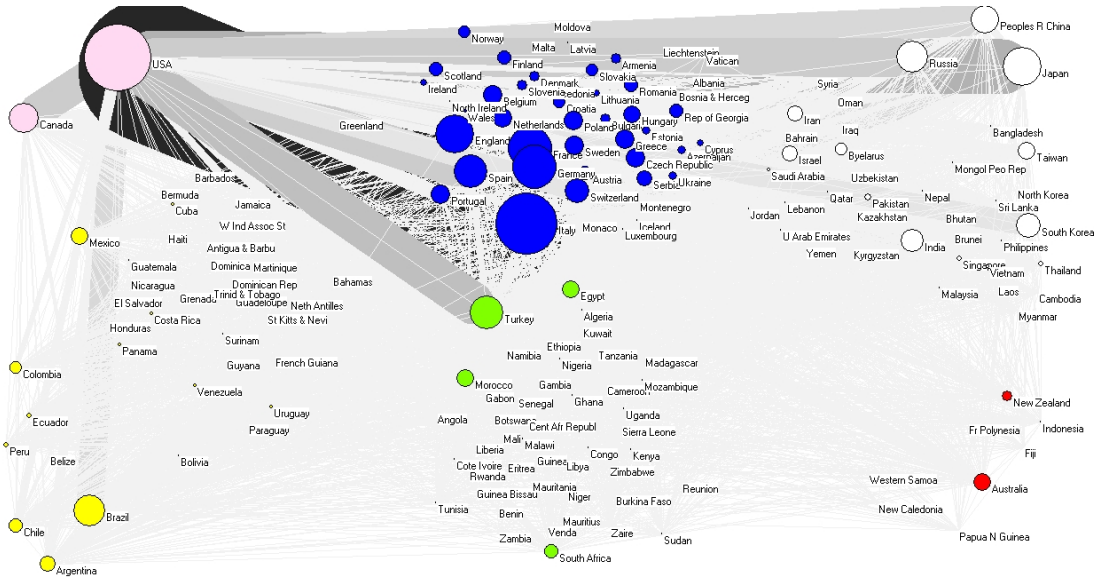

Figure 1. International Collaboration from LAC communications in WoS Core Collection.

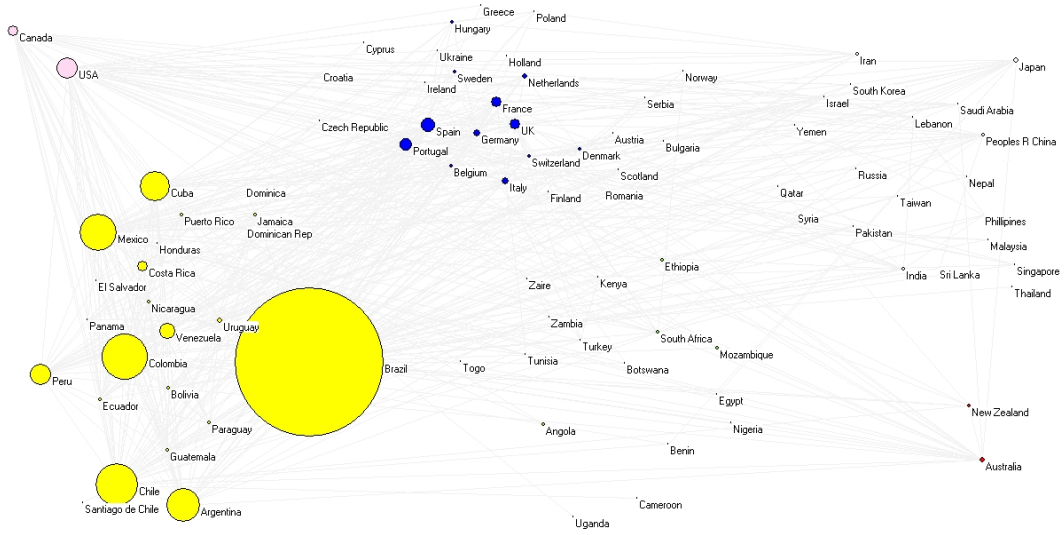

Figure 2. International Collaboration from LAC communications in SciELO CI.

Although it deserves further research, we expect collaborations in SciELO to be a better representation of South-South cooperation, which implies an exchange of resources and ideas within developing countries to solve similar development problems. Collaboration in Figure 2

[3] There is a United Nations Office for South-South cooperation with a website at http://ssc.undp.org/content/ssc.html.

within LAC, Africa and Asia might be a better representation of South-South cooperation. We expect less mediation of the North in the South-South collaboration for the case of SciELO CI indexed communications.

In summary, the differences between Figures 1 and 2 suggest distinct communication practices when (a) aiming at results with international visibility than when the main goal is (b) regional or local diffusion of scientific results through regional journals. While for WoS (Figure 1) strong ties can be indicated with North America and Europe, regional collaboration seems dominant in Figure 2. The participation of the USA in Figure 1 and Brazil in Figure 2 should be interpreted considering that these countries have the highest numbers of indexed journals in each of the respective databases.

This can also result from the different disciplines represented in each index. While WoS has some dominance of "hard" sciences, which are more prone to be published in English and in collaboration, for SciELO CI the disciplinary participation seems to favor the social sciences (see Figure 3 and 4).

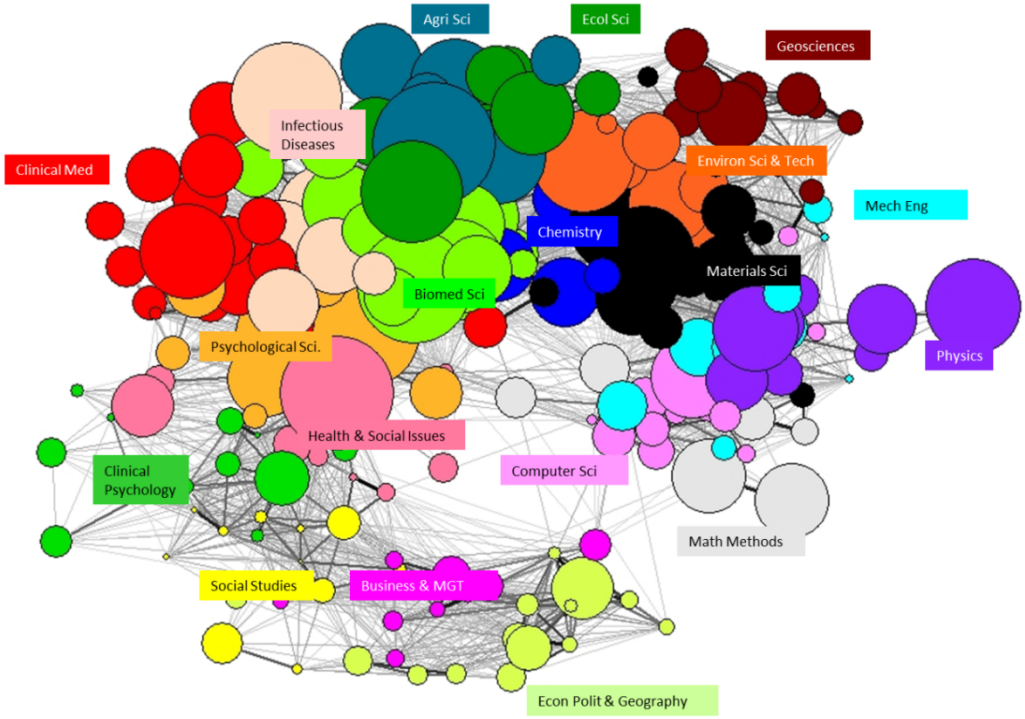

Figure 3. LAC map of Science, WoS Core Collection; 224 Web of Science Categories.

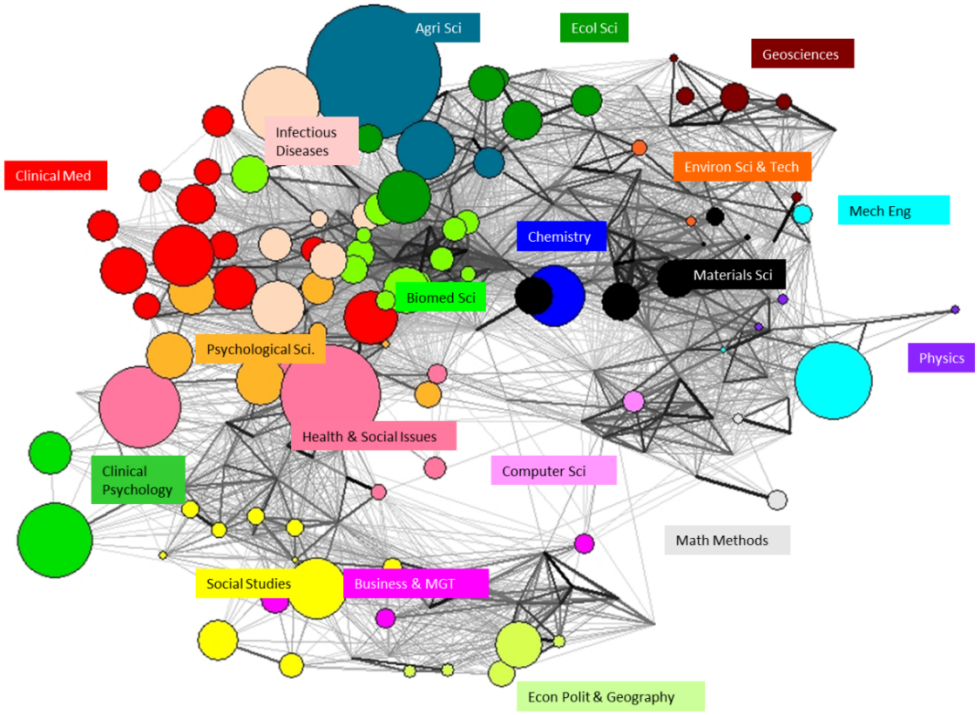

Figure 4. LAC map of Science, SciELO CI.; 224 Web of Science Categories.

Figures 3 and 4 suggest differences in the thematic orientation of the communications in each index. Contributions from the natural sciences are better represented in WoS Core Collection; nevertheless, SciELO CI provides a valuable insight into the regional scientific production in the social and health sciences (where social aspects of the health and medical sciences like research in public health has a better representation), and agriculture. Our expectation is that in-depth analysis of the subjects addressed by the communications would exhibit differences in the sets; communications in SciELO CI will address topics of regional relevance.

Reflections and Further Work

In the last twenty years, scientific development together with technological change and productive innovation have raised interest in the LAC countries, and as a consequence been targeted on the public-policy agenda. Important aspects in the institutionalization of scientific research, such as the consolidation of public institutions for the promotion of science technology and innovation, strengthening of public research institutes, the growth of PhD programs, and the formation and formalization of a journal structure, to socialize scientific results obtained in the region, have also characterized these last decades.

Although growth in the participation of LAC scientific production in traditional databases, such as Web of Science and Scopus, has also been the norm in this period, a common concern in the community has been the challenges to properly socialize scientific results when they are of little interest for mainstream scientific journals. The perseverance in LAC scientific communications of Spanish and Portuguese, as the main languages for communication, particularly in sciences with an important social component, demands alternative means of communication outside international journals as they might have their own structures. Leydesdorff and Bornmann (in press), for example, found a specific citation pattern of Spanish and Portuguese journals in library and information sciences (LIS).

This demand has been acknowledged and as a consequence, most LAC countries have an important structure of national journals. This poses other types of challenges in terms of

research assessment and evaluation. While rankings of international journals and measures based on citations allow researchers and librarians to make informed decisions on the expected quality of a scientific journal´s content, this distinction is more difficult and in occasions impossible when considering national publications. The proliferation of local journals edited by faculties or departments for the diffusion of mainly their own researchers' findings makes the distinction among journals harder.

The need to assess and monitor research results comes together with the demand for a transparent classification among scientific communications. How to assess scientific communications included in international journals versus regional or national journals? In part as a response to this need, different LAC countries have joined the SciELO program. SciELO, in our perspective, has had a positive impact on the consolidation of regional research capabilities and in providing a proper infrastructure for regional exchange and communication.

As was suggested in the collaboration networks analyzed, the SciELO program seems to have transcended the LAC region and includes authorships from Africa and Asia suggesting a platform for South-South collaboration. Other causes for the dominance of the international collaborations in scientific communications in WoS are the cognitive dominance of the biomedical and natural sciences, where collaboration among geographical dispersed groups of individuals is very common. The type of research that results in publications indexed in WoS Core Collection might also cause the dominance of international collaboration in WoS when compared to SciELO CI. Researchers from LAC countries might have a marginal participation in these collaboration networks. This position results of a collaboration among many authors and contributions in the form of data processing instead of cognitive contributions and argumentations. Successful collaborations in the region should hold the researchers in leadership positions (Moya Anegón et al., 2013).

From a cognitive perspective, the inclusion of SciELO CI into WoS offers new opportunities of coverage of disciplines and specialties where the particularities of the territory and the social context are important. Public health, social sciences and agriculture are relevant in SciELO CI; the participation of the LAC scientific communications in these disciplines in the core collection of the WoS has traditionally been low. In this sense, the 15% overlap of Scielo CI journals in both indexes suggests that the inclusion of SciELO CI in the WoS benefits WoS in terms of coverage of regional scientific advances, particularly of communications that have a local object of study and where communication is more original and responds to regional capabilities, but also regional issues and problems.

The inclusion of SciELO CI has raised some concerns among the editors of Spanish[4] and Portuguese journals that have benefitted from a special treatment and inclusion in WoS but that do not have an important position in SciELO CI. Editors of these journals fear that the policy of articulation of SciELO CI into the WoS might result in exclusion of their journals from WoS.

Inclusion of SciELO CI into WoS, responds to the need for a more inclusive representation of scientific results despite regional constrains and conditions. This has resulted from the competition of services offered by Thomson Reuters and Elsevier. The strategies aimed at improving regional visibility are different in Scopus and in the Web of Science. While Scopus has aimed at increasing coverage by increasing their base of regional journals, the globalization of the Web of Science (Testa, 2011) has meant the articulation of regional exercises. The Chinese Journal Database has been hosted in the WoS since 2008, the

[4] FECyT (Spain´s foundation for science and technology) has had an important role in certifying quality of its quality journals in order to support their inclusion in the WoS after an alliance with Thomson Reuters around 2007 (FECyT, 2011)

inclusion of SciELO CI and the Korean Journal Database has been operative since 2014. We believe that the strategy followed by Thomson Reuters provides the cumulative expertise of circulation and visibility promoted regionally, by programs similar to SciELO. We would like to explore this issue further in the future to understand how the inclusion of SciELO CI might put the WoS back in the competition for visibility of regional results.

Abstract
This study aims to gain a better understanding of communication patterns in different publication types and the applicability of the Book Citation Index (BKCI) for building indicators for use in both informetrics studies and research evaluation. The authors investigate the differences not only in citation impact between journal and book literature, but also in citation patterns between edited books and their monographic authored counterparts. The complete 2005 volume of the Web of Science Core collection database including the three journal databases and the BKCI has been processed as source documents. Annual cumulative citation rates in a three-year (x3) and a nine-year (x9) citation window are applied to compute the citation impact of different types of publications. The ratio x3/x9 is utilized as a kind of prospective Price index to examine the extent of ageing. The results of this study show that books are more heterogeneous information sources and addressed to more heterogeneous target groups than journals. Comparatively, the differences between edited and authored books in terme:s of the citation impact are not so impressive as books vs. journals. Humanities have the most different citation impact between books and journals, whereas life sciences have the most similar impact between two groups.

Conference Topic
Journals, databases and electronic publications; Citation and co-citation analysis

Introduction

Some consequences of the absence of books in bibliometric analyses

In contrast to the natural and life sciences, social scientists and humanists publish in different formats, specifically, they rather produce books and contributions to edited volumes and monographs than journal articles (Bourke & Butler, 1996; Pestaña, Gómez, Fernández, Zulueta & Méndez, 1995; Nederhof, 2006; Sivertsen & Larsen, 2012). Books should not be ignored by bibliometrics, not only because they are a major output type but also due to their high impact. Hicks (1999) states that the best social science is often found in books, which is reflected in their citation rates. The danger of ignoring books is illustrated by research, which explores the differences between the worlds of book and journal publishing (e.g., Nederhof, van Leeuwen & van Raan, 2010; Butler & Visser, 2006; Amez, 2013; Clemens, Powell, Mcllwaine & Okamoto, 1995; Hicks & Potter, 1991; Bourke & Butler, 1996; Chi, 2014a). Furthermore, citations to and from books are distributed differently from those to and from journal articles, and often originate from outside the cited work's specialty (Broadus, 1971). Some studies show that books reference more books than articles, and journal articles refer to more articles than books (Larivière, Archambault, Gingras & Vignola-Gagné, 2006; Line, 1979), indicating that citations from journal articles are not the largest source of citations obtained by book publications.

Even though the importance of books in scholarly communication, notably in the social sciences and humanities, was proved by previous studies, only few and small-scale case studies investigating the characteristics of books were conducted by bibliometricians due to the lack of a reliable and comprehensive data source providing citation links. These studies either investigate the citations of so-called non-source items in the references of Web of

Science (WoS) journal papers (Butler & Visser, 2006; Hammarfelt, 2011; Amez, 2013; Chi, 2014a) or analyse citations in other alternative databases such as Google Books or Google Scholar (Kousha & Thelwall, 2009; Kousha, Thelwall & Rezaie, 2011; Samuels, 2011, 2013). All in all, large-scale bibliometric studies analysing the citation patterns of book literature have not been conducted in the past decade.

A new approach to explore citation patterns of books and its limitations

In 2011, Thomson Reuters released a new collection in the WoS, Book Citation Index (BKCI), to allow users to discover book literature and trace its comprehensive citation links alongside journal literature (Adams & Testa, 2011). BKCI covers over 60,000 editorially selected books starting from 2005 with an additional 10,000 new titles each year (Book Citation Index, 2015).

Even though the BKCI broadens the coverage of WoS and allows researchers to tackle studies based on numerous and qualified bibliographic data of books and book chapters in different aspects, the new database is not fully developed yet (Leydesdorff & Felt, 2012; Torres-Salinas, Robinson-García, Jiménez-Contreras & Delgado López-Cózar, 2012; Gorraiz, Purnell & Glänzel, 2013; Torres-Salinas, Robinson-García, Campanario & Delgado López-Cózar, 2013a; Torres-Salinas, Rodríguez-Sánchez, Robinson-García, Fdez-Valdivia & García, 2013b; Torres-Salinas, Robinson-García, Cabezas-Clavijo & Jiménez-Contreras, 2014). Some limitations mentioned in previous studies include:

- Coverage
  BKCI indexes 61% of 60,000 books in the social sciences and humanities (in November 2014, see Book Citation Index, 2015), which is not too arguable due to the nature of the publication behavior of scholars in different fields. However, its indexing bias in terms of language, country, and publisher is large. For example, 96% of the indexed books are written in English (Torres-Salinas et al., 2014) and the United States and England account for 35% of all publications and 75% of publishers in BKCI (Gorraiz et al., 2013; Torres-Salinas et al., 2014). Furthermore, Springer, Palgrave and Routledge alone account for 50% of the total database (Torres-Salinas et al., 2014) evincing a rather high concentration of publishers.
- Completeness of records
  Gorraiz et al. (2013) report the absence of affiliation data in BKCI but it has been confirmed by Torres-Salinas et al. (2014) that their later downloaded data does include affiliation information which could be used to analyse research units such as countries or institutions. Moreover, the low share of BKCI indexed items with references data (<30%, see Chi, 2014b) would also limit the validity of relevant studies.
- Document type classification
  A further limitation of the BKCI comes from the lack of a clear distinction of document types due to the different forms of book literature.
  - *Books*
    Gorraiz et al. (2013) argue that 'book' might be considered to be at a higher hierarchical level as 'journal' instead of being treated as a document type, and consequently point out the lack of cumulative citation counts from different hierarchies in BKCI. It is in line with the warning raised by Leydesdorff and Felt (2012) that monographs may be underrated in terms of citation impact or overrated using publication performance indicators. Furthermore, Gorraiz et al. (2013) question the fuzzy boundaries of subtypes of book and how to treat new editions.

  - *Monographs and edited volumes*

It was discovered that edited books usually have a greater impact than non-edited books (Leydesdorff & Felt 2012, Torres-Salinas et al., 2014, Chi, 2014a; Amez, 2013). This may be because of the effects of working collectively with a more diverse content and the higher average number of book chapters per book (Torres-Salinas et al., 2014). However, a global consensus on how to cite the book editor(s), the book author(s) or the author(s) of the book chapter is lacking (Gorraiz et al., 2013). Even though it is possible to distinguish bibliometrically between monographs and edited volumes among the type 'book', a normalization for the credit of a monograph is required (Leydesdorff & Felt, 2012).

- *Book series and annual series*
  BKCI covers annual series, which are part of the journal and series literature and indexed by other collections of WoS as well. They are assigned to the pubtype 'Journal' in BKCI (the other two pubtypes are 'Books' and 'Books in series'), and all are published by the publisher Annual Reviews. Leydesdorff and Felt (2012) indicate the problems from ignoring differences between book series and annual series. As noticed by Torres-Salinas et al. (2012, 2013b), this publisher presents an outlier pattern showing a behavior more closely linked to journals rather than monographs.

The research purposes of this study

In this study, we analyse and compare BKCI items jointly with journals literature to answer the following open questions based on the revealed limitations of using the database. Some of these questions have already been addressed but not yet answered by, e.g., Adams & Testa (2011) and Gorraiz et al. (2013). These issues apply to differences in citation impact between journal and book literature but also to the question whether edited books with different contributors for each chapter essentially deviate in their citation patterns from their monographic authored counterparts.

1. What is the feature of books in the sciences (including life sciences, natural sciences, technical sciences), social sciences and humanities through the lens of the BKCI?
2. Is there any difference between the ageing of periodical and monographic literature?
3. Is there a difference in citation patterns of edited and authored books?

The findings are expected to allow a better understanding of communication patterns in different publication types and the applicability of the BKCI for building indicators for use in both informetrics studies and research evaluation.

Methodology

Data sources

The complete 2005 volume of the Web of Science Core collection database including the three journal databases Science Citation Index Expanded (SCIE), Social Sciences Citation Index (SSCI) and Arts & Humanities Citation Index (A&HCI) as well as the Book Citation Index (BKCI) has been processed as source documents. The two proceedings editions of the core collection have been excluded because of the large overlap among the book, proceedings and journal databases (cf. Gorraiz et al., 2013). The choice of volume 2005 was made for two reasons, particularly, because 2005 was the first BKCI volume and this allowed us to trace citations till end of 2013, i.e., for a full period of nine years.

In addition, we have split up the BKCI database into two parts, namely those books that could be identified as edited books and the rest, which was considered to refer to authored books. Overlap with proceedings and journals were removed to obtain a correct dataset for the

analysis. Only so-called citable document types have been taken into account, that is, articles, letters and reviews for journals, books and citable book chapters for the BKCI. All documents extracted from the BKCI have been analysed both individually and aggregated to the book level.

Subject classification

All items extracted from the database have been assigned to the 74 individual subfields according to the *modified* Leuven-Budapest classification system. Multiple assignments are quite frequent at this level of granularity. The original scheme was introduced by Glänzel and Schubert (2003) and has been recently modified to provide a better categorisation for the social sciences and humanities. The modified version has been developed for the use with the BKCI but is also fully compatible with the journal and proceedings editions of the WoS Core Collection as it is based on the WoS and Journal Citation Reports (JCR) subject categories. Major fields and subfields in the sciences of the previous version have not been changed. The modified classification scheme is presented in Figure 1.

THE LEUVEN – BUDAPEST CLASSIFICATION SCHEME FOR THE SCIENCES, SOCIAL SCIENCES AND HUMANITIES

0. **MULTIDISCIPLINARY SCIENCES**
   - X0 multidisciplinary sciences

1. **AGRICULTURE & ENVIRONMENT**
   - A1 agricultural science & technology
   - A2 plant & soil science & technology
   - A3 environmental science & technology
   - A4 food & animal science & technology

2. **BIOLOGY (ORGANISMIC & SUPRAORGANISMIC LEVEL)**
   - Z1 animal sciences
   - Z2 aquatic sciences
   - Z3 microbiology
   - Z4 plant sciences
   - Z5 pure & applied ecology
   - Z6 veterinary sciences

3. **BIOSCIENCES (GENERAL, CELLULAR & SUBCELLULAR BIOLOGY; GENETICS)**
   - B0 multidisciplinary biology
   - B1 biochemistry/biophysics/molecular biology
   - B2 cell biology
   - B3 genetics & developmental biology

4. **BIOMEDICAL RESEARCH**
   - R1 anatomy & pathology
   - R2 biomaterials & bioengineering
   - R3 experimental/laboratory medicine
   - R4 pharmacology & toxicology
   - R5 physiology

5. **CLINICAL AND EXPERIMENTAL MEDICINE I (GENERAL & INTERNAL MEDICINE)**
   - I1 cardiovascular & respiratory medicine
   - I2 endocrinology & metabolism
   - I3 general & internal medicine
   - I4 hematology & oncology
   - I5 immunology

6. **CLINICAL AND EXPERIMENTAL MEDICINE II (NON-INTERNAL MEDICINE SPECIALTIES)**
   - M1 age & gender related medicine
   - M2 dentistry
   - M3 dermatology/urogenital system
   - M4 ophthalmology/otolaryngology
   - M5 paramedicine
   - M6 psychiatry & neurology
   - M7 radiology & nuclear medicine
   - M8 rheumatology/orthopedics
   - M9 surgery

7. **NEUROSCIENCE & BEHAVIOR**
   - N1 neurosciences & psychopharmacology
   - N2 psychology & behavioral sciences

8. **CHEMISTRY**
   - C0 multidisciplinary chemistry
   - C1 analytical, inorganic & nuclear chemistry
   - C2 applied chemistry & chemical engineering
   - C3 organic & medicinal chemistry
   - C4 physical chemistry
   - C5 polymer science
   - C6 materials science

9. **PHYSICS**
   - P0 multidisciplinary physics
   - P1 applied physics
   - P2 atomic, molecular & chemical physics
   - P3 classical physics
   - P4 mathematical & theoretical physics
   - P5 particle & nuclear physics
   - P6 physics of solids, fluids and plasmas

10. **GEOSCIENCES & SPACE SCIENCES**
    - G1 astronomy & astrophysics
    - G2 geosciences & technology
    - G3 hydrology/oceanography
    - G4 meteorology/atmospheric & aerospace science & technology
    - G5 mineralogy & petrology

11. **ENGINEERING**
    - E1 computer science/information technology
    - E2 electrical & electronic engineering
    - E3 energy & fuels
    - E4 general & traditional engineering

12. **MATHEMATICS**
    - H1 applied mathematics
    - H2 pure mathematics

13. **SOCIAL SCIENCES I (GENERAL, REGIONAL & COMMUNITY ISSUES)**
    - Y1 education, media & information science
    - Y2 sociology & anthropology
    - Y3 community & social issues

14. **SOCIAL SCIENCES II (ECONOMIC, POLITICAL & LEGAL SCIENCES)**
    - L1 business, economics, planning
    - L2 political science & administration
    - L3 law

15. **ARTS & HUMANITIES**
    - K0 multidisciplinary
    - K1 arts & design
    - K2 architecture
    - K3 history & archaeology
    - K4 philosophy & religion
    - K5 linguistics
    - K6 literature

Figure 1. The modified version of the Leuven-Budapest classification scheme for the WoS.

Data processing

In order to analyse citation impact and ageing patterns over subfields, we have calculated the following statistics:

- Annual citation rates (both increments and cumulated) for the year of publication 2005 (1) till 2013 (9). In this study, however, we only use cumulative citation impact in a three-year (x_3) and a nine-year (x_9) citation window.
- The ratio x_3/x_9 as a kind of prospective Price index and an indicator of ageing.

We have calculated all statistics on the basis of both individual book chapters, where available, and for the complete books. Chapters were considered the equivalent of journal articles in terms of the aggregation level. Unfortunately, chapter-based citation statistics proved not to be reliable since citations to individual chapters could not be identified in many cases as they were assigned to the book in the database. This is not necessarily due to the database producer: often the authors of the citing documents are responsible for this uncertainty. In order to avoid biased indicators or otherwise incomplete or distorted results we decided to use only citation indicators for complete books, which, of course, results in a serious loss of information and a more intricate interpretation. This applies above all to edited books, where chapters are authored by different contributors, and a distinction between different chapters would be of paramount importance.

A further issue is the small size of the publication set resulting from this restriction. We have found many subfields with fewer than 30 books each: This threshold might be critical for the interpretation and reliability of statistics like mean values and shares (e.g., Glänzel & Moed, 2013). Furthermore, we have not assigned books to corporate addresses of authors/editors because the availability of author affiliation in books is rather low (see, e.g., Gorraiz et al., 2013).

Results

It is not the aim of the present paper to study the subject coverage of the BKCI database since, on one hand, we can refer to the study by Adams and Testa (2011) in the context of broader subject areas and, on the other hand, a subject analysis at the level of subject categories can easily be conducted using the analyse tool of the web version of Thomson Reuters WoS Core Collection. Nevertheless we would just like to mention in passing that we can confirm that subfields in the social sciences and humanities have a better representation in the BKCI than in the other databases of the WoS.

Ten subfields had a share larger than 5% in the 2005 volume of the BKCI: Among those 10 subfields applied mathematics was the only representative of the sciences. Slightly more than 12% of all books could be assigned each to business, economics, planning and political science & administration, respectively. All books in the humanities (except for multidisciplinary and arts & design) as well as education, media & information science and sociology & anthropology in the social sciences were among the top ten in terms of subject representation.

In the first step we looked at citation patterns of book and journals literature by disciplines in a nine-year citation window. What we intended to do was not to compare citation impact over across fields but to compare subject-specific citation patterns between journals and books. It is a well-known fact that the subject is one of the factors influencing citation impact; the document type is another one (cf. Glänzel, 2013). Thus the publication type such as journal, proceeding, or monograph is expected to play a role in this context as well. Figure 2 plots the mean citation rates of subfields based on the nine-year citation window of books against the corresponding journal indicators. The volume year of the source items was 2005. Only subfields have been chosen in which at least 30 books have been published in that year. Subfields are ranked according the subfield impact in the BKCI. The results are somewhat unexpected here: Not the life sciences – as expected from journal literature – exhibit the highest citation impact for books but disciplines in chemistry and the geosciences. Consequently, the correlation between the corresponding x_9 values is medium ($r = 0.420$). In this respect, there are no dramatic differences between edited and authored books. The correlation between these two book types with $r = 0.762$ is relatively strong.

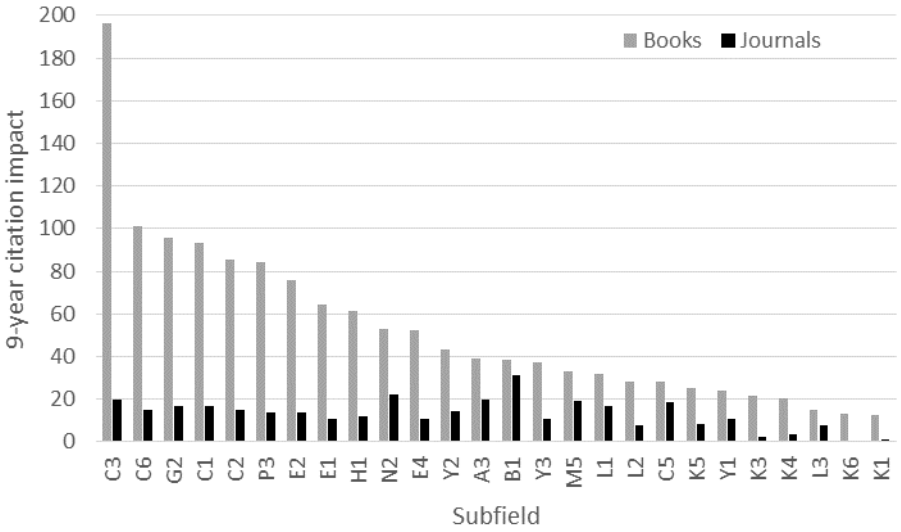

Figure 2. Most cited subfields in the mirror of the BKCI vs. SCIE/SSCI/AHCI. [Data sourced from Thomson Reuters Web of Science Core Collection].

It is known from journal literature that ageing is the fastest in the life and the natural sciences, followed by applied sciences, mathematics, social sciences and humanities (see Glänzel & Schoepflin, 1999). Ageing patterns can be characterised as a combination of phases of maturing and decline in citation processes (Glänzel & Schoepflin, 1995; Moed, van Leeuwen & Reedijk, 1998). The transition from the first to the second phase is marked by a peak in the annual increments of citation impact. This peak ranges according to the ageing of the discipline under study typically between the second and the fifth year beginning with the date of publication. The ratio (x_3/x_9) can thus serve as a proxy for literature ageing in the mirror of citation processes.

The plot of the prospective 'Price Index' (x_3/x_9) of books indexed in the 2005 volume of the BKCI against the corresponding journal indicators for the same volume is shown in Figure 3. The x_3/x_9 ratios are ranked in descending order according to the journal database editions of the WoS. At the left-hand side the disciplines with the fastest aging (highest ratios) can be found, while the low end is formed by slow-ageing subfields (cf. black bars in Figure 3). The grey bars representing the subfields in the BKCI show a rather subject-balanced situation. High (between 20% and 25%) as well as low (between 10% and 15%) shares can be found in both science and SSH subfields. The correlation between the x_3/x_9 ratios for books and journals is practically zero. This is illustrated in Figure 4. We just mention in passing that also the correlation between the corresponding ratios of edited and authored books is low ($r = 0.110$) as well. This substantiates that citation processes of books are more complex as these apparently depend on more factors than in the case of journal literature. Notably ageing seems not to be principally characterised by subject-specific peculiarities. Books are thus more heterogeneous information sources and addressed to more heterogeneous target groups than journals (and possibly proceedings).

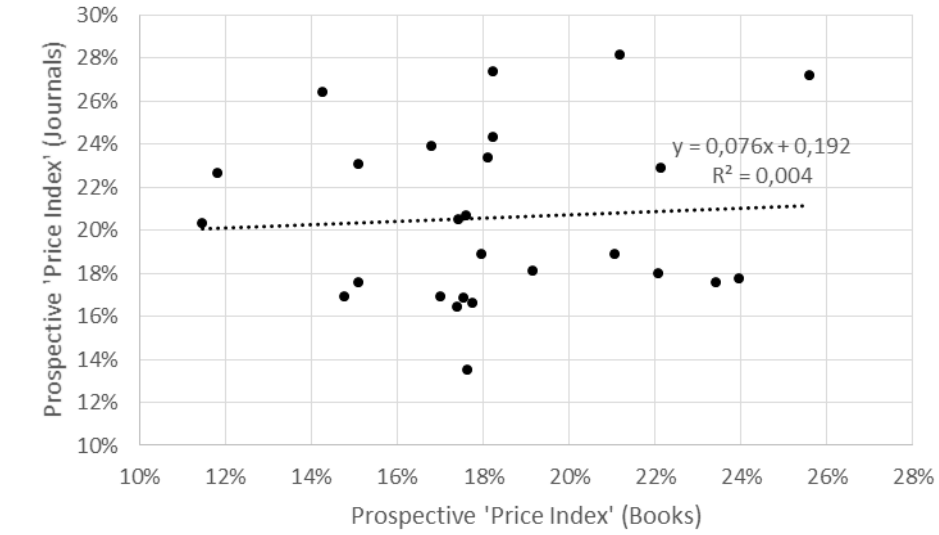

Figure 4. Scatter plot of prospective 'Price Index' of subfields in the BKCI vs. SCIE/SSCI/AHCI. [Data sourced from Thomson Reuters Web of Science Core Collection].

Conclusion

It is confirmed in this study that subfields in the social sciences and humanities have a higher representation in the BKCI (59%) than they have in the other databases of the WoS (12%). Disciplines in chemistry and the geosciences, instead of life sciences, have the highest citation impact for books. Humanities is the field having the highest difference between citation impact of books and journals. In contrast, life sciences have the most similar impact in books and journals. Compared to other sciences, technical sciences have relatively moderate characteristics in different perspectives.

It is not surprising to see that the social sciences and humanities have the largest increase of both the coverage and citation impact in the BKCI compared to journal literature in the other databases of the WoS. The BKCI could be an initial approach to explore wider targets of bibliometric analyses in the social sciences and humanities. The books in the basic sciences have unexpectedly high citation impact, whereas books in the life sciences do not reflect the

dominant position in journal literature but have been found to be on a relatively similar scale of citation counts as journals. This may imply that using BKCI data for bibliometric analyses in basic sciences would be a powerful approach to drag in more citation information.

For the ageing of periodical and monographic literature, the results of this study indicate a clear boundary between the two groups. The differences between books and journals are obvious, but the ageing of books is balanced between subjects. The differences between edited and authored books in terms of the 9-year citation impact are not so impressive as the other group books and journals. However, their disparities in ageing ratios are more evident than those of citation impact. The more complex citation processes of books, compared to journal literature, are shown in this study, the more heterogeneous characteristics of books should therefore be addressed.

The different ageing patterns of book and journal literature, i.e., books do not have as strong discipline specific patterns as journals, may lead to a universal condition for applying or building indicators in the collections of BKCI. It especially needs to be taken into account while designing indicators that are sensitive to the observed citation period. Moreover, the heterogeneous characteristics of books from their different formats such as edited or authored volumes result in more complex citation patterns than journals. These findings on the differences between periodical and monographic literature are worth further studies of indicator design to take into account.

Abstract
With the acceleration of scholarly communication in the digital era, the publication year is no longer a sufficient level of time aggregation for bibliometric and social media indicators. Papers are increasingly cited before they have been officially published in a journal issue and mentioned on Twitter within days of online availability. In order to find a suitable proxy for the day of online publication allowing for the computation of more accurate benchmarks and fine-grained citation and social media event windows, various dates are compared for a set of 58,896 papers published by Nature Publishing Group, PLOS, Springer and Wiley-Blackwell in 2012. Dates include the online date provided by the publishers, the month of the journal issue, the Web of Science indexing date, the date of the first tweet mentioning the paper as well as the Altmetric.com publication and first seen dates. Comparing these dates, the analysis reveals that large differences exist between publishers, leading to the conclusion that more transparency and standardization is needed in the reporting of publication dates. The date on which the fixed journal article (Version of Record) is first made available on the publisher's website is proposed as a consistent definition of the online date.

Conference Topic
Journals, databases and electronic publications

Introduction
The process of scholarly communication, which usually begins with the formulation of a research idea and hypothesis and ends with publishing results to share them with the scientific community (Garvey & Griffith, 1964), has been sped up by means of electronic publishing (Dong, Loh, & Mondry, 2006; Wills & Wills, 1996). The publication delay, which Amat (2008, p. 382) defined as the "chronological distance between the stated date of reception of a manuscript by a given journal and its appearance on any print issue of that journal", has been accelerated by email and online manuscript handling systems as well as online publication (Wills & Wills, 1996). The delay period consists of the review process, which constitutes the main delay and ends with the acceptance of the manuscript, followed by technical delays of journal production and paper backlog.

Various studies have analyzed publication delays and found differences between scientific fields, journals, and publishers (e.g., Abt, 1992; Amat, 2008; Björk & Solomon, 2013; Das & Das, 2006; Diospatonyi, Horvai, & Braun, 2001; Dong et al., 2006). Since long delays interfere with priority claims and slow down scientific discourse, publication speed plays an important role for authors and scholarly communication (Rowlands & Nicholas, 2006; Schauder, 1994; Tenopir & King, 2000). Short publication delays can therefore be considered as a quality indicator reflecting the up-to-dateness of scientific journals (Haustein, 2012). Publishers have begun to reduce delays by making so-called *early view*, *in press*, *ahead of print* or *online first* versions of accepted papers available before they appear in an (print) issue. It has been shown for food research journals that online ahead of print publication has reduced publication delay by 29% (Amat, 2008), while Das and Das (2006) reported for 127 journals in 2005 average lags of three months between online and print issues publications

with particular differences between publishers. Tort, Targino, and Amaral (2012) showed that this lag increased significantly over time for six neuroscience journals. Online dates are now being recorded in bibliometric databases like Scopus, which impacts bibliometric analyses (Gorraiz, Gumpenberger, & Schlögl, 2014; Heneberg, 2013). Together with the increasing popularity of preprint servers (such as arXiv and SSRN) and institutional repositories, such *in press* versions have helped to speed up the read-cite-read cycle. As a result manuscripts increasingly cite papers that have not been officially published in a journal issue. Although scholarly communication has always involved sharing different versions of a manuscript with colleagues before, during, and after formal publication—such as exchanging drafts for feedback before submission or diffusing preprints after acceptance—, the electronic era makes these versions 'public', searchable, and (often) permanently retrievable on the web. To define and distinguish between various versions, the National Information Standards Organization (NISO) agreed upon the following versions of a journal article (NISO/ALPSP Working Group, 2008):

- Author's Original (AO) – manuscript ready to submit.
- Submitted Version Under Review (SMUR) – manuscript under formal peer review.
- Accepted Manuscript (AM) – version of journal article accepted for publication.
- Proof (P) – copy-edited version of accepted article.
- Version of Record (VoR) – fixed version of journal article formally published.
- Corrected Version of Record (CVoR) – VoR in which errors have been corrected.
- Enhanced Version of Record (EVoR) – VoR updated or enhanced with supplementary material.

It is important to note that by the NISO definition, the VoR is defined as a "fixed version of a journal article that has been made available by any organization that acts as a publisher by formally and exclusively declaring the article 'published'" (NISO/ALPSP Working Group, 2008, p. 3). This definition includes early views and in press articles without information on volume and issue or other identifiers as long as the content and layout of the article are fixed.

When it comes to bibliometric indicators, the acceleration of the publication process has been reflected in obsolescence patterns (Egghe & Rousseau, 2000) as well as citing half-lives (Luwel & Moed, 1998). These increasing online-to-print lags were shown to artificially increase citation rates including the immediacy index and impact factor (Heneberg, 2013; Seglen, 1997; Tort et al., 2012). The speed of scholarly communication becomes particularly visible in the context of social media metrics (the so-called altmetrics); for example, mentions of scientific documents on Twitter happen within hours (and sometimes within minutes) of online availability (Shuai, Pepe, & Bollen, 2012).

We argue that in the fast-moving digital era, the use of the publication *year* of the journal issue as the smallest level of time aggregation for bibliometric indicators is becoming insufficient, particularly in research evaluation contexts, due to the following factors:

a. acceleration of the read-cite-read cycle due to electronic publishing;
b. commonplace of online publication before publication of the journal issue; and
c. increasing online-to-print lags.

Following NISO's terminology, we suggest that the date of the first public online appearance of the VoR is the most relevant and should be used as the basic time unit to determine the official publication date of a paper. This would allow for the construction of more accurate citation and social media event windows, for example, citation windows of equal length (in days or months) for papers published in January or December, as well as the construction of more exact benchmarks by aggregating citations and social media events per week (e.g., tweets and Facebook shares) or month (citation rates) depending on the evaluation context.

Although many publishers now report online publication dates, many different dates are presented and the information provided varies between publishers, as no official standards

exist on publication dates. This paper explores and aims to verify various 'publication' dates in order to find a good proxy for the actual date of online availability. Thus, the paper aims to answer the following research questions:

1. Which publishers specify online dates and how do they provide them?
2. How reliable are dates provided by the publishers and how do they compare to each other?
3. What other existing dates can be used as a proxy of the online publication date of the VoR?

Methods and Materials

The dataset of this study was retrieved from the Web of Science (WoS) (as the major citation database) and is restricted to the publication year 2012 to limit effects of changes over time. To validate the publication dates provided by the publishers, the dates of the first tweet mentioning the particular paper were obtained from Altmetric.com. We argue that a tweet cannot link to a paper before it exists, thus the first tweet cannot have appeared before the online publication date. Tweets captured by Altmetric.com are linked to the documents via the DOI resulting in 313,301 WoS 2012 papers with at least one event captured by Altmetric.com (Haustein, Costas, & Larivière, 2015). Altmetric records that contained an arXiv ID or Astrophysics Data System (ADS) ID were removed to exclude tweets to preprints, which could have been made public before the online publication of the VoR. Twitter mentions are thus restricted to the mentions or links to the publisher's website, DOI, or PubMed ID.

Table 6. Top 10 publishers according to number of papers with types of dates available according to data provided by the publisher via API (a), in the metadata (m) of the webpage, on the webpage only (w), or as dynamic content only (d). Publishers selected for this study are highlighted in grey.

Publisher	Papers	Received	Revised	Accepted	Version of Record	Online	Publication	Date	Journal Issue	Journal Issue Online

Sage	8,776				w	w		m	w,m	

[i] Wiley provides two online dates "article published online" as well as "online date". See explanations below.

The top 10 publishers[1] of papers in the WoS-Altmetric dataset can be found in Table 1 together with the date information provided via API, in the metadata, in the webpage only, or as dynamic content of the webpage. It can be seen (in the headings of the table) that multiple terms exist to describe the online publication date and that multiple types of dates are made available on the website, in the metadata, or via the API; these include received, revised, accepted, version of record, online, publication, and date. Based on checking samples of articles for each of the publishers, we assume that the dates provided as *Version of Record*, *Online*, *Publication* and *Date* (Table 1) refer to (first) online appearances of the VoR required

[1] Publisher names from WoS were cleaned searching for name variants, but mergers and acquisitions were not accounted for. For example, BMC is considered an independent publisher, although it was acquired by Springer in 2008.

for this study. Wiley-Blackwell, Springer, PLOS, and Nature Publishing Group (NPG) were chosen due to their coverage and the technical feasibility of retrieving online date information. While Elsevier was the most represented publisher in this sample, it was difficult to obtain the required date information for their articles using PHP because this information is inserted dynamically into the webpage using JavaScript; Elsevier offers an API, but when queried[2] it was found to provide access to only the issue date and not to the online publication dates required for this study.

Using the DOI, the respective publishers' web platforms were queried to retrieve online dates. PLOS, Springer, and NPG each offer an API, but it was found that in some instances additional date information was only made available by searching the web page. In order to obtain the dates for Wiley, Springer and NPG, a PHP script was written that retrieved the HTML of the page. The HTML was then searched for metadata containing date information (e.g. <meta name="prism.publicationDate" content="2012-01-05"/>). When date information was found, it was saved to a relational database for evaluation. In instances where the article website had no (or missing) metadata available, the HTML was parsed and the contents of specific HTML tags found to contain date information was extracted and saved to a relational database; for the Wiley articles, a second script was written to retrieve dates not found in the metadata.

To compare different dates available and test in how far they can be used as proxies for online publication dates, other date information was obtained from WoS and Altmetric, so that together with the information from publishers the following dates were available:

- *online date*: retrieved from the publishers websites as part of the article metadata. For NPG ("Advance Online Publication"[3]), Springer ("Online First"[4]), and Wiley-Blackwell ("Early View"[5]) this date marks when the VoR was made publicly available on the publisher's website. For PLOS the online date equals the publication date because there is no difference between online and issue dates.
- *journal issue date*: the date from the journal issue as recorded by WoS. Since only a minority of papers provided the day of the month, the journal issue date was converted to the first of each month. Based on all 1.3 million papers in WoS published in 2012, 3.2% were published in issues spanning several months (such as JAN-FEB for a double issue). These were converted to the first day of the first month. A small percentage (0.5%) of papers appeared in seasonal issues (SPR, SUM, FAL, WIN). Since the data indicates that these are published at the beginning, middle, as well as the end of the particular season, these dates were disregarded. An additional 11.3% of all 2012 papers did not provide any issue date. Figure 1 provides an overview of the distribution of the 1.3 million WoS 2012 papers per journal issue date information.
- *Altmetric publication date*: the publication date as recorded by Altmetric.com, which is a mix of the journal issue date and online date (personal communication with Euan Adie and Jean Liu) as retrieved from the publisher. This is also the date Altmetric.com uses to compute the Altmetric score and provide benchmarks for papers of the same age. As shown in Figure 2, particular peaks can be observed for January 1 of each year as well as the first or last of each month. This might reflect common publishing practices, but could also be caused by aggregating data without actual day (and month) information. It was found that 15.1% of Altmetric.com records[6] did not have any publication date or they had incorrect dates (e.g. dates up to 2037).

[6] Based on 2.1 million Altmetric.com records collected in August 2014.

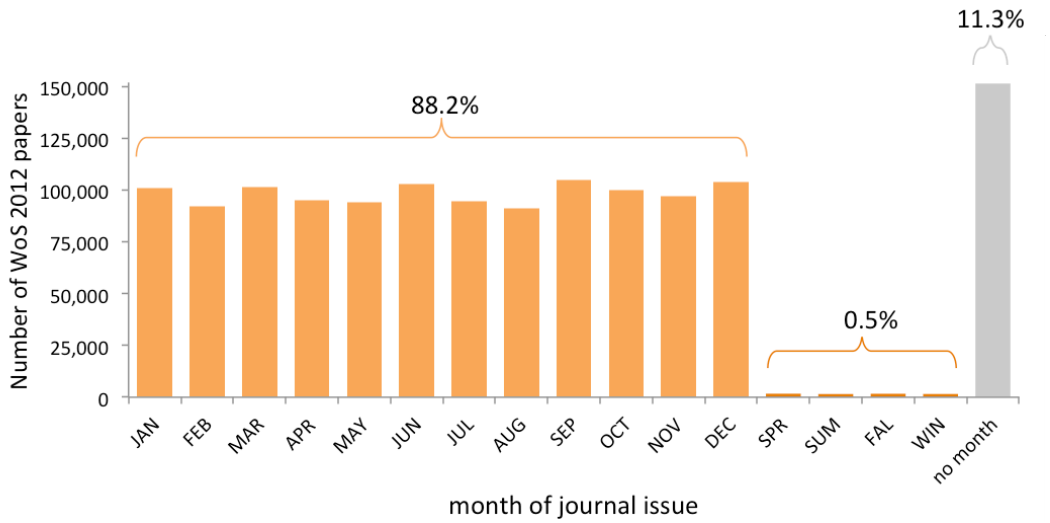

Figure 1. Number of WoS 2012 papers per months of journal issue.

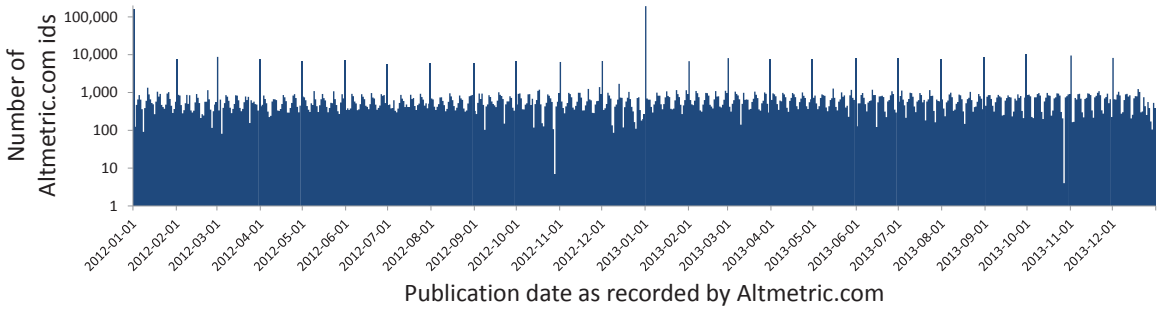

Figure 2. Number of Altmetric.com ids per Altmetric.com publication date from January 2013 to December 2014.

- *Altmetric first seen date*: the datestamp when Altmetric.com captured the first event for a particular document, which is missing for 4% of all records.[7]
- *First tweet date*: the datestamp of the first tweet[8] captured by Altmetric.com (excluding all papers with links to arXiv IDs or ADS IDs to ensure that the tweet did not refer to a preprint).
- *WoS indexing date*: the day when the document was indexed by WoS, which for 2012 papers was mostly during (37.7%) or in the month before (11.5%) or after (29.4%) the journal issue month.

In addition to the dates above we were also able to retrieve the following information for the papers published by Wiley-Blackwell:

- *Manuscript received*: the date the AO was submitted.
- *Manuscript accepted*: the date the AM was accepted.
- *Article first published online*: we could not determine the exact meaning of this date; for 95.6% of the total 34,507 Wiley-Blackwell documents it was identical with the *online date* and for 1.6% it was missing. For 2.3% of papers the *article first published online date* occurred before the *online date* by, on average, 35 days, which suggest

[7] Based on 2.1 million Altmetric.com records collected in August 2014.
[8] Twitter is the most common source covered by Altmetric.com (Robinson-García, Torres-Salinas, Zahedi, & Costas, 2014), so it makes sense to work with this date and not from other less common sources (e.g. Facebook or blogs).

that it marks the publication of the AM. However, in 137 cases (0.4%), it followed the *online date* by, on average, 52 days.

The final dataset—that is, the match of WoS, Altmetric.com, and papers with online dates retrieved from the four publishers—included 71,175 papers. For better comparison, it was restricted to papers for which all five dates tested as proxies for online publication (i.e., journal issue, Altmetric publication and first seen date, first tweet and WoS indexing date) were available. This amounted to a total of 58,896 papers, 12.5% NPG, 16.3% PLOS, 24.6% Springer and 46.6% Wiley-Blackwell.

Results and Discussion

Descriptive statistics comparing the online date to the five potential proxies are presented in Table 2, highlighting particular differences for the four publishers. Based on the assumption that the online date provided by the publishers were correct, the Altmetric publication date, first seen date, as well as the first tweet date seem to be the best proxies for online publication, while the journal issue and WoS indexing date show the largest deviations from the online publication dates. These differences reflect the nature of these dates. For example, Altmetric collects its publication dates from the publishers websites and while first tweets are known to happen shortly after publication (Shuai et al., 2012), WoS processing takes more time, namely, on average between 39 days for PLOS or 163 days for Springer papers. The 61 (NPG), 84 (Wiley-Blackwell), and 146 (Springer) days between online and journal issue date mostly reflect the backlog between online availability and publication of the journal issue. Although the (print) issue is generally assumed to follow online publication chronologically, results in Table 2 show that for 3.47% of Springer, 9.09% of Wiley-Blackwell, and 20.04% of NPG papers analyzed the online date came after the journal issue date, which is considered negative delay (Das & Das, 2006).

Although Altmetric and Twitter dates work better than journal issue and WoS indexing, none of the dates seem to reflect the online date well and large differences can be observed between publishers, in particular for Wiley-Blackwell, which questions the validity of any of the five dates as a reliable proxy of the publication of the VoR across publishers. The Altmetric publication date, which overall shows the smallest difference compared to the online date provided by the publishers—on average, 9 days for Springer, 12 days for NPG, 27 days for PLOS, and 121 for Wiley-Blackwell—is also problematic, because it is set to a date prior to online publication in 43.37% of Springer, 55.38% of NPG, 63.83% of Wiley-Blackwell, and 66.49% of PLOS papers. The variance between publishers affects Altmetric scores (but arguably also citation scores) when benchmarking a paper's scores against that of papers of the same reported age.

Based on the assumption that a tweet cannot mention a paper before it exists in the online space it links to, the online dates provided by Wiley-Blackwell seem to be the most problematic (Figure 3), as 14.52%[9] of the 27,432 analyzed papers had tweets linking to them before the date that the publisher identifies as the online publication date. On the other hand, none of the PLOS papers and few of the Springer (0.08%) articles were mentioned on Twitter before the online publication date. Although all of the papers analyzed have been tweeted, the mean number of days between online date and first tweet was higher than expected, ranging from 15 days for PLOS to 92 days for Springer. Moreover, the first mention on Twitter happened on the day of online publication for 1.06% (Springer) and 34.47% (NPG) sampled papers, which—particularly considering that about 80% of recent papers are never tweeted

[9] Results change only slightly when using the *article first published online* date, i.e. 14.61% of Wiley-Blackwell papers had a tweet appear before this date.

(Haustein, Costas, & Larivière, 2015)—limits the usefulness of the first tweet date as a proxy for online publication.

Table 2. Statistics for chronological distance (in number of days) of the journal issue month, Altmetric publication and first seen date, first tweet date and WoS indexing date with the online date for NPG, PLOS, Springer and Wiley-Blackwell.

[i] First of the journal issue month as recorded by WoS.
[ii] PLOS does not distinguish between online and issue date, so that the two dates are actually identical.

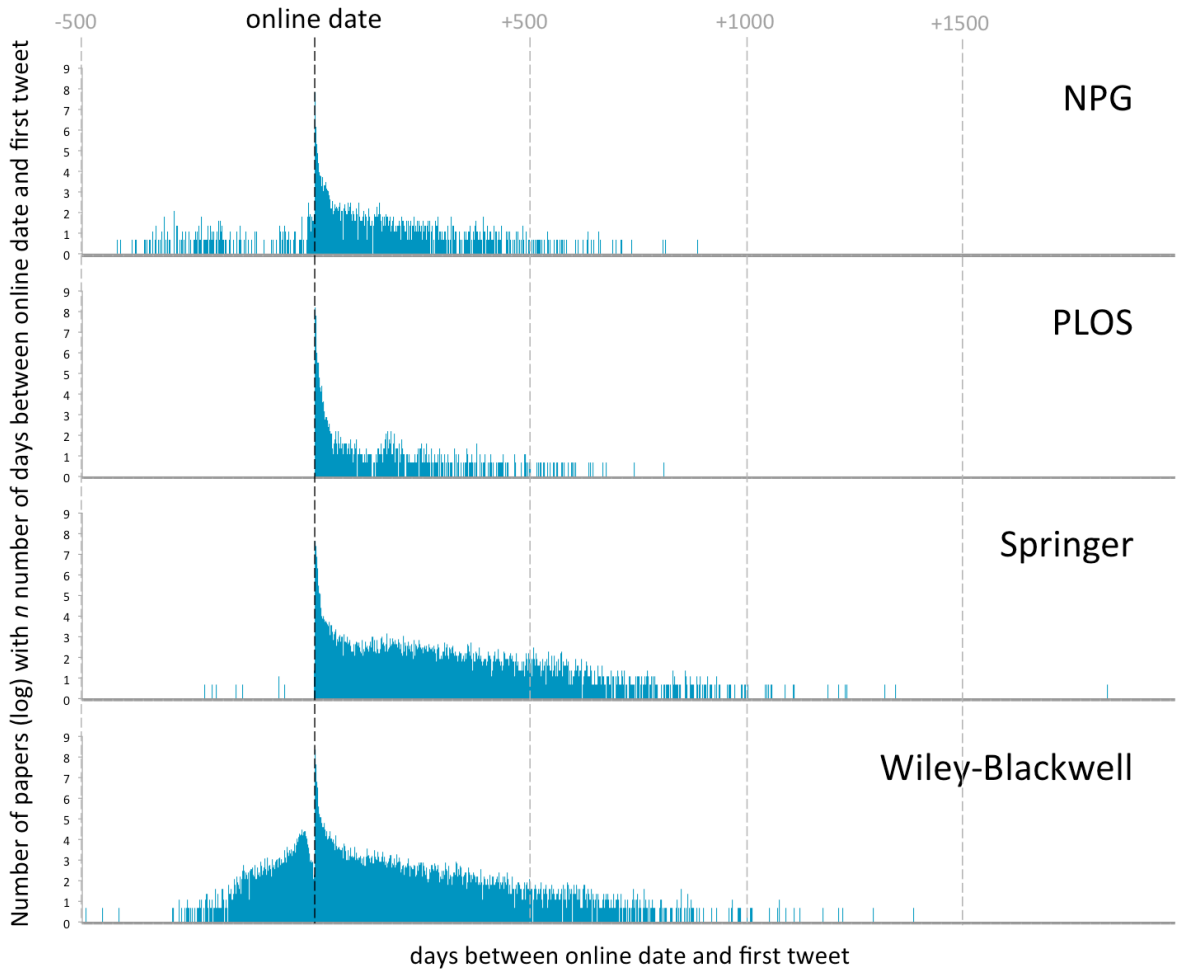

Figure 3. Number of papers (log) with *n* days between online date and first tweet per publisher.

Conclusions and Outlook

Currently none of the investigated dates represent a good proxy for the date a journal article was actually available online. In particular, the finding that a considerable amount of Wiley-Blackwell papers had been mentioned on Twitter before the online date, suggests that inconsistencies exist in terms of how publishers report online dates. This applies to the technical aspects as well as to actual content and vocabulary used. Thus, even when online dates can be retrieved from the publishers' websites or via API, they do not seem to always (and in a similar way for every publisher) mark the actual point in time when something was made accessible online. There is, thus, an urgent need for transparency and standardization of various dates reported by publishers in order to assure comparability of online dates across publishers. Adopting the vocabulary developed by NISO, specific dates could be reported for each version of the journal article, and the first appearance of the VoR would thus mark the date the fixed version of the document appeared online. A standardized vocabulary and a common definition of what various publication dates mean would not only improve benchmarking in the context of research evaluation but would also help to accurately determine the start of open access embargo periods required by certain funders, such as the NIH in the United States or the European Research Council. Currently these embargo periods, delaying green open access by a couple of months to years to protect publishers' revenue, are supposed to begin with publication of the article, which can refer to either journal issue or

online date.[10] Setting the start date of the embargo to the online publication date of the VoR would remove a potential loophole that allows the publishers to increase the embargo period during which they have the exclusivity of access.

Until such a standard is implemented, research on metrics should focus on obtaining more publisher-independent date information. One potential proxy for online publication could be the date when a DOI resolved successfully for the first time. Recently CrossRef has implemented the DOI Chronograph, a tool which tracks various deposits of metadata by the publisher as well as the first day of successful DOI resolution (Wass, 2015). Future work will investigate in how far these dates can be used to create fine-grained benchmarks needed in the context of social media metrics. Regarding citations, where monthly proxies are sufficient, the WoS Indexing date should be further investigated.

Acknowledgments

Abstract

This study analyzes the correlation between the obsolescence of citations and access concerning a broad range of subjects, including fields that have not been dealt with in previous studies, shedding light on the differences between these two types of obsolescence and the characteristics for each field. The analysis investigates approximately 1,200 journals that were randomly sampled from 11 subject fields in SpringerLink and 20 subject fields in ScienceDirect. Metrics such as cited half-life and download half-life are employed to examine the relationship between the rate of obsolescence of citations and access. As a result, no strong correlation between citations and access is observed in most fields with regard to the short-term obsolescence. As for the long-term obsolescence, on the other hand, comparatively strong and significant correlations are seen in natural sciences other than medicine-related fields ($p < 0.05$).

Conference Topic

Journals, databases and electronic publications

Introduction

This study analyzes the relationship between the obsolescence of citations and access for usage of electronic journals in Japanese university libraries. The Big Deal, which is a package contract for electronic journals, has been rapidly adopted among Japanese university libraries. Irrespective of the university's size, the Big Deal drastically increased the number of accessible titles of journals at contract universities. However, with ongoing budget cuts and increasing journal prices, price hikes for the Big Deal are putting pressure on library budgets. This situation makes it difficult for libraries not only to subscribe to new journals but also to maintain existing subscriptions. As withdrawal from the Big Deal results in a drastic decrease in the number of accessible titles of journals, and thereby a collapse of the library's academic information framework, collection building of journal backfiles is necessary to alleviate the impact of these losses.

The collection development of journal backfiles differs from that of current files, which have a strong tendency to become fixed owing to budgetary considerations. This is because library staffs at many universities select and propose journal backfiles to be introduced under their own direction, for example, by utilizing special proposals received from publishers shortly before the accounting period. However, few Japanese universities have sought to implement a planned introduction of journal backfiles by scrutinizing the level of on-campus demand and the effectiveness of such an introduction.

As Takei, Yoshikane, and Itsumura (2013) pointed out, effective methods of collecting journal backfiles have rarely been studied in the literature. Investigating the development of backfiles requires perspectives focusing on the articles that fall into disuse, that is, obsolescence. Slower obsolescence represents stronger demand of researchers for older articles in the concerned field. Obsolescence analysis has been performed on library

collections to evaluate a decrease in the use of documents over time. The obsolescence of books is assessed on the basis of the number of times a book is used by lending year and accession year. In contrast, obsolescence of journals is based on citations and access to documents. Understanding the relationship between the obsolescence of citations and access will make it possible to estimate the obsolescence of access on the basis of information regarding the obsolescence of citations. This relationship has already been examined in certain fields, such as chemistry, and for specific journals, as will be described in the next section. However, the nature of documental use (citations and access) varies by field, and trends in the differences between the obsolescence of citations and access may also differ by field. Thus, this study employs several indices of obsolescence, some of which had not been adopted before our previous study (Takei, Yoshikane & Itsumura 2013), and analyzes obsolescence of access and citations for a wide range of subjects, including fields that have not previously been examined. We shed light on the differences between both types of obsolescence and their characteristics in each field.

Related Research

There are some indices for analyzing the relationship between citations and downloads (access). Impact Factor (IF), Immediacy Index (II), and Cited Half-life (CHL) are major indices of citations, while Download Impact Factor (DIF), Download Immediacy Index (DII), Download Half-life (DHL), and Usage Half-life (UHL), which is used as a synonym of DHL, are indices of downloads. According to the definition of Journal Citation Reports (JCR), IF is "the average number of times articles from the journal published in the past two years have been cited in the JCR year," II is "the average number of times an article is cited in the year it is published," and CHL is "the median age of the articles that were cited in the JCR year." IF and II indicate how frequently articles in the journal are cited within several years after publication and immediately after publication, respectively. CHL shows the degree of demand for older articles in the journal. In contrast, DIF and DII analogically apply the definitions of IF and II to downloads, respectively, and both DHL and UHL replicate the definition of CHL to access. Using these indices, many studies have been conducted on the relationship between citations and downloads to evaluate journal collections. For instance, Duy and Vaughan (2006) analyzed local citation data and IF with journal usage in the fields of chemistry and biochemistry. Good correlations were seen between local citation data and journal usage, whereas no significant correlation was observed between IF and journal usage. Other examples can be found in Chu and Krichel (2007), McDonald (2007), Bollen and van de Sompel (2008), and Watson (2009). In particular, there are some studies on obsolescence of access and citations related to electronic journals. For instance, Nicholas et al. (2005) surveyed synchronous obsolescence of access, revealing that over half of all usage was accounted for by items published within the last 15 months. Moreover, several studies have analyzed the relationship between obsolescence of citations and access by calculating and comparing the densities of citations and access (e.g., Kurtz et al., 2005; Moed, 2005; Brody et al., 2006).

In recent years, Schloegl and Gorraiz (2010; 2011) conducted more multifaceted studies related to oncology and pharmacology, using indices such as IF, II, and CHL. In the case of oncology journals in 2006, the results indicated that the means of UHL and CHL were 1.7 years and 5.6 years, respectively. Similar results were found in the case of pharmacology journals in the same year. Furthermore, they calculated CHL and found a medium-sized correlation between CHL and UHL in pharmacology ($r = 0.42$). Wan et al. (2010) examined the relationship between DII and citation indicators using the Chinese full-text database, the Chinese National Knowledge Infrastructure (CNKI).They found that DII had the potential to be a predictor for other indices such as h-index. While a moderate correlation between DII

and II was observed in the field of agriculture and forestry (r = 0.57), a strong correlation was found in psychology (r = 0.8). In addition, Gorraiz, Gumpenberger and Schloegl (2013) investigated the differences in obsolescence between citations and downloads in five fields in ScienceDirect, and Guerrero-Bote and Moya-Anegon (2013) observed the influence of language on the relationship between citations and downloads.

However, these analyses have only been performed for limited fields, including organic chemistry, astronomy, and astrophysics, and for selected journals in those fields. Although our previous work analyzed the obsolescence of citations and access with regard to all fields in Springer's SpringerLink and suggested the predictability of the long-term obsolescence of access on the basis of that of citations (Takei et al., 2013), its sample size for each field was small and insufficient for generalizing the results for the whole field.

Therefore, this study examines Elsevier's ScienceDirect in addition to SpringerLink to increase the sample size. SpringerLink is a collection comprising 11 fields focusing on Science, Technology, and Medicine (STM), whereas ScienceDirect is a collection comprising 23 fields including social sciences as well as STM. Analyzing both collections will enable a survey for a wider range of fields; besides, as for the fields included in both, it will facilitate an analysis based on more samples. It is assumed that indices of obsolescence that are effective for predicting the effects of backfiles will differ by field. Utilizing data of the two collections, we clarify the relationship in obsolescence between citations and downloads for each field.

Methodology

This study targeted Yokohama National University (YNU) in Japan, a medium-sized national university without a medical school. YNU consists of four undergraduate colleges (Education and Human Sciences, Economics, Business Administration, and Engineering Science) and five graduate schools (Education, International Social Sciences, Engineering, Environment and Information Sciences, and Urban Innovation). The university comprises around 600 full-time teaching staff and 10,000 students (around 2,600 graduate and 7,500 undergraduate students).

The survey employed the 2009–2012 editions of JCR as citation data, and statistics on the use of full text by publication year in the style of COUNTER Journal Report 5 for SpringerLink (2010–2012) and ScienceDirect (2001–2012) as access data. COUNTER Journal Report 5 defines the number of downloads, the number of times accessed, and the number of times used as the number of times the "full text" of an article is used. As with many studies, we employed this definition and referred to it as access count. COUNTER report has some limitations, for example, it does not reflect all of researchers' activities or could not distinguish the number of access by unique users. However, it reflects a certain amount of user's needs and it is useful to evaluate journal collections. We examined all the 11 fields in SpringerLink and 20 of the 23 fields in ScienceDirect (excluding Decision Science, Nursing and Health Professions, and Veterinary Science and Veterinary Medicine, for which the number of journals suitable for our analysis was less than 10). Because, for both collections, statistics contained sections in which the access count for multiple publication years had been summed up, the access count was divided by the number of years in the section to calculate the access count for each year.

The main concern of this study is to examine the practical predictability of local usage (i.e., access count in a given university) for each field based on global citation data, which is easily available from JCR, for collection management. Although local data does not always correspond with global data as shown in earlier studies (e.g., Duy & Vaughan, 2006; Bollen & van de Sompel, 2008), there may be a certain relationship between them because the

former is a part of the latter and the former partly reflects the latter. Thus, we compared local access data to global citation data in order to reveal the predictability of local access.

The sampling procedure was as follows. First, from all 2,782 journals in SpringerLink and all 1,792 journals in ScienceDirect, we extracted the journals whose fields could be identified on the basis of the title lists of publishers, excluding journals whose full text had never been accessed at YNU. As for ScienceDirect, where journals are classified into multiple fields, this study employed the fields first listed in Web of Science to ensure the same analysis conditions as for SpringerLink. Consequently, 1,567 and 1,657 journals were selected from SpringerLink and ScienceDirect, respectively.

Next, journals with index values listed in the relevant edition of JCR were sampled and rearranged in descending order of cumulative ratio of access counts for each field. These journals were separated into three layers according to the cumulative ratio of access counts as illustrated in Figure 1, i.e., less than 70%, 70% up to (not including) 90%, and 90% and above.

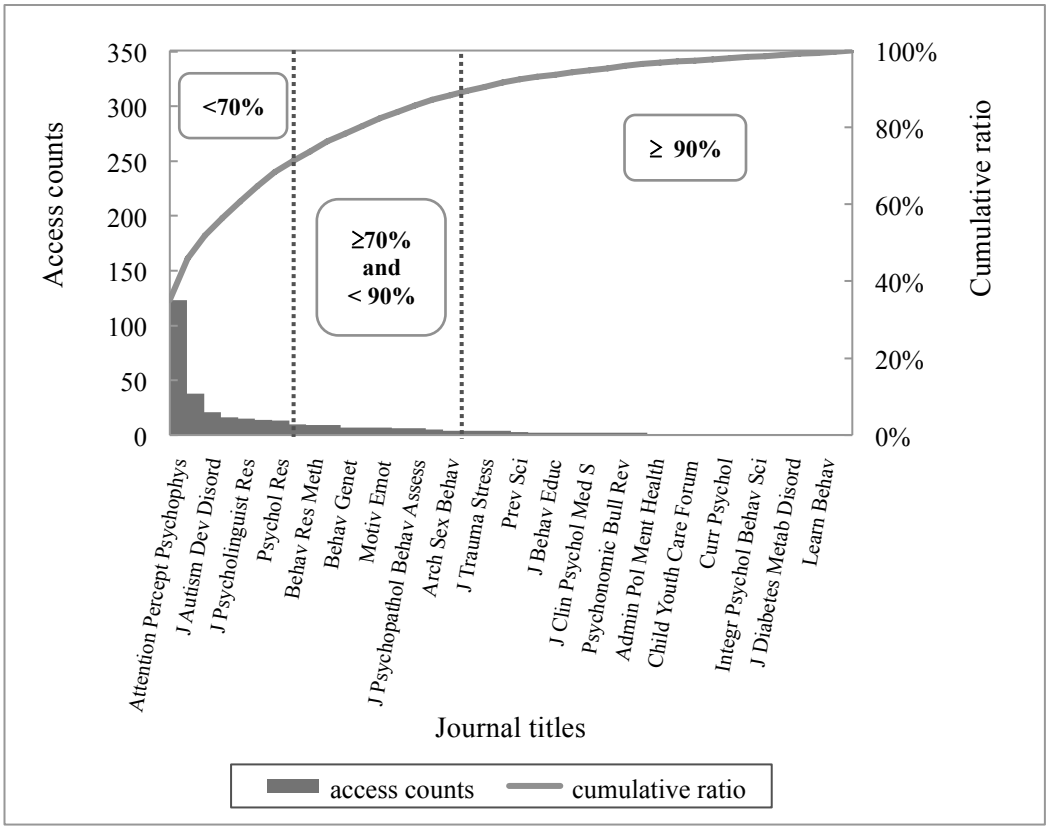

Figure 1. An example of 3 layers according to the cumulative ratio of access counts (Behavioral Science in SpringerLink).

To examine overall trends in each field, 15 journals were then randomly sampled from each of the layers in each field other than the three fields of ScienceDirect described above; for layers with less than 15 journals, all journals were considered. On this occasion, we sampled the journals that fulfilled the following conditions to obtain data for calculating the indices regarding obsolescence as of 2011 and 2012:

(a) Journals whose access count in 2011 and 2012 is not zero to analyze long-term obsolescence.

(b) Journals included in collections from 2011 to 2012 to analyze short-term obsolescence.

(c) Journals that fulfill the conditions of both (a) and (b) to examine the relationship between the two types of obsolescence.

As a result, the number of titles that became the targets of research was as follows:

SpringerLink: (a) 417, (b) 469, (c) 135

ScienceDirect: (a) 773, (b) 752, (c) 571

Tables 1 and 2 show the number of titles by field in the collections of SpringerLink and ScienceDirect, respectively. With regard to the sampling condition (c), we excluded 6 fields of SpringerLink (Behavioral Science; Business and Economics; Computer Science; Humanities, Social Sciences and Law; Mathematics and Statistics; and Medicine) and one field of ScienceDirect (Psychology) for which we obtained only 10 samples or less.

Sampling conditions: (a) Journals whose access count in 2011 and 2012 is not zero to analyze long-term obsolescence; (b) Journals included in collections from 2011 to 2012 to analyze short-term obsolescence; (c) Journals that fulfill the conditions of both (a) and (b) to examine the relationship between the two types of obsolescence.

This study employs the following indices as measures of obsolescence:

(1) Obsolescence of citations:
  (1A) Cited Half-life (CHL)
  (1B) Immediacy Index/Impact Factor (II/IF), i.e., ratio between II and IF
(2) Obsolescence of access:
  (2A) Download Half-life (DHL)
  (2B) Download Immediacy Index/Download Impact Factor (DII/DIF), i.e., ratio between DII and DIF

CHL and DHL express slower obsolescence, while II/IF and DII/DIF express faster obsolescence, as values become higher. In addition, whereas CHL and DHL are indices of obsolescence of use that take into consideration long periods of time, II/IF and DII/DIF particularly focus on the change in usage during several years after publication. DII/DIF, the ratio between DII and DIF, had not been used in obsolescence analysis before our previous study (Takei et al., 2013). However, given that the use of journals is generally concentrated at the time immediately after publication, it seems that DII/DIF would also prove useful as an index representing the nature of documental use in each field. For example, as for 2012, DII/DIF of Medicine is 5368.33 whereas DII/DIF of Earth and Environmental Science is 41.17 in SpringerLink. This means that the former field tends to progress quickly and the "latest" findings attract a lot of attention in the field whereas the latter field is inclined to emphasize not only the "latest" results but also previous ones. Therefore, DII/DIF was used in combination with II/IF in this study. The survey examined the degree of accordance—that is, correlation—of obsolescence between citations and access for each field with respect to the long-term (CHL and DHL) and the short-term (II/IF and DII/DIF). First, the values of these indices were calculated as of 2012. Data for CHL, II, and IF was obtained from the JCR of 2012. DHL, DII, and DIF analogically apply the definitions of CHL, II, and IF in JCR, respectively, to access count. To compute these indices, we set the sampling conditions (a) and (b) described above. In the analysis of short-term obsolescence based on the sampling condition (b), DII and DIF were used with the addition of one to avoid division by zero. Furthermore, to compare the tendencies in 2012 with those in the preceding year (i.e., to observe changes in documental use), the values as of 2011 were also obtained in the same manner.

If good correlations are found between the indices of citations and access in some fields, the information of CHL or II/IF obtained from JCR greatly helps us to determine the strategy to collect journal backfiles for these fields. That is, the correlations suggest the predictability of the use of journal backfiles by the information that can be obtained before introducing them.

Results

First, to determine the degree of accordance of obsolescence of citations and access, correlations between each pair of indices were observed: (A) between CHL and DHL; and (B) between II/IF and DII/DIF. The samples for analyzing (A) and (B) were extracted on the sampling conditions (a) and (b), respectively. The distributions of II/IF and DII/DIF had high values of skewness (2.71–12.97). Moreover, we cannot obtain exact values for CHL from JCR, in which the maximum value of CHL is 10, that is, even if its true value is greater than 10, CHL is described as 10. Thus, Spearman's rank correlation coefficient ρ was employed instead of Pearson's product-moment correlation coefficient r, which should be applied to interval or ratio scale data following a normal distribution.

Table 3 shows the correlation coefficients for (A) CHL and CHL and those for (B) II/IF and DII/DIF by field. There are differences between SpringerLink and ScienceDirect, both in the number and scope of fields. Therefore, to make it easier to compare the results of both collections, we reclassified all fields into the following 6 fields: Humanities and Social Sciences, Medicine, Chemistry and Engineering, Mathematics and Computer Science, Agricultural and Environmental Science, and Physics, as shown in Table 3.

As for 2012, the correlation coefficients for all fields were (A): $\rho = 0.50$ ($p < 0.05$) and (B): $\rho = 0.04$ ($p < 0.05$) in SpringerLink; (A): $\rho = 0.30$ ($p < 0.05$) and (B): $\rho = 0.03$ in ScienceDirect. While a moderate correlation was observed for (A), almost no correlation was found for (B). With regard to individual fields, in the case of (A), the strongest and statistically significant correlation was seen for Physics and Astronomy ($\rho = 0.59$, $p < 0.05$) in SpringerLink and for Energy ($\rho = 0.62$, $p < 0.05$) in ScienceDirect.

	EP (E)	0.32	*	0.27		0.32	*	−0.21	
	EN (E)	0.62	*	0.11		0.73	*	0.23	
	PA (E)	0.35	*	0.10		0.33		−0.30	
Whole	(S)	0.50	*	0.04	*	0.45	*	0.01	
	(E)	0.30	*	0.03		0.37	*	0.08	*

(A): correlations between the indices of long-term obsolescence (CHL and DHL) on the sampling condition (a).
(B): correlations between the indices of short-term obsolescence (II/IF and DII/DIF) on the sampling condition (b)
(S): fields in SpringerLink. (E): fields in ScienceDirect. *Significant ($p < 0.05$)

In the case of (B), the correlation was significant and stronger in Chemical Engineering (ρ = 0.32, $p < 0.05$) in ScienceDirect than in other fields, and negative correlations were witnessed in some fields unlike in the case of (A). Meanwhile, as for 2011, the correlation coefficients for all fields were (A): $\rho = 0.45$ ($p < 0.05$) and (B): $\rho = 0.01$ in SpringerLink; (A): $\rho = 0.37$ ($p < 0.05$) and (B): $\rho = 0.08$ ($p < 0.05$) in ScienceDirect. With regard to individual fields, the correlation between indices changed according to the base years of observation. In the case of (A), for example, while Energy showed the strongest significant correlation both in 2012: ρ = 0.62 ($p < 0.05$) and in 2011: $\rho = 0.73$ ($p < 0.05$), the correlation for Chemistry varied from ρ = 0.66 ($p < 0.05$) in 2011 to 0.30 ($p < 0.05$) in 2012 in ScienceDirect. In the case of (B), for example, the correlation for Medicine varied from $\rho = 0.39$ ($p < 0.05$) in 2011 to 0.19 in 2012 in SpringerLink.

Concerning the 6 fields after reclassification, somewhat strong and significant correlations were seen between the indices of long-term obsolescence (CHL and DHL) in natural sciences other than Medicine, particularly in Physics and in Chemistry and Engineering.

Engineering (EG), Computer Science (CS), and Physics and Astronomy (PA) are included in both SpringerLink and ScienceDirect. Comparing SpringerLink and ScienceDirect, we find differences in the degree of correlation for these fields. The access count of the latter fluctuated considerably by year compared to that of the former in YNU. The gap between global data and unrepresentative local data might result in these differences.

Furthermore, we examined the correlations of pairs of indices for journal usage, including pairs other than (A) and (B), based on the sampling condition (c). To enable comparison with the results of previous studies and to take into account the strength of raw values, Pearson's product-moment correlation r was also studied along with Spearman's rank correlation ρ. When calculating the product-moment correlations, the data was logarithmically transformed to reduce skewness of distribution. As examples, Tables 4 and 5 show the correlation coefficients for SpringerLink (in 2012). Similar results were also obtained for SpringerLink (in 2011) and ScienceDirect (in 2011 and 2012). An example of these was shown in Table 6. The gray-colored cells in the tables indicate the correlations between the indices for citations and access, and moreover, the cells enclosed in boxes indicate the correlations between the indices relating to the obsolescence of citations and access. Little difference exists between the results of the three types of correlations, i.e., the rank correlation and the product-moment correlations before and after logarithmic transformation.

Table 4. Rank correlation ρ between indices for all 6 fields in 2012 in SpringerLink on the sampling condition (c).

	II	IF	DII	DIF	CHL	DHL	II/IF	DII/DIF
II	1	0.81 *	0.17 *	0.24 *	−0.04	−0.01	0.53 *	0.00
IF		1	0.05	0.20 *	−0.01	0.07	0.01	−0.15
DII			1	0.55 *	0.07	−0.19 *	0.10	0.57 *
DIF				1	0.21 *	0.01	0.05	−0.30 *

DHL						1	−0.10	−0.20 *
II/IF							1	0.12
DII/DIF								1

*Significant ($p < 0.05$)

Among pairs of the indices relating to obsolescence, while the strongest significant correlation (around 0.5, $p < 0.05$) was observed between CHL and DHL, which are the indices corresponding to (A), only weak correlations were found in the remaining pairs. However, an exception was found for Energy (ScienceDirect in 2011): a strong and positive

correlation was also seen between II/IF and DII/DIF, the indices corresponding to (B), as shown in Table 7.

Table 5. Product-moment correlation *r* after logarithmic transformation between indices for all 6 fields in 2012 in SpringerLink on the sampling condition (c).

Discussion and Conclusions

Results of the analysis indicated that, for 8 fields of SpringerLink and 7 fields of ScienceDirect, statistically significant positive correlations of over 0.4 were observed between CHL and DHL, which are the indices of long-term obsolescence, in both or either year. Furthermore, having reclassified all fields of both collections into 6 fields, comparatively strong and significant correlations were seen between CHL and DHL in natural sciences other

than Medicine, particularly in Physics and in Chemistry and Engineering. This result suggests that, to a certain degree, it is possible to predict the long-term obsolescence of access on the basis of the value of CHL obtained from JCR with regard to natural sciences.

In addition to Spearman's rank correlation coefficients ρ, we also examined the correlations between indices for all fields using Pearson's product-moment correlation coefficients r, and no major differences were observed between both types of correlations. Comparing with previous studies such as Schloegl and Gorraiz (2010; 2011) and Wan et al. (2010), our results indicated the same tendency regarding the indices of long-term obsolescence (CHL and DHL). However, in the case of other indices, a different tendency was observed. Wan et al. (2010), for example, investigated many indices and reported the following correlations between indices: DII and II showing $\rho = 0.24$ ($p = 0.0964$), DII and IF showing $\rho = 0.41$ ($p = 0.0034$), II and IF showing $\rho = 0.59$ ($p < 0.0001$) in agriculture and forestry; DII and II showing $r = 0.8$ in psychology. Meanwhile, in this study, almost no correlations were witnessed between DII and II and between DII and IF in most fields, whereas strong and significant correlations were observed between II and IF ($\rho = 0.81$, $r = 0.82$) as indicated in Tables 4 and 5. This is thought to be partly due to the characteristics of local use along with differences in the fields and databases. For example, citation speed in YNU may be slower than that of global trends, or research areas of researchers in YNU may be specific and narrow, i.e., a large proportion of the journals that they read may not be core journals for their research and thus their research activities (citations) may not correspond to global trends. If one focuses on this issue, the relationship between local access and local citation should be investigated. In addition to this, citation age may also influence the results. Citation age is larger than publication time lag of the citing article, which is mostly around one year. In contrast, downloads (access) tend to be concentrated in the publication year, that is to say, there is little time lag. This might cause different tendencies of downloads and citations in the short-term (e.g., weak correlation between DII and II in Tables 4–6).

Furthermore, the results of 2011 and 2012 for both collections indicate that the degree of correlation in several fields such as Chemistry may vary considerably by year, and the indices with a strong correlation differ depending on the field. Regarding the variation in the indices of short-term obsolescence (II/IF and DII/DIF), we can guess that it would be easily influenced by such factors as the change in the number of papers, the frequency of publication, and special issues of journals. In contrast, regarding the variation in the indices of long-term obsolescence (CHL and DHL), factors such as the transfer to another publisher, title change, and discontinuation of publication may exert influence.

This study focused on the relationship between the obsolescence in local access and global citation for the purpose of grasping the predictability of the former based on the latter. Although one should take into consideration various ways such as cost-effectiveness (e.g., Bergstrom et al., 2014) when introducing journal backfiles efficiently, our approach would also be useful for making a decision.

In future research, aiming to clarify the characteristics themselves of document use by researchers in Japan, we will investigate the citation data in Japanese universities, including YNU, and compare it with the corresponding access data. Moreover, we would like to observe the obsolescence of access and citation for a longer period for further examination of the tendency concerning the variation in the relationship between them.

Acknowledgments

This work was partially supported by Grant-in-Aid for Scientific Research (C) 23500294 (2013) from the Ministry of Education, Culture, Sports, Science and Technology, Japan, and we would like to show our gratitude to the support.

Introduction

Normally research assessment methodologies assume that the highest scores should be given to articles published in recognised high impact journals. While these high impact journals are mostly published in the US and UK, lower citation rates are particular to journals published in other countries. Subsequent to expansion of the Web of Science in 2007–2009, the research platform was generously augmented with scientific journals issued by local publishers of non-English speaking countries (Leeuwen et al., 2001; van Raan, van Leeuwen, & Visser, 2011). Analysts agree that papers in national journals are usually less frequently cited in comparison to articles published in English (Haiqi & Yamazaki, 1998; Meneghini & Packer, 2007; Moed, 2002; Ponomariov & Toivanen, 2014; Russell, 1998; Tijssen et al., 2006). Research evaluations in several Eastern European countries largely build on data from Thomson Reuters and Elsevier databases. An overview provided by Dejan Pajić (Pajić, 2014) demonstrates that methodologies of most countries award papers in leading international journals rather than national ones. In some countries, articles published in national journals either receive a lower score or are given no score. The Lithuanian methodology is but an illustration of this.

The way a journal reflects the internationalized nature of science may be determined by many methods, one of which is based on the distribution of authoring and citing countries (Zitt & Bassecoulard, 1998).

The aim of the paper is to analyse the impact of the national assessment policy on the development of research journals published in the same country.

Lithuanian Assessment Methodologies and Journal Publishing in Lithuania 2005–2013

Five Lithuanian research assessment methodologies were designed in the period 2005–2010. It should be underlined that there is a great difference between assessment of papers in Sciences and papers in Social Sciences & Humanities. While in Social Sciences and Humanities, researchers have to be published in peer-reviewed journals only, papers in the Sciences have especially high requirements: to gain a score, they have to be published in journals indexed by Web of Science and have an impact factor. The methodology of 2010 was grossly disadvantageous to most Lithuanian journals as it was centred on papers published in high ranking journals (Maskeliūnas, 2011). Lithuanian research journal publishing and other quantitative indicators as well as technical publishing issues have already been analysed in several papers (Dagiene, 2011, 2013). In 2006, Thomson Reuters Web of Science database had only 5 indexed Lithuanian journals; while in 2007, it had 21; and since 2008, there were 29 journals in WoS with Lithuania as the publishing country. One supplementary journal—BALT J OF MANAGEMENT—has been added to this list although its country of origin is England and it is published by Emerald, the Editor-in-Chief and the Managing Editor are from Lithuania.

Data and Methodology

All data analysed in this research has been retrieved from the Web of Science databases: SCIE, SSCI and A&HCI. All indicators employed in this research and listed below have been analysed for two periods: 2008–2010 and 2011–2013. This is done because Lithuanian methodology was changed in 2010, using not only journal impact factors but also JCR data with thresholds measuring the "citation quality" of journals. The main quantitative and qualitative indicators of the Lithuanian journals are presented in the appendix. NJCS – Normalized journal citation score is the impact of the journal set normalized in relation to its sub-fields (average=1.00) (Sandström, 2009).

Citation indicators showed an improvement over the recent years: in 2011–2013, the number of cites by foreign researchers increased by 10% compared to 2008–2010; besides, citation from core journals increased by 19%, which confirms the growing internationalization of Lithuanian journals.

Figure 1 presents dynamics of internationalization indicators of Lithuanian journals.

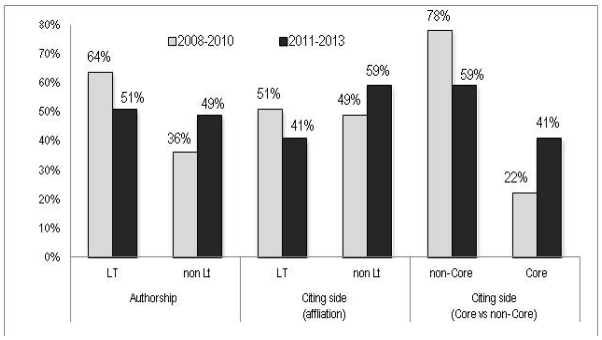

Figure 1. Dynamics of internationalization indicators of Lithuanian journals.

Authorship: from period I to period II, there's an overall drop in LT share and growth of foreign researchers from 36% to 49% if we count averages of all LT journals.

Conclusions

National policy has an influence on scholarly communication and puts the pressure on the national journals. There is some tension but also a response from the journals; thus, over a short period of time we see rather substantial changes.

Firstly, from 2008–2010 to 2011–2013, the relative share of the Lithuanian authors in authorship became smaller; secondly, papers published in Lithuanian journals are more often cited by researchers affiliated to non-Lithuanian institutions; thirdly, papers published in Lithuanian journals are more often cited by papers published in core journals defined as such by Leiden (CWTS 2014).

Introduction

Scientists continuously generate research data but only a few part of them are published. If these data were accessible and reusable, researchers could examine them and generate new knowledge. Currently, the barriers to data sharing are phased out and public research organizations are demanding ever more insistently that publications resulting from publicly funded projects and data that support them should be published in open (Savage & Vickers, 2009). The purpose of this work is: a) to analyse policies concerning open availability of raw research data in journals in the Information Science & Library Science (ISLS); and b) to determine whether there is a correlation between the impact factor and policies of these journals concerning storage and reuse of scientific data.

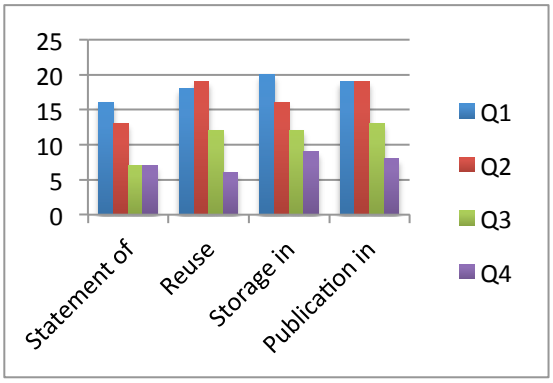
Method

We reviewed the policies related to public availability of papers and data sharing in the 85 journals included in the ISLS category of Journal Citation Reports, 2012 edition. We reported information about the statement of policy regarding: a) complementary material; b) reuse; c) storage in repositories; d) publication on a website; e) journal impact factor; and f) quartile (Q). We have performed a statistical analysis using Chi-square test of the difference regarding each point considered.

Results

The results obtained after analysing the four main variables are presented in Table 1. The variable "Statement of complementary material" was accepted in 50% of the journals. The results were quite similar between the first and second Q and between the third and fourth Q. Regarding the reuse of data, 65% of the journals support this possibility. The highest percentage of response was in the journals of the first Q that accept the reuse of data (86%). The variable "Storage in thematic or institutional repositories", 67% of the journals specified that it was possible. The percentage of journals that accepts storage in institutional repositories decreases by the quartile of journals (e.g., journals in lower quartiles are less supportive). For publication of the manuscript in a website, 69% of the journals accepted it (Figure 1).

Figure 1. Journals supporting each variable by quartile (Q).



Statistical analysis:
Chi-square tests suggest that there is a strong correlation between being a top quartile journal and allowing (a) complementary material (χ^2=11.318, p <.001); (b) reuse of research data (χ^2=19.888, p <.001); (c) storage in thematic and institutional repositories (χ^2=13.080, p <.001); and (d) in personal websites (χ^2=17.350, p <.001).

Conclusions

Our results show that, of the four variables analysed, three have an acceptance rate close to 70% (reuse, publication of the manuscript in a website and storage in thematic or institutional repositories), while the percentage of journals that include the ability to deposit data as supplementary material is lower (50%). These percentages are somewhat higher than those found in a previous study that analysed public availability of published research data in Substance abuse journals (Aleixandre-Benavent et al., 2014). In another study that analysed the same variable in high-impact journals (Alsheikh-Ali et al., 2011), 88% had a statement in their instructions to authors related to public availability and sharing of data, which is 38 percentage points above the average found in the LSIS journals (50%). We found a positive correlation between being a top journal in JCR and having an open policy. A previous paper pointed out that, despite the willingness of some journals to accept supplementary materials, policies, when present, were weak (Borrego & Garcia, 2013). As future research, it would be interesting to raise the question whether journals having high impact factor and open research data is related to the fact that these journals are often owned by rich publishers that are more open for new developments and also have the financial capacities to support such developments.

Acknowledgments

This work has benefited from assistance by the National R+D+I of the Ministry of Economy and Competitiveness of the Spanish Government (CSO2012-39632-C02-01) and Prometeo Program for excellent research groups of Generalitat Valenciana (GVPROMETEO2013-041).

Introduction

Today prominent and comprehensive databases such as Thomson Reuters' Web of Science (WoS) or Elsevier's Scopus are highly in use for bibliometric research. However, these databases do not index full texts hindering researchers to carry out more detailed analyses. Besides, it is possible that some indexed publications do not have DOI numbers playing an important role to access full texts. This paper focuses on how these above-mentioned deficiencies might be overcome by harnessing the Web sources CrossRef and OAI-PMH. Glenisson, Glänzel, Janssens, & De Moor (2005) and Alexandrov, Gelbukh, & Rosso (2005) stated and showed that full text can have an added value in comparison to abstract and title combination when mapping or clustering disciplines and subfields are in question. Therefore, automatic, rapid and free access to full texts of scientific publications might yield a significant contribution to bibliometric research.

Sources

CrossRef

CrossRef provides, besides its other valuable services, a Text and Data Mining (TDM) service enabling researchers to access full-texts of scientific papers for free (Lammey, 2014). This initiative might be a good alternative when considering the policies of the publishers over TDM hindering or retarding the scientific initiatives (Van Noorden, 2012). In this context, by means of a CrossRef REST API, which is free to be used by the public, the developer can access the metadata that CrossRef assembles from more than 4,400 publishers. Besides the metadata such as title, source (e.g. journal, book chapter etc.) name, co-author names, volume year, volume, issue, subject category, two additional important items might be given. These records are *license* and *links* where *link* gives the related full text link and *license* presents an URL link to the license which must be accepted when a GET request is triggered to access the full text. Figure 1 depicts how to access a full text through CrossRef for a given sample digital object identifier (DOI) and a java GET request. In CrossRef's web site, other methods are given to access full text. Since it is not mentioned in the site, we opt to give a java sample through a snippet.

Figure 1. Process of accessing a full text presented by CrossRef by applying *license* and *link* information.

As of 22/12/14, CrossRef has thousands of publications metadata having both full text and license info from the publishers using creative commons license (CC-BY) which encourages the reuse and distribution of content. These publishers are given in Figure 2.

Publisher	CrossRef Number	CrossRef & WoS Number
HINDAWI PUBLISHING CORPORATION	123552	30737
PENSOFT PUBLISHERS	2233	1712
AIP PUBLISHING	273	5
AMERICAN ASSOCIATION OF PHYSICISTS IN MEDICINE (AAPM)	39	11
AMERICAN VACUUM SOCIETY	4	1
ACOUSTICAL SOCIETY OF AMERICA (ASA)	1	0

Figure 2. Number of publications according to publishers using creative commons license (CC-BY) with full text info within CrossRef and within CrossRef-WoS DOI combination.

On the figure's last column, the number of publications, which appear in both CrossRef and WoS, is given for those WoS records only having a DOI. Even though only a few publishers are willing to allow their contents to be mined, we believe that this number will increase over time as also stated by Van Noorden (2014).

Open Archives Initiative – Protocol for Metadata Harvesting (OAI-PMH)

OAI-PMH emerged aiming at enabling e-print archives to be interoperated (Van de Sompel & Lagoze, 2000). The content of the metadata depends on data provider, for example, while BMC

is providing full texts as well as other metadata, most of data providers such as arXiv do not provide full text or they just mention the URL link not guaranteeing that the full text can be freely downloaded. Below, some example links are given from arXiv and BMC which can be applied to harvest data.

http://www.pubmedcentral.nih.gov/oai/oai.cgi?verb=ListRecords&from=2014-01-01&metadataPrefix=pmc&set=bmcbiology (1)

http://export.arxiv.org/oai2?verb=ListRecords&metadataPrefix=arXiv&set=cs (2)

While former link gives the results only for the journal BMC Biology and those recorded in the repository later than 2014/01/01, later link invokes all the data from computer science discipline in arXiv repository without any date limitation. Note that both results will be invoked in accordance with their own XML schema.

Application

Combining WoS - arXiv - CrossRef

Leveraging arXiv repository, we harvested their OAI-PMH compatible data (See (2)) to combine with our WoS database by matching titles through a character N-Gram text matching process (Abdulhayoglu, Thijs, & Jeuris, 2014). In particular, from arXiv we retrieved title and DOI information for only the *computer science(cs)* discipline to deal with a relatively small data set. There were about 60,000 arXiv records while we have, in WoS, more than 35 million records indexed between 1991 and 2014. We searched for arXiv records within WoS and we found around 18,000 matches having a Salton similarity score higher than 0.90.

Besides 10,000 matches having identical titles, there were more than 7,000 matches having both Salton and Kondrak scores higher than 0.90. Finally, there were only about 200 matches having lower similarity Kondrak scores which can be re-checked manually or simply removed.

We examined the matches having very high similarity scores around 0.90-0.99 and saw that the small character corruptions might appear both on the database or repository side. Additionally, some terms might be given as a text string while it might appear as a symbol in the other source for exp. alpha and α. As a result a similarity score higher than 0.90, especially for Kondrak, can be applied for string matches. So, considering the observations just mentioned, we retained about 6,000 matches having both Salton and Kondrak scores higher than 0.90 and DOI information from the arXiv side.

The retrieved DOI numbers were supposed to be used for accessing full texts through CrossRef. However, a few accessed records have a CC-BY license and we could only grab 286 publications and download their full texts in pdf format. We controlled each full text whether they are correct by checking titles. During this optional process we applied a java pdf parser (*itextpdf*) and correctly extract the title information of those 286 publications. Besides *itextpdf*, CrossRef has its own tool named *pdfextract,* however, it is only applied on Linux environment. Lipinski, Yao, Breitinger, Beel, & Gipp (2013) compare some other extractors.

Conclusions and Discussions

Employing CrossRef and OAI-PMH, a process of accessing full texts of scientific publications indexed in WoS database is explained. Computer science articles from arXiv repository are matched with whole WoS database. Despite a high number of matches, the number of publications appearing within CrossRef repository having creative commons license is quite low. Though a small number of publications has creative commons license, CrossRef seems to ease the issue of accessing full texts freely in time (Van Noorden, 2014).

Acknowledgments

Authors would like to thank Rachael Lammey and Karl Ward from CrossRef, Meshna Koren from Elsevier, Mikail Shaikh from Springer and IT admins from arXiv for their valuable guidance and helps for their TDM systems.

Introduction

Scopus has been one of the main abstract and citation databases introduced by Elsevier in 2004 to the scientific area. With the multidisciplinarity and international coverage aspects, it is one of the largest databases of peer-reviewed literature in the fields of science, technology, medicine, social sciences, arts, and humanities. There have been several literature studies assessing different aspects of Scopus since the very beginning. The following consists mainly of a description of Scopus, comparing it with the other databases, from the point of usability and accessibility, evaluations regarding the number of citations, and so on. Although there have been many studies about content evaluation and comparisons with other databases, to our knowledge no study has been published focusing on the journal selection criteria of Scopus. The main goal of this study is to evaluate Scopus journals and draw a picture regarding the quality of the journals indexed in Scopus. The two research questions of this study are:

- Do the journals indexed in Scopus match with the Scopus indexing criteria?
- Is there any contribution of the journals that does not fulfil the criteria of Scopus with respect to diversity of authors, institutions and countries as well as internationality of referees, editors and authors?

Methodology

The universe of the study consists of the 2013 Scopus journal list downloaded from SCImago Journal Rank (SJR) on September 18th, 2014. Two groups of countries that have more than 1,000 journals and less than 100 journals in Scopus were left out of the content of this study because of their projected effects on the sample. As a result, 6,151 journals from 23 countries constituting the sample frame were sampled with the systematic sampling method with a rate of 1:30 and 203 journals were chosen for the sample in proportion to 23 countries' journal counts in Scopus.

These 203 journals were evaluated according to the criteria outlined in Table 1, which is mainly based on Scopus journal selection criteria.[1] The contextual criteria were removed because of the requirement to have a comprehensive knowledge of related field. Furthermore, revised Scopus criteria and some new added criteria are marked with grey in Table 1.

Table 1. Criteria selected and used to evaluate Scopus journal content.

Criteria categories	Criteria
Minimum technical criteria (Pre-selection conditions)	Peer-review content and have a publicly available description of the peer review process
	Have an International electronic Standard Serial Number (eISSN) as registered with the ISSN International Centre
	English abstracts and titles
	Regular publication
	References in Roman script
	Publicly available publication ethics and malpractice statement
Journal policy	Editorial policy available
	Type of peer review
	Reviewer list available online
	Diversity in geographical distribution of editors
	Volume of editorial board
	Diversity in geographical distribution of authors
Journal standing	Citedness of journal articles in Scopus
Publishing regularity	No delays or interruption in the publication schedule
Online availability	Full journal content available online
	Journal website available
	English language journal website available
General information about journal	Country of the journal
	Number of issues per year
	First publishing year of the journal
	Journal back issues available on the journal website

Findings and Results

There are only 13 journals providing all of the minimum technical criteria of Scopus. The majority of the journals (190) did not meet at least one criterion. Six journals fulfilled only one criterion of Scopus. Journals and their fulfilment of evaluation criteria are shown in Figure 1. The baseline of the radar graphic (Fig. 1) was created by using "yes"

[1] http://www.elsevier.com/online-tools/scopus/content-overview#content-policy-and-selection

answers to the criteria. We found that 32% of journals did not have an International Electronic Standard Serial Number available (eISSN). Most of the journals (82% and 69% respectively) did not match the criteria of reviewers list being available online and having publicly available publication ethics and malpractice statement. Journals were successful about applying the criteria of available references in Roman script, regular publication and English abstracts and titles.

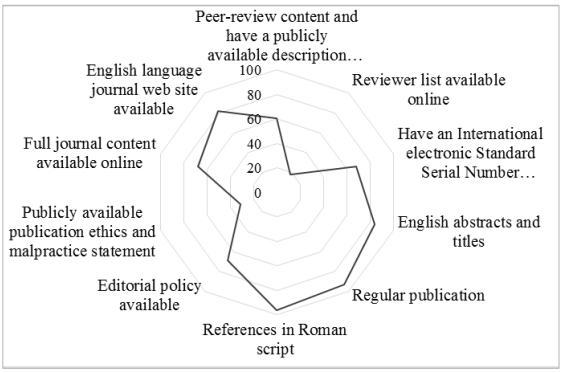

Figure 1. Radar graphic presentation of journals' fulfilment of evaluation criteria.

The evaluation criteria were divided into five classes in this study. These classes are accessibility, peer-review process, policy issues, internationalization and citation levels of journals. The detailed evaluation of each criterion is found in the following sections of this study.

We decided that accessibility on the web, regular publication and references in Roman script consist of the main components of the accessibility criteria in our study. Fifty-one percent of journals in our sample have had all the issues since the launch of their websites and had websites that included full contents of the issues (titles, abstracts, full texts, etc.). Almost all journals had references in Roman script (97%) and most of the journals had English titles/abstracts (84%) and English websites (82%).

The criteria of peer-review process consists of a journal having detailed information about how it is managed and its peer-review board list being available online. We found that 40% of the journals did not have any information on their websites about the peer-review process. Those that did, 73% did not have any information about how their peer-review processes were managed (e.g., double blind, single blind and so on). Only 18% of journals published a list of their reviewers. Under these circumstances, it was hard to determine the diversity of reviewers.

Having accessible publication policies and publicly available publication ethics and malpractice statements were regarded as policy issues. We found that 32% of the journals did not have any editorial policy on their websites. In addition, 68% of the journals did not have any publicly available publication ethics and malpractice statements. Because policy issues were parts of Scopus's minimum criteria, it was expected that journals without these policies would not have passed the preliminary evaluation. However, all these journals have been indexed in Scopus over the years.

The diversity of authors and the editorial board were important for Scopus' evaluation team. We evaluated the diversities as part of this study. Twenty-nine percent of the journals did not have a list of editorial board on their websites. The median for geographic diversity of editors was about 6 within the rest of journals. Eight journals had editors from more than 20 countries. A journal had editors from 53 different countries, while 21% had editors from only one country.

Author diversity is also important for internationalization of journals. We calculated the number of countries by using author affiliations of the last 10 published articles/reviews of each journal. Nine journals did not give any country information for their authors. The median for geographic diversity of authors was 4 within the rest of the journals. Authors were from only one country in 26% of the journals.

Citations are essential for indexed journals within citation databases, as almost all the performance evaluations rely on citations. We evaluated the citation levels of journals by using total cites (three years) indicator of SCImago database. The median number of citations was calculated as 26. Fourteen journals did not have any citations during the three-year period. Six journals had over 1,000 citations.

Conclusions

Citation databases are important for authors, decision-makers, institutions, countries and others. Therefore, it is vital to index high-quality journals for them. Citation databases have strict selection criteria to evaluate journals before indexing to achieve their aims. The criteria of databases are generally based on journal policy, regularity of publication, diversity and so on. We evaluated the journal selection criteria of Scopus and checked the extent of their implementation within this study.

According to the results of our study, the publishers, editors and Scopus should strive to enhance quality. On Scopus' side, Scopus must put the selection criteria into practice strictly and control indexed journals on the aspects of these criteria. Because of the huge competitive environment in the journal market recently, Scopus as well as other publishers of commercial citation databases should consider quality issues more importantly than commercial concerns. A comparative study on journal selection of citation databases may be the continuation of this study.

On the Correction of "Old" Omitted Citations by Bibliometric Databases

Fiorenzo Franceschini[1], Domenico Maisano[2] and Luca Mastrogiacomo[3]

Abstract
Omitted citations – i.e., missing links between a cited paper and the corresponding citing papers – are the main consequence of several bibliometric-database errors. To reduce these errors, databases may undertake two actions: (i) improving the control of the (new) papers to be indexed, i.e., limiting the introduction of "new" dirty data, and (ii) detecting and correcting errors in the papers already indexed by the database, i.e., cleaning "old" dirty data. The latter action is probably more complicated, as it requires the application of suitable error-detection procedures to a huge amount of data. Based on an extensive sample of scientific papers in the Engineering-Manufacturing field, this study focuses on old dirty data in the Scopus and WoS databases. To this purpose, a recent automated algorithm for estimating the omitted-citation rate of databases is applied to the same sample of papers, but in three different-time sessions. A database's ability to clean the old dirty data is evaluated considering the variations in the omitted-citation rate from session to session. The major outcomes of this study are that: (i) both databases slowly correct old omitted citations, and (ii) a small portion of initially corrected citations can surprisingly come off from databases over time.

Conference Topic
Data Accuracy and disambiguation

Introduction
An important branch of the bibliometric literature examines errors in bibliometric databases. Several studies show that the major consequence of database errors is represented by omitted citations, i.e., citations that should be ascribed to a certain (cited) paper but, for some reason, are lost (Moed, 2005; Buchanan, 2006; Jacsó, 2006, Li et al., 2010; Olensky, 2013).

Franceschini et al. (2013) proposed an automated algorithm for estimating the omitted-citation rate of bibliometric databases. This algorithm requires the combined use of two or more bibliometric databases and is based upon the hypothesis that the mismatch between the citations occurring in one database and another one is evidence of possible errors/omissions.

In a further study by Franceschini et al. (2014), this algorithm was applied to a relatively large set of publications, showing that, depending on the bibliometric database in use (Scopus or WoS), omitted citations are not distributed uniformly among publishers; e.g., regarding the publications in the Engineering-Manufacturing field, citations from papers published by Wiley-Blackwell are more likely to be omitted by Scopus, while those from papers published by ASME (American Society of Mechanical Engineers) are more likely to be omitted by WoS. A reason behind this result is that some editorial styles imposed by certain publishers can probably hamper the correct identification of the cited papers by some databases.

The presence of database errors, as well as journal coverage or author disambiguation, is probably one of the major concerns of database administrators. In the authors' opinion, database administrators may undertake two actions for reducing database errors:

1. Limiting the introduction of "new" dirty data in a database, i.e., errors concerning new papers to be indexed;
2. Cleaning "old" dirty data, i.e., errors concerning papers/journals already indexed by a database.

The recent effort by reviewers, publishers and database administrators in checking the cited article lists of new papers probably contributes to reducing "new" dirty data. This hypothesis is corroborated by a recent study by Franceschini et al. (2015), which shows that the databases' propensity to omit newer citations is generally lower than that to omit older citations.

Cleaning up old dirty data is certainly much more complicated because it requires the systematic application of suitable error-detection procedures to a huge amount of data. However, this effort would be essential for improving the quality of a database significantly.

This paper focuses on the ability of the major multidisciplinary bibliometric databases, i.e., Scopus and WoS, to clean up old dirty data. For this evaluation, we use a new procedure, derived from the automated algorithm by Franceschini et al. (2013). This procedure consists in (i) repeating the omitted-citation-rate analysis on the same sample of (cited and citing) articles, but in different-time sessions, and (ii) observing any variation in the results. A database's ability to clean old dirty data will be evaluated considering the variation in the omitted-citation rate from one session to another one.

The remainder of this paper is organized into four sections. The section "Automated algorithm for examining the omitted citations" briefly recalls the algorithm by Franceschini et al. (2013). The section "Methodology" describes the methodology used in our study, focusing on data collection and analysis. The section "Results" illustrates the results of the analysis, investigating similarities and differences between the two databases examined. Finally, the section "Conclusions" summarizes the original contributions of this paper, highlighting the major results, limitations and suggestions for future research.

Automated algorithm for analysing the omitted citations

Before recalling the algorithm, we present an introductory example to illustrate how it works. Let us consider a fictitious paper of interest, indexed by Scopus and WoS. The number of citations received by this paper is four in Scopus and six in WoS (see Table 1).

Table 1. Citation data relating to a fictitious article, according to Scopus and WoS. The union of the citations recorded by the two databases (see the first column) is a total of eight citations. Among the citations, only five come from sources officially covered by both databases (highlighted in grey).

Citation No.	Scopus	WoS
1	✓	
2		✓
3	Omitted	✓
4	✓	✓
5	✓	✓
6	Omitted	✓
7		✓
8	✓	Omitted
Total	4	6

The union of the citations recorded by the two databases is a total of eight citations. Among the citations, only five come from sources (i.e., journals or conference proceedings) officially covered by both databases (highlighted in grey in Table 1). Focusing on these five "theoretically overlapping" (TO) citations, two are omitted by Scopus (but not by WoS) and one is omitted by WoS (but not by Scopus). Therefore, from the perspective of the paper of interest, a rough estimate of the omitted-citation rate is $2/5 \approx 40\%$ in Scopus and $1/5 \approx 10\%$ in WoS. The same reasoning can be extended to multiple papers of interest and more than two bibliometric databases.

The automated algorithm, which is based on the combined use of two bibliometric databases (Scopus and WoS in this case), can be summarised in three steps:

1. Identify a set of (P) papers of interest, indexed by both the databases.
2. For each (i-th) paper of the set, identify the TO citations, defined as the portion of documents issued by journals officially covered by Scopus and WoS. The number of TO citations concerning the i-th paper of interest will be denoted as γ_i.
3. For each (i-th) paper of the set and for each database, determine the number (ω_i) of TO citations that do not occur in it and classify them as omitted citations. The omitted-citation rate (p) relating to the P papers of interest, according to a database, can be estimated as:

$$\hat{p} = \sum_{i=1}^{P} \omega_i / \sum_{i=1}^{P} \gamma_i \,. \qquad (1)$$

We emphasize that p is estimated on the basis of (i) a set of papers of interests and (ii) a portion of the total citations that they obtained (i.e., that ones related to citing articles purportedly covered by both the databases). For a more detailed description of the algorithm, we refer the reader to Franceschini et al. (2013).

The ability of bibliometric databases to clean old dirty data will be evaluated by applying this algorithm to the same sample of TO citations, in three different-time sessions.

Methodology

The study is based on the analysis of the citations obtained from a relatively large sample of papers of interest. The papers were issued by 33 scientific journals (i) included in the ISI Subject Category of Engineering-Manufacturing (by WoS) and (ii) covered by Scopus; Table 2 reports the list of these journals. For each journal, we considered the papers published in the time-window from 2006 to 2012 and the citations that they obtained from papers issued in the same period.

Data collection was repeated in three different-time sessions, spaced about seven months apart: i.e., session I on August 2013, session II on March 2014 and session III on September 2014. We remark that the duration of each data-collection session (i.e., a few days) is negligible with respect to the time period between two consecutive sessions.

To enable comparisons between data collected in different sessions, we adopted two measures:

1. Among the papers of interest (or cited papers) – i.e., those issued by the 33 Engineering-Manufacturing journals – we selected those indexed in each of the three sessions, by both the (Scopus and WoS) databases; in formal terms:

$$A = A^{(I)} \cap A^{(II)} \cap A^{(III)}, \qquad (2)$$

   A being the set of cited papers selected for our analysis and $A^{(I)}$, $A^{(II)}$ and $A^{(III)}$ the sets of papers indexed by both the databases, at the moment of session I, II and III respectively.

   Also, we excluded articles without DOI code or whose DOI code is not indexed by both databases, as they would be difficult to disambiguate.
2. Among the citations, we selected the so-called TO citations, i.e., those obtained from journals purportedly covered by both databases and issued in the 2006-to-2012 time-window. To avoid any misunderstanding, we excluded citations from journals covered in the 2006-to-2012 time-window, but later banned from the database[1]. The official lists of documents covered by the databases in use – which are essential for determining the TO

[1] A possible misunderstanding arises from the fact that, in some cases (mostly on Scopus), the expulsion of a journal from a database entails the entire removal of previously indexed papers, while in other cases (mostly on WoS), previously indexed papers are not necessarily removed.

citations – were retrieved from the databases' websites (Scopus Elsevier, 2015; Thomson Reuters, 2015).

The sample of TO citations used in the analysis is the union of the TO citations (that meet the above requirements), collected in each of the three sessions. In formal terms, this sample of TO citations is:

$$B = B^{(I)} \cup B^{(II)} \cup B^{(III)}, \quad (3)$$

$B^{(I)}$, $B^{(II)}$ and $B^{(III)}$ being the TO citations collected during session I, II and III respectively.
This sample of TO citations will be used for estimating the omitted-citations rate of a certain database, in a certain session; the relationship in Eq. 1 can be used, being:

- $\hat{p}$ the estimate of the omitted-citation rate related to a certain session and a specific database;
- P the number of (cited) articles of interest;
- γ_i the number of TO citations relating to the i-th of the P articles of interest;
- ω_i the portion of the TO citations, collected in a certain session, which are omitted by a specific database.

Being $\hat{p}$ just an estimate of p – albeit the best possible – a relevant symmetrical $(1 - \alpha)$ confidence interval (*CI*) can be constructed as[2]:

$$\hat{p} \pm z_{1-\alpha/2} \sqrt{\frac{\hat{p} \cdot (1 - \hat{p})}{\sum_{i=1}^{P} \gamma_i}}, \tag{4}$$

with:

α, the type-I error;

$z_{1-\alpha/2}$ the unit normal deviate corresponding to $1 - \alpha/2$.

In this case, we consider a symmetrical 95% *CI*, therefore $\alpha = 5\%$ and $z_{97.5\%} \approx 2$.

By adopting this procedure, we will obtain six different estimates of the omitted-citation rate, i.e., one for each of the three sessions and each of the two databases in use. The comparison of these estimates will tell us whether the databases examined are able to correct old omitted citations.

Results

The total number of papers of interest, i.e., those issued by the Engineering-Manufacturing journals examined, is $P = 23{,}806$. The corresponding TO citations are $\Sigma\gamma_i = 97{,}698$. Table 3 contains the $\hat{p}$ values and the relevant 95% *CI*s, relating to the three sessions and the two databases examined.

Table 3. Main results of the (repeated) analysis of the omitted-citation rate of databases. Citing and cited articles were issued from 2006 to 2012. Statistics concern each of the three sessions (i.e., session I, II and III) for Scopus and WoS respectively.

		(a) Scopus				(b) Wos			
Session	$\sum_{i=1}^{P} \gamma_i$	$\sum_{i=1}^{P} \omega_i$	$\hat{p}$	95% *CI*		$\sum_{i=1}^{P} \omega_i$	$\hat{p}$	95% *CI*	
I (August 2013)	97,698	5,183	5.3%	5.2%	5.4%	7,370	7.5%	7.4%	7.7%
II (March 2014)	97,698	4,607	4.7%	4.6%	4.8%	6,376	6.5%	6.4%	6.7%
III (October 2014)	97,698	4,473	4.6%	4.4%	4.7%	6,404	6.6%	6.4%	6.7%

$P = 97{,}698$ is the total number of (cited) articles, published by 33 Engineering-Manufacturing journals;

$\sum \gamma_i$ is the total number of TO citations (which is independent on the session);

$\sum \omega_i$ is the total number of omitted citations relating to each session and each database;

$\hat{p}$ is the estimate of the omitted-citation rate relating to each session and each database;

The 95% *CI* around $\hat{p}$ is obtained applying the approximated relationship in Eq. 4.

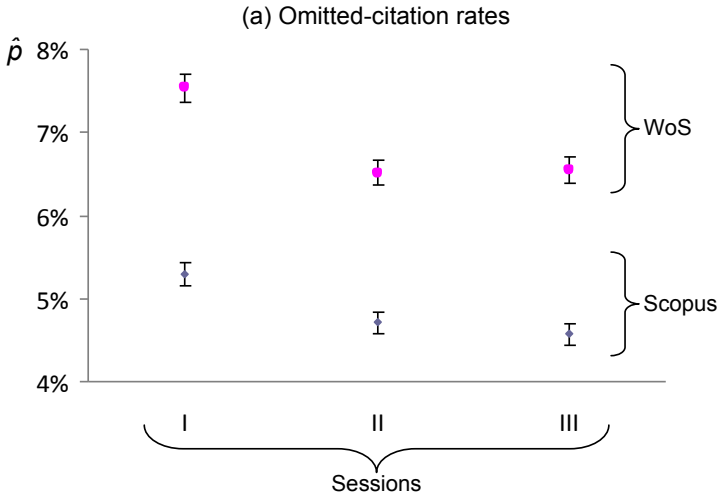
[2] The *CI* construction in Eq. 4 is grounded on the following considerations:

- For a generic sample consisting of $n = \Sigma\gamma_i$ TO citations, the number of omitted citations will be a binomially distributed variable with mean value $n \cdot p$ and variance $n \cdot p \cdot (1 - p)$;
- The aforesaid binomial distribution can be approximated by a normal distribution with the same mean value and variance. This approximation is acceptable in the case $n \cdot p \geq 5$ (Ross, 2009), which is generally satisfied when considering relatively large sets of TO citations.
- Based on the previous approximation, the percentage of omitted citations for a sample of n TO citations will be a normally distributed variable with mean value p and variance $p \cdot (1 - p)/n$. Since p is not known, it can be replaced by its best estimate $\hat{p}$.

In conclusion, Eq. 4 defines a symmetric *CI* around $\hat{p}$, which – with a probability $(1 - \alpha)$ – will include the "true" p value.

The $\hat{p}$ values of both databases tend to decrease over time, denoting that dirty data have been partially cleaned. Interestingly, the major reduction in the $\hat{p}$ values is between the session I and II for both databases; on the other hand, variations between session II and III are not significant, since the 95% *CI*s are partially overlapped (see Figure 1(a)); as regards WoS, we can even notice an imperceptible increase in the $\hat{p}$ value between session II and III.

The overall reduction in the number of omitted TO citations ($\Sigma\omega_i$) for WoS is greater than that for Scopus (i.e., 7,370 – 6,404 = 966 against 5,183 – 4,473 = 710); however, consistently with what observed in other studies (Franceschini et al., 2014; 2015), we note that the omitted-citation rates in Scopus are generally lower than those in WoS. Figure 1(b) shows that the overall percent variations in the $\hat{p}$ values between session I and III are very similar (i.e., -13.7% and -13.1%, for Scopus and WoS respectively).



(b) Relevant percent variations

$$\Delta p = \left(\frac{\hat{p}_{final} - \hat{p}_{initial}}{\hat{p}_{initial}} \right)$$

	Δp		
	I to II	II to III	I to III
Scopus	-11.1%	-2.9%	-13.7%
WoS	-13.5%	0.4%	-13.1%

Figure 1. (a) Graphical representation of the omitted-citation rate in the three sessions, for Scopus and WoS, and (b) relevant percent variations.

Having verified that both databases tend to slowly correct old omitted citations, we now investigate the possible differences in the indexing of individual TO citations, from one session to another one. Table 4 summarizes the eight possible events concerning the correct/missing indexing of individual TO citations. Since there are two possible indexing states (i.e., correct or missing indexing) for each of the three sessions, the total number of possible events is $2^3 = 8$; the file containing the complete list of individual TO citations, with the relevant cited papers, and their session-by-session indexing by the databases, is available under request to authors.

Not surprisingly, the most frequent events are those with no variation (i.e., the type 1 and 2 events in Table 4), in which the TO citations are indexed correctly ("✓") or incorrectly ("×") in all the three sessions; the portion of TO citations with no variation is 98.7% for Scopus and 98.5% for WoS). The type 3 and 4 events represent corrections in the TO-citation indexing, in session II and III respectively. The total number of corrections in WoS is basically larger to that in Scopus, probably due to the larger level of "initial dirt" in the former database, compared to that one in the latter. Moreover, we note that almost all of the corrections by WoS are concentrated in session II (i.e., 1193 out of 1215).

Despite these differences, the percentage of TO citations corrected by Scopus and WoS are pretty close to each other (i.e., roughly 1% and 1.2% respectively). This similarity is even more interesting if we consider the fact that, among the set of corrected TO citations, a relatively small subset is shared between the two databases (i.e., 392 citations out of (997 + 1,215 – 392) = 1,820, corresponding to about 21.5% of the set of corrected TO citations).

Table 4. Overall statistics concerning the indexing of the individual TO citations, in each session. Symbols "✓" and "×" respectively identify the TO citations correctly indexed or omitted in a certain session.

Type of event		Session			(a) Scopus				(b) Wos			
					Single event		Aggregated events		Single event		Aggregated events	
		I	II	III	TO citations	Percent	TO citations	Percent	TO citations	Percent	TO citations	Percent
No variation	1	✓	✓	✓	92,296	94.5%	96,411	98.7%	90,195	92.3%	96,214	98.5%
	2	×	×	×	4,115	4.2%			6,019	6.2%		
Correction	3	×	✓	✓	765	0.8%	997	1.0%	1,193	1.2%	1,215	1.2%
	4	×	×	✓	232	0.2%			22	0.0%		
Anomalous variation	5	✓	×	×	102	0.1%	290	0.3%	164	0.2%	269	0.3%
	6	✓	✓	×	112	0.1%			77	0.1%		
	7	×	✓	×	0	0.0%			0	0.0%		
	8	✓	×	✓	76	0.1%			28	0.0%		
				Total	97,698	100%	97,698	100%	97,698	100%	97,698	100%

The type 5 to 8 events are characterized by anomalous variations, in which some TO citations, which are correctly indexed in a certain session, are omitted in one (or more) subsequent sessions. It is surprising how citations, which were initially indexed correctly, can come off from a database over time; in other words, these events represent a form of generation of dirty data, which is independent of the introduction of new data in the database. Fortunately, the incidence of these abnormalities is rather low (coincidentally, about 0.3% for both Scopus and for WoS); in the future, we may conduct a thorough analysis of these anomalies, based on their manual examination.

Conclusions

The analysis presented in this paper shows that the two bibliometric database examined tend to gradually reduce the number of old omitted citations, although this reduction is relatively slow for both. It would be interesting to see to what extent these cleanings were due to error-correction campaigns structured by database administrators, or simply due to impromptu database-inaccuracy reports by authors and/or database users (even checking and cleaning up bibliometric data in personal research profiles, such as ResearcherID, Scopus Author ID, ORCID, etc.).

Results of this study show other interesting similarities/coincidences between the two databases examined:

1. Comparing the results related to session I and III (spaced about fourteen months apart), we noticed a 13-to-14% reduction in the *p* values for both Scopus and WoS.
2. For both databases, the greatest reduction in the omitted-citations rate was registered in session II and not in session III. This could be just a coincidence or it could denote a sort of "seasonality" of the two databases in cleaning up old dirty data.
3. The portion of TO citations whose indexing varies in the three sessions is roughly the same for both databases, i.e., roughly 1 to 1.5%. Apart from the previously omitted TO citations that have been justly corrected, they include a small portion of abnormal variations, i.e., TO citations correctly indexed in some session and subsequently omitted. Coincidentally, the percentage of abnormal variations is 0.3% for both databases.

The proposed analysis has several limitations. Even though the set of TO citations includes almost one-hundred thousand citations, the relevant cited papers are all confined within the Engineering-Manufacturing field. Also, the analysis was repeated in three sessions over a

total period of about 14 months; therefore, it reflects a database's ability to correct errors in short/middle-term period, but not in the long-term period.

In the future, we plan to extend the study to a longer time-scale (e.g., 2 or 3 years) and/or to scientific articles in other disciplines. Furthermore, the study will be expanded for investigating possible links between the omitted citations' propensity to be corrected and the publishers of the relevant citing papers.

Abstract
In this paper we explore the possibility of using bibliographic databases for tracking the geographic origin of surnames. Surnames are used as a proxy to determine the ethnic, genetic or geographic origin of individuals in many fields such as Genetics or Demography; however they could also be used for bibliometric purposes such as the analysis of scientific migration flows. Here we present two relevant methodologies for determining the most probable country to which a surname could be assigned. The first methodology assigns surnames based on the most common country that can be assigned to a surname and the Kullback-Leibler divergence measure. The second method uses the Gini Index to evaluate the assignment of surnames to countries. We test both methodologies with control groups and conclude that, despite needing further analysis on its validity; these methodologies already show promising results.

Conference Topic
Data Accuracy and disambiguation

Introduction
Tracking the geographical origin of individuals has multiple applications and is of interest to many fields. For instance, in biomedical research it is used for racial and ethnic classification as this information is useful for identifying risk factors in epidemiological and clinical research (Burchard et al., 2003). It is also of interest in the field of Demography to analyse migration movements (e.g. Chen & Cavalli-Sforza, 1983) or migratory influences in a given country (Hatton & Wheatley Price, 1999). In the field of bibliometrics, scientific migration flows between countries has been a subject of study as they are considered beneficial for the exchange of new ideas and scientific knowledge between countries (Moed & Halevi, 2014) as well as to analyse case studies to identify the spread of researchers of a given nationality around the world (Costas & Noyons, 2013).

Surnames have been used as a proxy of geographic, ethnic and even genetic origin for some time now. According to Kissin (2011) "the use of surnames in human population biology dates back to 1875, when George Darwin used frequency of occurrences of the same surname in married couples to study in-breeding". Geographic information related to surnames may also be of use in the field of bibliometrics, especially with regard to collaboration and mobility studies. So far only few papers have been found using surname data for bibliometric purposes. Kissin and colleagues (Kissin & Bradley, 2013; Kissin, 2011) have performed several studies focused on the analysis of Jewish surnames in the database MEDLINE. Also Freeman and Huan (2014) recently analysed the effect of diversity of authorship in the impact of scientific publications.

Until recently, these studies relied on manually curated lists of surnames related to ethnic groups, languages or countries. In the last few years, surname research has been developed and many methodologies have been proposed to discern statistical approaches to geographically classify surnames (a good review on the subject can be found in Cheshire, 2014). In this regard, two types of approaches can be found: 1) probability and Bayesian

methods and 2) clustering techniques. For this, we can focus either on the concentration of surnames by areas or on tracking surnames to their original region (Cheshire, 2014).

So far the results reported are quite satisfactory (Mateos, 2007). While regional studies with large data sets offer relatively accurate results due to the skewness of the surnames distribution (Cheshire, 2014), there are still problems when applying these methodologies at a global level. Such limitations are due to migratory movements and data restrictions. For instance, the surname 'Lee' is considered in many studies as British. However, it is most common in the United States and at the same time in Asia. Also data availability may be an issue as most of it comes from census data and demography studies which usually come from different sources and present differences between them.

In this paper we suggest the use of a single data source to develop a methodology to track the geography of surnames worldwide. We propose using the authors' affiliation data from a scientific bibliographic database. For this purpose we analyse two different useful methodologies: one based on the application of information theoretic measures, and a second one based on the use of inequality indexes.

This paper is structured as follows. First we describe the data collection and processing. Then we describe each of the two methodologies proposed for assigning countries to names: one based on the Kullback-Leibler divergence (Kullback & Leibler, 1951) and a second one using the Gini Index, usually used in the field of Economics. In order to test the validity of each methodology, we compared our results with those from a list of surnames based on language origin for 11 different languages. Finally we conclude discussing the limitations of our methodologies, further developments and the potential use of this type of studies for the field of bibliometrics.

Data collection and processing

The goal of this paper is to develop a methodology to assign surnames to countries based on the bibliographic data offered by authors from a scientific database. For this we used the in-house CWTS version of the Web of Science database (not including the Conference Proceedings Citation Index or the Book Citation Index). This database covers all publications and authors for the 1980-2013 time period. The next step needed was to identify authors and relate them with their country of origin. Such approach assumes certain limitations:

- *Reliance on a single data source*. This means that errors or misrepresentations by countries derived from the Web of Science database will reflect on the quality of the result findings reported. Also, the surname information is restricted to the time period employed in the analysis, meaning that migration flows which have taken place before 1980 are not considered. This means that the origin of the surname is tracked according to a fixed image.
- *Limitations in the data*. We are working with a bibliographic database, implying that scholarly related patterns (e.g. migrations of scholars, mobility programs, issues related on how scholars use their name in publications, etc.) as well as database-coverage related problems (e.g. orientation of the database towards Anglo-Saxon countries, the lack of coverage of surnames that have never published, etc.) can play a role. Also, possible mistakes from the database (e.g., wrong linkage of authors to addresses, typos, transcription problems, lack of information, etc.) should be taken into account when interpreting the results.

In Figure 1 we offer an overview of the methodology followed. For all the surnames in all the publications covered in the Web of Science we detected all the 'trusted' linkages between authors and countries. By a trusted linkage we mean a surname-country relationship that is

unambiguously registered in a publication[1] based on linkages between authors and countries according to bibliographic data. This implies that only in those cases where there is strong evidence that an author is linked to a country, the link is created and the combination (surname-country) is taken into consideration for the statistical analysis. These trusted linkages were created based on the following author-country combinations:

- Authors and countries from the *reprint address* field in the Web of Science are directly linked to their affiliation (Costas & Iribarren-Maestro, 2007).
- *Registered combinations of author and affiliations* recorded in the Web of Science, as from 2008 onwards WoS registers the linkage between authors and countries as they appear in the publications.
- *First authors* are assigned to the *first address* in the publication. As Calero and colleagues (2006) show the linkage of the first author with the first address of the publication is quite reliable.
- *One country publications*. For all publications with only one address or only national collaboration all their authors can be assigned to this country.

As a result, a matrix distribution of surnames by countries was created. Based on this matrix, two approaches were considered to assign surnames to countries. The first one consisted on assigning surnames to the countries with the highest frequency (in terms of publications containing the surname-country trusted linkage) which complied certain levels of assurance. This level of assurance was obtained by means of the Kullback-Liebler divergence or information gain measure. The second approach was to assign surnames according to their relative concentration by countries. This was done by using the Gini Index. In the next two subsections we detail each of the two methods proposed and the results obtained for each of them.

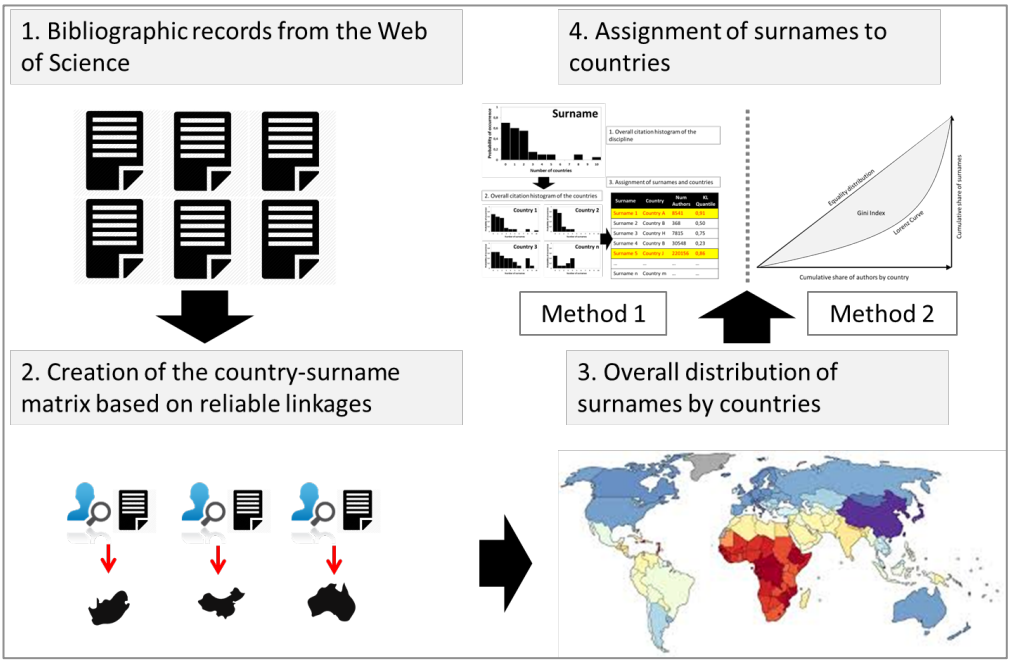

Figure 1. Overview of the methodology followed for assigning countries to surnames.

[1] For many publications in the Web of Science, not all the authors are directly linked to their affiliations in the paper, therefore sometimes it is very difficult to establish to which affiliation (and country) belongs every author.

Method 1: Kullback-Leibler divergence and distribution by country

When identifying the geographic origin of a surname one plausible approach is to consider that a surname will belong to the country with the largest number of occurrences. However, this assumption entails two problems that have to be solved. Firstly, while using raw data will benefit countries with a large presence in the database (e.g. Western and Anglo-Saxon countries), relative indicators will benefit smaller countries, preventing from a balance between countries. Secondly, some surnames may show similar numbers in various countries.

In order to overcome such limitations, we need a reasonable method to characterize the belonging of surnames to each country; and secondly, we have to be able to measure what is the amount of relative information between such characterizations. Here we propose the use of the information gain or Kullback-Leibler divergence measure (Kullback-Leibler, 1951). This measure allows us to select the country that contributes with more information to a given surname. It compares two distributions: a true probability distribution $p(x)$ and an arbitrary probability distribution $q(x)$, and indicates the difference between the probability of X if $q(x)$ is followed, and the probability of X if $p(x)$ is followed. Although it is sometimes used as a distance metric, information gain is not a true metric since it is not symmetric and does not satisfy the triangle inequality (making it a semi-quasimetric) (García et al., 2013).

In this paper, the true probability distribution $p(x)$ is represented by the authors' distribution of a given surname in the country with the highest number of such surname, while the arbitrary probability distribution $q(x)$ is represented by the frequency distribution of the surname in the rest of the countries. The objective is, on the one hand, to characterize the information gain between two probability distributions with a minimal number of properties, which are natural and thus desirable. Second, it aims to determine the form of all error functions satisfying these properties, which we have stated to be desirable for predicting surname-country dissimilarity. This analysis allows identifying similar and dissimilar distributions from a given one, but it does not explain the reasons for such dissimilarity. Such an approach has been previously used in the field of bibliometrics for very different purposes. For instance, Waltman and van Eck (2013) use it to identify national journals from international journals. García and colleagues (2013) use the Kullblack-Leibler divergence measure to determine similar academic institutions (García, et al., 2013). Finally, Torres-Salinas and colleagues (2013) apply it to characterize the field-specialization of publishers based on the citation patterns of book chapters (Torres-Salinas et al., 2013). In Figure 2 we summarize the main steps followed for assigning countries to surnames.

If we predict the similarity between the given surname and the country based on their information gain, then we can set a minimum value of information gain that should be reached in order to ensure that the assignment made is correct, thus relating the surname with the country that leads to the most alike assignment to the frequency distribution. In this case we have established a minimum value up to the percentile 0.8[2] of the overall distribution of surnames and main country by the Kullback-Leibler divergence measure in order to determine a good assurance in the surname-country association.

[2] In other words, we consider that up to 80% of the surname-country linkages based on the highest KL divergence measures are informative, and we disregard 20% of the combinations in which the surname and the country cannot be considered as a reliable linkage (as the surname could also reasonably belong to another country, based on the overall distribution of the surname across countries).

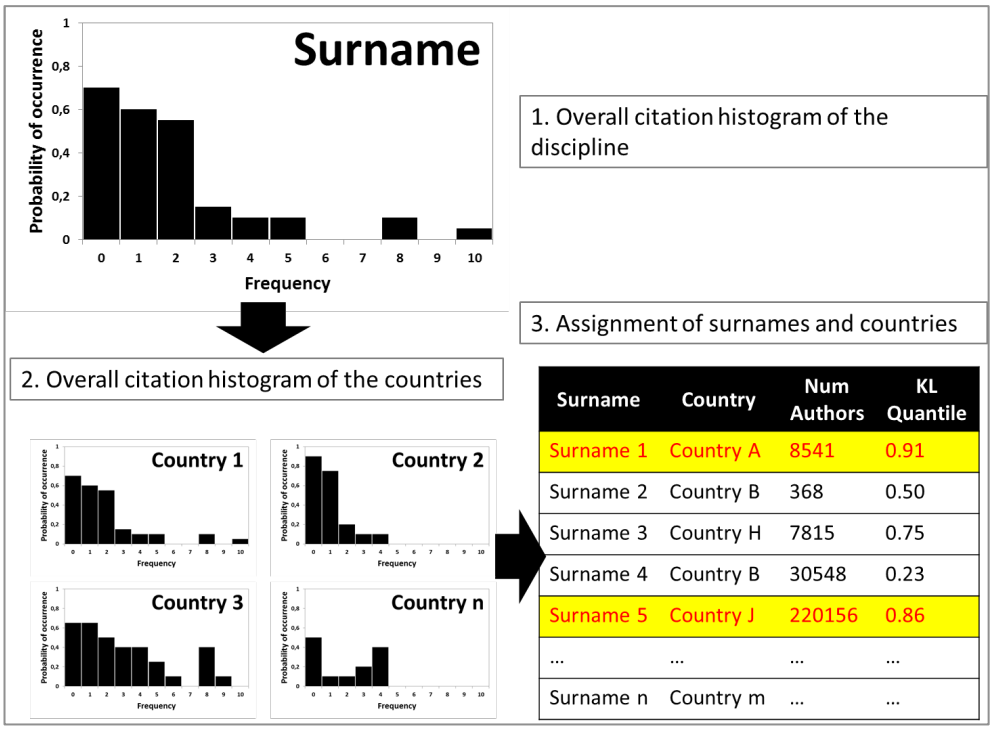

Figure 2. Overview of Method 1 employing the Kullback-Leibler divergence measure.

Results

A total of 1,568,052 surnames were assigned to 119 different countries. Table 1 shows the distribution by surnames of the 36 countries with the higher number of surnames assigned. As observed, the largest number of surnames is assigned to France (8.8%), followed by Germany (8.0%), Russia (7.1%) and Spain (4.9%).

As observed, some countries with the same language appear in this list, such as England and United States for English language or Spain and Mexico for Spanish language. Also some manual normalization of countries was required due to changes in the name of countries (i.e., USSR and Russia or Germany and Federal Republic of Germany).

Method 2: Gini inequality index and concentration by country

Another plausible approach to assigning countries to surnames is to consider the right country as the one where a given surname is more concentrated. For this, we suggest the use of inequality indexes such as the Gini Index. This indicator has already been used in the field of bibliometrics. For example, Torres-Salinas and colleagues (2014) employ it to determine the level of specialization of academic publishers indexed in the Book Citation Index. It is a measure of statistical dispersion. It is defined based on the Lorenz Curve, which plots the proportion of population (y axis, surnames in our case) that is cumulatively concentrated by the bottom *x*% of the population. In Figure 3 we represent its interpretation. The equality distribution is represented by a 45 degrees line. The Gini Index is defined as the ratio of the area that lies between the line of equality and the Lorenz Curve. Its value ranges between 0 and 1, 0 meaning total equality (or dispersion) and 1, total inequality (or concentration). The hypothesis we pose is that a surname can be assigned with certain levels of reliability to the country which shows a higher concentration of such surname, hence relativizing the presence of a given country in the database.

In Table 2 we show the distribution of surnames by countries for the top 36 countries with the highest number of surnames. A total of 1,885,782 surnames were matched to a list of 343 countries. The country with the largest number of surnames assigned is the United States, representing 16.5% of the total share, and followed by France (6.25%) and Germany (5.9%). In general terms we observe that this methodology distributes surnames among a larger number of countries, showing a less skewed distribution.

Validation

In order to validate the results of each method and determine their performance, we tried to compare them with a 'valid' list of surnames by countries. However, identifying such a list entails certain limitations. First, there is no 'perfect' and unique linkage between countries and surnames. Secondly, these linkages are not usually done for countries but rather for languages, cultures, ethnicities, etc. We decided to use a list of surnames by language provided from Wikipedia[3] and select a sample of languages.

Table 3. Control table of correspondences between countries and languages.

Normalized country	Languages	Countries
Denmark	Danish	Denmark; Greenland
England	Celtic; Anglo-Cornish; English; Scottish; Irish	Antigua & Barbuda; Australia; Bahamas; Barbados; Belize; Bermuda; Canada, England, Ghana; Gibraltar; Grenade; Guyana; Ireland; Jamaica; Liberia; Malawi; Mauritius; Micronesia; N Wales; Namibia, New Zealand, Nigeria; Scotland; Sierra Leone; Solomon Islands; South Africa, St. Kitts & Nevis; St. Lucia; St. Vincent; Trinidad & Tobago; USA; Wales; Zambia
Finland	Finnish	Finland
France	Breton; French	Benin; Burkina Faso; Congo; Côte Ivoire; Polynesia; France; French Guayana; Gabon; Guadeloupe; Guinea; Haiti; Ivory Coast; Mali; Martinique; Monaco; New Caledonia; Niger; Reunion; Senegal; Togo; Upper Volta
Germany	German	Austria; Germany; Liechtenstein
Greece	Greek	Greece
Iceland	Icelandic	Iceland
Italy	Italian	Italy; San Marino; Vatican
Japan	Japanese	Japan
Netherlands	Afrikaans; Dutch	Holland; Netherlands; Surinam
Portugal	Portuguese	Angola; Brazil; Cape Verde; Guinea Bissau; Mozambique; Portugal
Spain	Basque; Catalan; Galician;	Andorra; Argentina; Bolivia; Chile; Colombia; Costa Rica; Cuba; Dominican Republic; Ecuador; El Salvador; Guatemala; Honduras; Mexico; Nicaragua; Panama; Paraguay; Peru; Spain; Uruguay; Venezuela

We chose 20 different languages grouped in what we called 12 'normalized' countries, that is, the most representative countries of these 20 languages. Then we crossed our sample table with the surnames obtained from Web of Science and identified the countries to which each of the two methods proposed assigned these surnames. The list of countries was then processed in order to identify the 20 languages selected. We assigned to each retrieved country one of the selected language if one of the following premises was given (Table 3):

1. It was the official language of the country. For instance, French is the official language of countries such as Gabon, Haiti or Martinique.

[3] http://en.wikipedia.org/wiki/Category:Surnames_by_language

2. It is not the main language but it is only spoken in a given area. For instance, Galician, Basque and Catalan surnames were assigned to Spain, or Breton to France.
3. There is more than one official language (which is also used in other countries). This is the most important limitation noted from our validation method, as it excludes countries such as Switzerland, Belgium or Luxembourg (which have several languages spoken in more than one country). The only exception noted is Canada, which has been attributed to English language, acknowledging the important limitation towards French language.

Our validation list from Wikipedia contains a total of 8,239 surnames. After crossing this list with our list of surnames retrieved from Method 1, a total of 7,625 surnames were matched. In Table 4 we include the distribution of surnames by normalized countries according to our control list (Table 3), the coverage of 'valid' assignments made, that is, those surnames which could be assigned with certain levels of assurance according to their information gain; and the share of correct assignments.

Table 4. Distribution of surnames by countries of the control sample for 12 normalized countries according to their language, valid assignments and correct assignments according to the two methods proposed.

	METHOD 1*			METHOD 2**		
Countries	**Surnames**	**% coverage**	**% correct**	**Surnames**	**% coverage**	**% correct**
DENMARK	123	91.06%	68.75%	123	100%	60.16%
ENGLAND	932	28.76%	80.97%	929	100%	58.56%
FINLAND	225	99.11%	94.62%	224	100%	91.96%
FRANCE	562	88.08%	68.28%	560	100%	50.54%
GERMANY	2186	52.24%	69.00%	2170	100%	43.78%
GREECE	170	84.12%	78.32%	168	100%	78.57%
ICELAND	29	100.00%	65.52%	28	100%	100.00%
ITALY	972	87.65%	86.97%	968	100%	64.77%
JAPAN	1349	98.74%	98.95%	1347	100%	91.39%
NETHERLANDS	471	88.11%	60.96%	468	100%	41.67%

Total	**7625**	**73.22%**	**79.03%**	**7585**	**100%**	**61.29%**

*** Method 1:** Kullback-Leibler divergence; **** Method 2:** Gini Index

As observed, in general terms the coverage of 'reliable' assignments made was of 73.2% of the sample list. However, significant differences can be found by country. While in the case of Iceland all surnames were assigned with certain levels of assurance (>80 quartile of the Kullback-Leibler divergence distribution), in the case of England only 28.8% of the surnames were considered valid. Also the coverage figures are quite low for Germany (52.2%). From these surnames covered, around 80% of them were assigned to the correct country. The highest figures of correct assignments are observed for Japan (98.9%, also with a coverage of 98.5%), while the lowest figures go to Spanish surnames (48.7% of correct assignments with a coverage of 93.2%). In the case of England, although the coverage is low, 80.1% of the assignments were correct. In the case of Germany the share is lower (69%).

Regarding the methodology based on the Gini Index, a total of 7585 surnames were retrieved after crossing the list of surnames obtained with the control list. As observed, the coverage of 'reliable' assignments with this methodology is much higher (100%), however, many differences are observed on the share of correct assignments. In general terms this

methodology performs not as well as the first one, with 61.2% of all assignment correct. However, in some cases its share of correct assignments is higher. This is the case of Iceland where the 29 surnames of the control list were correctly assigned. Also the share of correct assignment for Spain increases (54.7%) but still shows low values.

Discussion and conclusions

In this paper we propose the identification of the geographic origin of surnames for bibliometric purposes. For this, we propose the use of scientific databases in order to work with data worldwide. In this way we overcome a major restriction of this type of studies regarding data availability (Cheshire, 2014). We propose two methodologies to assign countries to surnames. The first method is based on the number of surnames found in a given country when its Kullback-Leibler divergence measure is below the 80th percentile of all the combinations with the lowest Kullback-Leibler values. The second methodology is based on the concentration of a given surname in a country, using the Gini Index to calculate such concentration.

In this regard, a preliminary validation has been done comparing the coverage and correct assignments made with a sample list of 20 languages grouped into 12 'normalized countries'. The results reported are promising, especially for the first methodology. In fact, this has already been applied successfully elsewhere (Costas & Noyons, 2013). But the second methodology ensures a 100% coverage of all surnames. However, much research is still needed and further refinements in both methodologies. First, we believe that thresholds of minimum publications of a surname by country should be established in order to improve the methodology based on the Gini Index. Regarding the Kullback-Leibler divergence methodology, we considered reliable assignments those which were below the 80th percentile, however, different thresholds should be also tested. Finally, we will consider other validation lists as some questionable assignments were found in this control list (e.g., Pinto is assigned to Italian language, but it could also be assigned to Spanish or even Portuguese) which may blur the evaluation of the actual performance of each method. These methods should also be compared with those developed elsewhere.

The use of surnames to track demographic movements or analyse diversity in collaboration shows interesting opportunities for implementing these methodologies in bibliometric analyses. One example of such application is the recent work of Freeman and Huan (2014). However, frequently little attention to the methodology employed for assigning countries, languages or ethnicities to surnames is paid, something that may represent a challenge to results based on these data. Thus, understanding better the limitations and possibilities of these data is critical for a proper use. Although further research is still needed, we believe that applying methodologies such as the ones suggested here using bibliographic databases will lead to more reliable results.

An 80/20 Data Quality Law for Professional Scientometrics?

Andreas Strotmann[1] and Dangzhi Zhao[2]

Scientometric network error consequences

Only very recently have researchers begun looking at what concrete effect the errors in a network model caused by name ambiguities in the data sources may have on the results of popular types of network analysis. The results that they report are quite alarming in the aggregate: not only do typical evaluative analyses of individuals (e.g., citation rankings) suffer significantly from these errors, but there is mounting evidence that even the most basic statistical features of realistic large-scale networks are hugely distorted by ambiguities. Strotmann et al. (2009), for example, document significant distortions in co-authorship network visualizations, and Diesner and Carley (2013) report that "minor changes in accuracy rates of [name disambiguation] lead to comparatively huge changes in network metrics, while the set [of] top-scoring key entities is highly robust. Co-occurrence based link formation entails a small chance of false negatives, but the rate of false positives is alarmingly high."

In fact, Fegley and Torvik (2013) go so far as to dismiss one of the most famous recent results in large-scale social network analysis, the exact power-law distribution from preferential attachment (Barabási & Albert, 1999), at least in the case of scientific collaboration networks (Barabási et al., 2002), as a mere artefact produced by a lack of name disambiguation in the underlying dataset! The ultimate irony here is that Fegley and Torvik's (2013) data are consistent with an interpretation that Barabási's cooperation network power may have been induced by a power law distribution of name ambiguities rather than co-authorships.

Similarly, Strotmann and Zhao (2013) find that even highly stable statistical analysis methods of author co-citation analysis fail in the face of large-scale ambiguity errors in the underlying dataset.

While for evaluative bibliometrics the most serious problem is generally the "splitting" of individuals, i.e., the failure to recognize each and every one of an individual's contributions correctly (especially of high-performing individuals), Fegley and Torvik (2013) find that splitting is not the main concern in relational network analysis. Instead, they and Strotmann and Zhao (2013) both find that it is the erroneous "merging" of individuals, i.e., the failure to separate the contributions of multiple individuals correctly because their names are too similar, that causes major distortions of large-scale network analysis results in relational network analysis. Especially East Asian names are prone to extreme amounts of merging. While in European cultures there are relatively few common given names but a large variety of family names, in Chinese, Korean and other East Asian cultures the opposite is the case—a small number of surnames is shared by half their populations, but given names are much more varied. The old tradition in scientific publishing to list authors by their surnames and initials works, sort-of, when science is done in European-origin cultures, but all bibliographic databases have in recent years had to move to a full-name model as research boomed in the Asian Tiger nations (e.g., PubMed/MEDLINE in 2002).

When is a scientometric network sufficiently complete and clean?

As Torvik and Smalheiser (2009) make abundantly clear, it is for all intents and purposes impossible to disambiguate the names of all the individuals in a large dataset completely and fully correctly. With absolute perfection thus out of the question, what remains is to ask when a disambiguation is "good enough", and if (and how) it is possible for a typical researcher to go about disambiguating the dataset well enough. Unfortunately, there is very little research, if indeed any, into what constitutes "good enough" for a scientometric study. The few studies that have looked into what goes wrong when individuals are not recognized correctly do give us a hint, though.

First of all, "good enough" usually means that the most important contributions of the top-ranked individuals must be absolutely correctly attributed. Whatever other good methods (e.g., name disambiguation algorithms or author registries) we may find to disambiguate our data, in the end it will therefore be necessary to manually double-check, and where necessary fix, the highest-impact individuals' data. Secondly, some statistical procedures or network measures are more vulnerable than others to name ambiguities. Local network measures (e.g., node degree) are less affected than global ones (e.g., size of connected component), and evaluative studies (e.g., ranking) are more affected than relational ones (e.g.,

correlations) (Diesner & Carley, 2013; Strotmann & Zhao, 2012).

An 80/20 scientometric data quality rule?

For ranking studies, absolute correctness is paramount, and huge efforts need to be expended to get all the top-ranked individuals just right. When the "individuals" are research institutions, this can be a daunting task. For correlative studies, on the other hand, a study by Albert, Jeong, and Barabási (2000) warns us that, while global measures of power-law distributed networks may be quite resilient to *uniformly* distributed random errors, they are also quite vulnerable to the kind of *highly skewed* error distributions that we observe for name ambiguities, for example. In the case of an extremely skewed error distribution, they observed that an error rate as low as 10%-20% completely changed the measured values for a fundamental global network metric, namely, connectivity.

We can take this as a warning that, as a rule of thumb, we generally need to aim for a roughly 90% (but definitely 80% or better) complete and correct dataset when error distributions are skewed. Note that the requirement of 80% completeness or better applies, in particular, to the underlying citation index's coverage of the field being studied: a focus on high-impact literature implies a highly skewed error distribution! On the plus side, studies on the life sciences can thus be relied upon to yield reliable results as long as their disambiguations are good. Results from *any* scientometric study on the social sciences, however, are suspect as long as they rely on these databases and these databases cover much less than 80% of the literature in those fields.

Note that an 80% data correctness requirement for a professional scientometric study would apply to the data as it is used for network statistics. When both data collection *and* cleaning are subject to highly skewed error distributions, this means that we need 90% correct data collection *and* 90% correct data cleaning to guarantee 80% correct data for analysis.

Conclusions: the bad news and the good

This, then, is the bad news for those who aim to provide a truly professional scientometric service to their community: power-law-like data *and* error distributions may mean that only nearly-complete *and* nearly-clean datasets can be trusted to serve as a reliable basis for nearly *any* type of network or statistical analysis.

The good news is that there are plenty of successful bibliometric studies that imply that this level of correctness is also usually quite sufficient for meaningful studies, as long as only "local" measures or relational statistics are required. There *are* fields that are covered to 90%+ in citation databases, e.g., the citable literature of the life sciences, and there *are* disambiguation methods (e.g., some of those reviewed in Smalheiser & Torvik, 2009 or that of Strotmann et al., 2009) that do make reliable scientometric studies possible.

However, scientometric professionalism may well require that these methods be utilized in nearly *all* future studies, and thus, that they be applied to, and adopted by, the citation databases themselves.

Some Features of the Citation Counts from Journals Indexed in Web of Science to Publications from Russian Translation Journals

Maria Aksenteva

ms@ufn.ru
"Uspekhi Fizicheskikh Nauk" Editorial Office, Lebedev Physical Institute, Russian Academy of Sciences, Leninskii prosp. 53, 119991 Moscow (Russia)

Introduction

As it was emphasized by Moed, H.F., Glänzel W. & Schmoch U. (2005) in their editors' introduction to the *Handbook of Quantitative Science and Technology Research*: "A most important data source for analysis of the science system is the *Science Citation Index* (SCI) and related Citation Indexes published by the *Institute for Scientific Information* (ISI–Thomson Scientific, Philadelphia, PA, USA), or, in a more recent version, ISI's *Web of Science*." Due to this very competent opinion (supported of course by major part of scientists all over the world) it is very important for proper evaluation of the science and its development in Russia to investigate how publications in Russian journals indexed in SCI and how citations to these publications were counted and recorded in SCI in previous decades and is counted and recorded now in Web of Science (WoS).

Some systematic problems with proper indexing and correct counting of citations to publications in Russian journals in SCI was revealed by brilliant founder of modern bibliometrics ("statistical bibliography") Eugene Garfield long time ago in 1974. The greatest problems (according to Garfield) occurred with so-called "translation journals": "The term Russian journals is used here as it is daily used in libraries in the United States. We are aware of its inadequacy and inaccuracy, but plead its convenience. A few of the journals are Slavic, but not Russian. The term Soviet journals might seem more appropriate, but it would not be. An important group of the journals considered is published outside the Soviet Union the so-called translation journals. Neither Russian nor Soviet, they are nevertheless the product of Russian and Soviet research. They also present, as we learned in this study, a formidable stumbling block in journal citation analysis of this type. I speak here only in terms of statistical bibliography as regards the translation journals." (Garfield, 1974).

What was (and is now) the biggest problem with indexing and counting of citations of the "translation journals"? It was (and is now) the adopted by SCI (now Web of Science) policy of the counting of citations to original publications (articles, published in Russian) and to the English version of the same article, published in "translation journals". As it was found in the present research this policy were changed several times during the period of SCI existence and this policy can significantly affect the conclusions, which could be made about Russian science in many analytical reports and investigations, based on *Web of Science* data (see, for example, Albarrán et al., 2013).

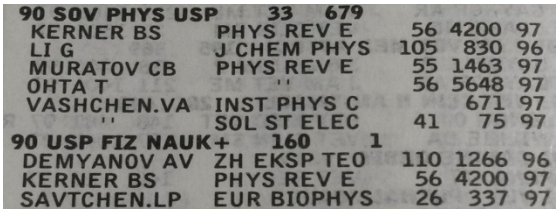
In this research we studied the style (the policy) of records for publications from Russian (and translation) journals and counting of citations to them in printed volumes of SCI in 1960-1998 years and compared these styles with the policy, adopted in the internet version of the successor of SCI (WoS) in 1990-es and now. It is possible to say after this investigation, that significant (sometimes huge) amount of citations (from the journals indexed in WoS) to Russian publications are not possible to find in WoS now without some complicated additional search. All these citations are not taken into account in many analytical reports about Russian science (especially about natural science such as physics, chemistry, biology etc.). At the same time it is not very difficult now to return back to the Garfield's old policy of records and calculations of the citations to Russian publications in translation journals, which could collect properly all citation using new possibilities of Internet linking of publications. (See, for example, UFN journal's web-site www.ufn.ru on which the citing articles are collected using CrossRef system (using Digital Objects Identifier - DOI) or www.mathnet.ru site for more precise and elegant citations collecting (Zhizhchenko & Izaak, 2009; Chebukov et al, 2013)).

Methodology and data

We compared the number of citations to an article published in "Uspekhi Fizicheskikh Nauk" (UFN) journal (or to the English translation to the same article published in "Physics-Uspekhi" (former "Soviet Physics-Uspekhi" journal until 1992 year) ─ cover-to-cover English translation of UFN journal) presented in printed volumes of SCI with the number of citations to the same article presented in Web of Science (on-line version) and with the number of citations, which could be found using CrossRef links (DOI) on www.mathnet.ru and/or www.ufn.ru web-sites (see details in Aksenteva, Kirillova & Moskaleva, 2013).

Results and discussion

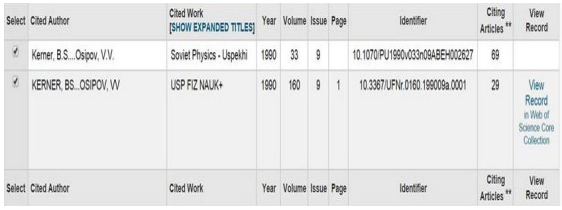
Let's consider (as a typical example) an article (Kerner & Osipov, 1990). First of all we have found that in printed volume of SCI (see Fig. 1) both Russian original article and its English translated version were indexed (citations to them were collected separately, but all citations were displayed, see Figure 1):



90 SOV PHYS USP	**33**	**679**		
KERNER BS	PHYS REV E	56	4200	97
LI G	J CHEM PHYS	105	830	96
MURATOV CB	PHYS REV E	55	1463	97
OHTA T	''	56	5648	97
VASHCHEN.VA	INST PHYS C		671	97
''	SOL ST ELEC	41	75	97
90 USP FIZ NAUK+	**160**	**1**		
DEMYANOV AV	ZH EKSP TEO	110	1266	96
KERNER BS	PHYS REV E	56	4200	97
SAVTCHEN.LP	EUR BIOPHYS	26	337	97

Figure 1. Copy from SCI (1997) for Kerner B.S.

But now in WoS (internet version) we cannot find citations to the English version of this article. It is possible to find them only by using the WoS's option "Cited References Search" (see Figure 2).



Select	Cited Author	Cited Work [SHOW EXPANDED TITLES]	Year	Volume	Issue	Page	Identifier	Citing Articles **	View Record
✓	Kerner, B.S....Osipov, V.V.	Soviet Physics - Uspekhi	1990	33	9		10.1070/PU1990v033n09ABEH002627	69	
✓	KERNER, BS...OSIPOV, VV	USP FIZ NAUK+	1990	160	9	1	10.3367/UFNr.0160.199009a.0001	29	View Record in Web of Science Core Collection
Select	Cited Author	Cited Work	Year	Volume	Issue	Page	Identifier	Citing Articles **	View Record

Figure 2. Cited references search in WoS core collection for article Kerner B.S. &Osipov, 1990.

It is possible to see on this figure, that there are 29 citations to the Russian version of this article and 69 citations to the English version of the article, but (unfortunately for the Russian journal) it is possible to view citing articles for the Russian version only (only 29 citing articles). 69 citations to the English version of this article are not taken into account in Prof. Kerner's (and of course for Prof. Osipov too) citation report, are not included into their Hirsh's indexes, are not taken into account for his laboratory and his institute bibliometrics etc. (and for Russian physics and science in general). On our web-site using CrossRef links it is possible to find 70 citing article: http://ufn.ru/ru/articles/1990/9/a/.

It is necessary to mention that for publications in UFN journal until September 2001 only citations to the Russian version are presented in WoS (but citations to the English version are not taken into account). We have checked more than one thousand articles (published in 1990-2000 years in UFN) and have found that about 67% of citations (in average) to these articles were not presented now directly in WoS (and so do not taken into account for any analytical scientometric report). According to WoS in 1990-2000 years 1190 articles were published in UFN (and indexed in WoS) and they have only 9002 citations (on April 25, 2015). Using DOI on our website we have found 14973 citations to 1167 articles, published in UFN in the same period.

Conclusions

It was found that now WoS show less than half of citations (from journals indexed in WoS) to described above article (Kerner, Osipov, 1990), but this is not an exceptional example. So all publications in Russian translated journals (indexed in WoS) lose a lot of their absolutely correct citations (about 60% in average) from journals indexed in WoS and therefore scientometrics, based on WoS direct data, underestimates the real impact of Russian scientists and science in general.

Acknowledgments

I am grateful to Prof. M.Yu. Romanovsky who has encouraged me to make this investigation.
The work was supported by the Russian Foundation for Basic Research (project No. 13-07-00672 a).

Semantics, a Key Concept in Interoperability of Research Information -The Flanders Research Funding Semantics Case

Sadia Vancauwenbergh

Sadia.Vancauwenbergh@uhasselt.be
ECOOM-UHasselt, Hasselt University, Research Coordination Office, Martelarenlaan 42, BE-3500 Hasselt (Belgium)

Introduction

In a knowledge-based economy, a good overview of the scientific and technological portfolio is essential for policy formation and driving knowledge transfer to the industry and the broad public. In order to enhance open innovation, the Flemish public administration has created a Flanders research information portal (FRIS, http://www.researchportal.be) that integrates information available from its data providers (research institutions, funding organizations…) using the CERIF (The Common European Research Information Format) standard. Although this standard allows for almost unlimited flexibility for modelling the research information, it has limitations when it comes down to communication to end-users, in terms of semantics. However, interoperability of research information is only meaningful when a well-defined semantics is used. This paper describes the implementation of a business semantics tool on data concepts and classifications for research funding as a means to unambiguously exchange and interpret these data.

The need of semantics

A couple of decades ago, the demands on the research community to report on research data were rather low. Results were published in preferably highly-rated journals and rather limited research reports were written. Over the years, more research data became available and the need for research databases grew. Unfortunately, these databases were predominantly developed per organization without consultation of other organizations. Moreover, because of the rather low data volume and people involved, there seemed no explicit need for defining an accompanying semantics.

However, as the research system expanded, there has been a massive increase in the amount and nature of the information stored as well as its information consumers. These changes are not only due to the advancements made in the research field itself, but are also explained by the global efforts undertaken to transfer the obtained knowledge to industry and the broad public. In Flanders, this resulted in the creation of the FRIS-portal which makes Flemish research information publicly available. This information is provided via a multitude of data providers that often use a different terminology for a similar concept or alternatively, use a similar terminology for a different concept. The correct interpretation of the information at the FRIS portal is realized by the addition of a semantic layer on top of the data by the data providers, which later on is translated to a general FRIS semantics resulting in data communication in the same language. The focus on the explicit semantic alignment with the data providers, adds further to existing initiatives like VIVO and CERIF based CMS (Guéret et al., 2013). Data unambiguity is increasingly important, in an era where many initiatives have seen light to measure and benchmark research and where public research reporting obligations are vastly growing. Obviously, the lack or incomplete definition of semantics puts large constraints on the interoperability of research information, and in extension on the policies drawn out of these data.

The Flanders research information landscape

In Flanders, research institutions receive funding from a broad range of research funding providers going from the regional to national and international level. Obviously, each funding provider has its own requirements with regards to the formats or classifications used for reporting on the resulting research output, thereby creating a multitude of largely similar research reports. Obviously, this places a large burden on the research community. Until now, the data providers tried to keep pace with this vast expansion of research reporting by improving or even creating databases, unfortunately without generally agreed upon semantics. At the same time, the data providers were feeding their information to the FRIS-portal in order to increase the visibility of the research in Flanders to third parties (i.e. companies, research institutions and individual researchers).

In line with the growing concern on the administrative burden put on the research community, a report was published by Peters et al. (2011) providing guidelines for the reduction of redundant research information reporting. Following these advices, the Flemish Department of Economy, Science and Innovation (EWI) is currently improving the FRIS-portal in order to be used as a virtual research information space, for information retrieval in a transparent and automated manner that can be used for research reporting (Figure 1) (Debruyne et al., 2011). This implicates

the use of unambiguous data concepts and research funding classifications. Until recently, funding organizations were using their own funding classification schemes which were semantically poorly defined and lacked concordance mappings to other (inter)national classifications.

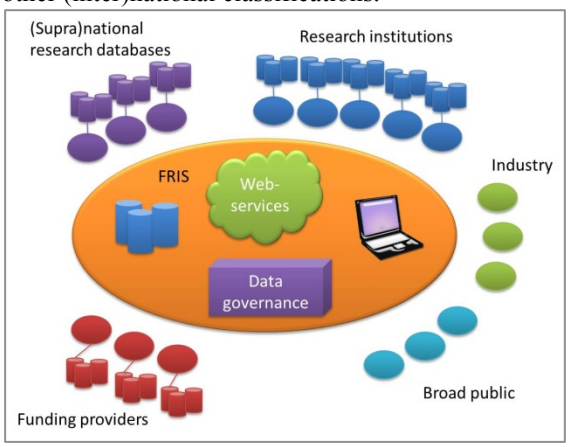

Figure 1: Representation of the FRIS design.

Funding data and classification governance

In order to add a semantic layer on top of the FRIS database layer, the Data Governance Centre® (DGC) platform of Collibra has been used. This platform allows data suppliers to manage their own data models used to describe, i.e. research funding together with the corresponding institution specific semantics (Figure 2).

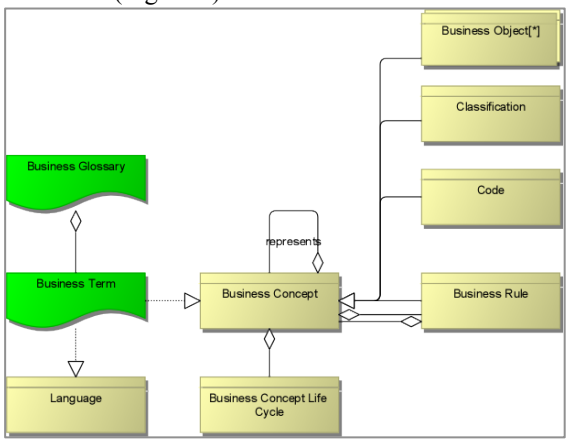

Figure 2. Incorporation of a business semantics glossary on the research funding model.

At the same time, the DGC platform has been used for the description of each individual component of the FRIS research funding model using definitions (Figure 3). By explicitly defining all concepts, the governance tool assists in the swift identification of semantic inter-organizational misalignments when mapping corresponding concepts by the stakeholders. The resulting ontologies can be exported and used to annotate data in relational databases, and hence render data meaningful. Furthermore, the DGC tool has been used for defining the semantics of classifications and code sets on research funding, which is essential when it comes down to consistent and unambiguous reporting on research funding to third parties. Obviously, the research community at large will benefit from this, as the information retrieved via FRIS will be much more reliable and accurate.

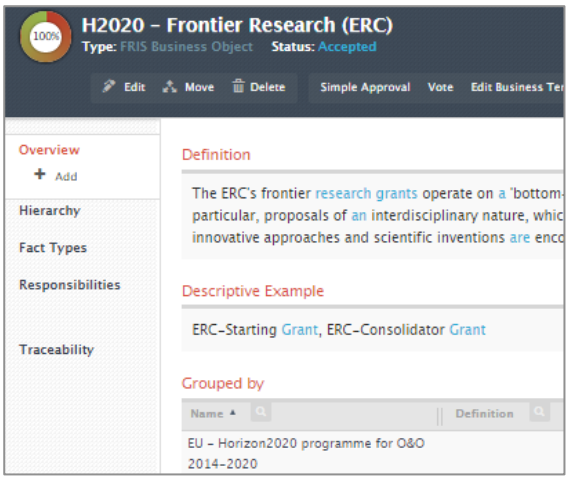

Figure 3: DGC as a governance tool for research funding classifications.

Altogether, the use of a data governance tool focused on semantics opens new avenues in terms of efficiency of the research ecosystem. Not only will governments be able to delineate better founded policies, also research administrations and researchers themselves can gain tremendously as research reporting could be automated from the FRIS-portal in a reliable manner, thereby reducing the administrative burden at the benefit of scientific discovery and innovation.

Introduction

Our work was focused on document retrieval from Scopus databases of the Escuela de Ingeniería de Sistemas y Computación (EISC) of the Universidad del Valle (Cali - Colombia).

The databases systems as WoS (Web of Science) or Scopus contain the knowledge produced by engineer schools. However, this information is ambiguous and the retrieving of the specific documents of one school is identity uncertainly (Pasula et al., 2003). Thus, the design of machines (search engines) to retrieve the relevant documents of engineer schools is a complex process.

After the work of Bucheli et al. (2013); Cuxac, Lamirel, & Bonvallot (2013) proposed a semi-supervised approach, mixing soft-clustering and Bayesian learning. Additionally, Huang et al. (2014) proposed a rule-based algorithm. Both approaches were for affiliation disambiguation.

We reproduced the model proposed by Bucheli et al. (2013). The results show that the model can be used to information retrieval of department-level. In addition, we proposed a new approach addressing the problem of classification using network science. The future work will be related with building a model according to the network science approach.

Methodology

Model of Bucheli et al. (2013)

We followed the methodology specified by Bucheli et al. (2013) shown in Figure 1(a).

1) The configuration of the initial search strategy proposed by Bucheli et al. (2013) was applied using the Scopus search engine to get a set **I** composed by documents that contains all the documents that belong to EISC and others that not belong to it.

2) The initial search strategy was based on a review of the research activity of the School and it proposes recovering a set of documents $\mathbf{I} = \mathbf{A} \cup \mathbf{J} \cup \mathbf{S} \cup \mathbf{O}$. The staff **S** set is made up by papers which are related to a list of school professors names explicitly. The journal set **J** is the bunch of documents published in the journals where the school has previously published. The address set **A** is related to the documents that have in their affiliation the name of the school explicitly. Finally, socio-semantic set $\mathbf{O} = \mathbf{S} \cup \mathbf{C}$, where the concepts set **C** is made up by the documents related to a bunch of research areas from a school. Every set mentioned before has an additional restriction; his documents must belong to the university that hosts the internal-level unit, in our case to the Universidad del Valle.

3) An Expert from EISC classified all the documents from the initial search and we built a relevant set **R** with **I** elements that belong to EISC.

4) We built a dataset where one paper or instance is characterized by a vector (with five positions). Each position is a binary variable, related to sets **A**, **S**, **J**, **O** and **R**, that tell us if the paper belongs or not to the corresponding set. Thus, the instance class is determined by the variable **R**.

5) Afterwards, we made the classification using the Naïve Bayes model of information retrieval illustrated in (1). It was evaluated based on all instances of the dataset. We used standard measurements over cross validation test 10 fold (Witten, 2005; Baeza-Yates, 1999). On the other hand, the publication year was taken into account as parameter of evaluation. Thus, we train the model with paper published between two specific years, for instance 1989-2010 and testing the model with papers published in the following years. This procedure was evaluated by the following years of training 1989-2011, 1989-2012 and 1989-2013.

$$p(R|J,S,O,A) = \frac{p(R)p(J,S,O,A|R)}{p(J,S,O,A)} \quad (1)$$

Proposed model based on network science

The machine learning process follows five phases: Selecting data, expert validation, co-author network building, feature extraction from network and classification, as shows the Figure 1(b).

The data selection trough the initial search strategy and the expert validation have be taken into account similarly to the review model of Bucheli et al. (2013). Here, the document corpus used is the same of evaluation model applied to the EISC, however the feature extraction changes and the features are related with network measurements.

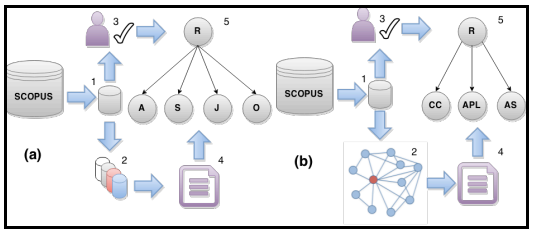

Figure 1. The five phases of the evaluated and proposed methodologies.

The document corpus contains information about co-authorship relations. Each author is identified by an ID that Scopus assigns. We build a co-authorship network, where, the network is traduced as a weighted and undirected graph in which the weight of the edges designates the number of documents where whichever two authors have participated. The new dataset is built as follows: one document or instance is a vector of values where each position is a variable related with one measurement of co-author network, in which, the specific paper was subtracted. Thus, for each instance, the authors that participated in the specific document are deleted and the measures are computed again. Additionally, the last variable **R** shows if the paper belongs or not belongs to the School. The measurements of networks are:

1. The Cluster Coefficient (**CC**): The local clustering coefficient captures the degree to which the neighbours of a given node link to each other. We use the average of all local clustering coefficients.
2. The average path length (**APL**) is the average distance between all pairs of nodes in the network.
3. The average strength (**AS**), is the average of the sum of the edge weights of each node. (Barabasi. 2012).

Finally, we develop a supervised learning environment through a Naïve Bayes Classifier and the proposed model is evaluated and compared with the model proposed by Bucheli et al (2013).

Results, discussion and future work

Table 1 shows standard evaluation measurements. Here, we introduce the cross validation fold 10 test, the measurements show in Bucheli. et al. (2013), and the evaluation for different publication years 1989-2011, 1989-2012 and 1989-2013. The results show that the model was applied to other School with similar performance measurements, in this sense the model is consistent and allows to build one search engine of department-level. Additionally, we evaluated the practical utility of the model, verifying that it is capable of doing an acceptable prediction of EISC's documents published after a specific date when it is trained with a set of documents published until that date.

In this work, we found the finger prints of department-level of universities that allow us to design search engines that retrieve relevant documents of department-level.

Table 1. Evaluation measurements of the model.

	Recall	Precision	ROC curve
EISC Univalle			
Cross Validation fold 10	0,932	1,000	0,989
Bucheli et al. (2013)			
Department of Industrial Engineering –University of Pittsburgh	0,494	0,997	0,984
Faculty of Engineering – Universidad de los Andes (Colombia)	0,954	0,992	0,965
EISC Univalle			
Training:1989-2011 Evaluation: 2012-2014	0.833	1.000	0.974
Training 1989-2012 Evaluation: 2013-2014	0.826	1,000	0.964
Training 1989-2013 Evaluation: 2014	0,786	1,000	0,939

The networks science approach is an opportunity to propose a mathematical model able to learn the structure of co-authorship network from a particular school. Then, we can design a classifier of relevant documents at department-level based on co-authorship relations. This allows making a classification with little a priori information about an organization, which turns into a more general model than Bucheli et al. (2013). We proposed a model, namely (2).

$$p(R|CC, APL, AS) = \frac{p(R)p(CC, APL, AS|R)}{p(CC, APL, AS)} \quad (2)$$

We suggest as future work to evaluate the model based on network measurements at the same school and other 3 schools of engineering from different universities.

Efficiency, Effectiveness and Impact of Research and Innovation: a framework for the analysis

Cinzia Daraio

daraio@dis.uniroma1.it
Department of Computer, Control and Management Engineering Antonio Ruberti, Sapienza University of Rome, via Ariosto, 25 00185 Rome (Italy)

Introduction, motivation and policy relevance

The main objective of this paper is to provide a framework for the assessment of the research activity and its impacts. This is a difficult task. First of all, because of the heterogeneity, partial overlapping and fragmentation of the different streams of literature. Secondly, due to the need of applying a systemic approach to account for the complexity of the research activity and its complementarities and interrelationships with teaching, third mission activities and other relevant dimensions of performance, including the inputs.

This work originated from Daraio (2015) which pointed out the unavailability of a best evidence on the "efficiency, effectiveness and impact of research and innovation" due to the lack of a suitable framework for a comprehensive analysis.

Two recent policy initiatives witness the need and call for the proposal of a general framework for assessing research and its impact. We refer to the STAR metrics in US and to the EC (2014) "Expert Group to support the development of tailor-made impact assessment methodologies for ERA" in Europe.

We discuss in the following the main dimensions of our framework which are: 1. Theory, 2. Methods, 3. Data.

Research and innovation in the theory

In theory, the following streams of literature have considered research and innovation as the main link of Science and Society interplay:

• *Economics of science and technology* as an emerging field, which draws on the fields of economics, public policy, sociology and management (Audretsch et al., 2002).

• *Growth theory* (Aghion & Howitt, 2009), within which «the residual» is considered as technology advance over time (Solow, 1957); or as our ignorance (Abramovitz, 1956). The old growth theory (Nelson & Phelps, 1966) considers as additional inputs investments in R&D and education while the new growth theory (Romer, 1986; 1994) emphasizes the influence of other factors such as technologies or efficiencies, spill-overs and incentive of agents.

• *Quantitative science and technology research*, organized as quantitative studies of science system, of technology system and of science-technology interface. The focus here is -though not exclusively- on scholarly publications and patents, it embraces bibliometrics, scientometrics (Moed, Glanzel & Schmoch, 2004) and informetrics (Egghe & Rousseau, 1990), more recently starting to consider also other non-scholarly and societal «altmetrics» dimensions (Cronin & Sugimoto, 2014).

• *Economics of innovation*, which is at the core of several different economic fields, including macroeconomics, industrial organization (strategies and interactions of innovative firms), public finance, policies for encouraging private sector innovation, and economic development (innovation systems and technology transfer) (Hall & Rosenberg, 2010).

• *Science of Science policy* (Fealing et al., 2011; National Academy of Science, 2014; Lane, 2011, 2014).

• *Science and Society interplay* (Etzkowitz & Leydesdorff, 2000; Aghion et al., 2009; Helbing & Carbone, 2012).

A neglected aspect within these streams of work is the building block of education. From the economics of education (Johnes & Johnes, 2004; Hanushek et al., 2011) we know that education is an investment in human capital analogous to an investment in physical capital. The missing link with previous streams of literature is people. People in fact carry out research and innovation activities; attend schools and higher education institutions, acquiring competences and skills. Here another link could be added with Dosi (2014).

Methods for the assessment of Research

The assessment of the performance of an activity can be carried out on its output, on its outcome (indirect output), on its productivity (partial or total factor productivity), on its efficiency, on its effectiveness, on its impact.

From a methodological point of view, a distinction between productivity and efficiency has to be done. Productivity is the ratio of the output/input. Efficiency, in the broad sense, is defined as the distance with respect to the frontier of the best performers (Daraio & Simar, 2007). The econometrics of production functions is different than that of production frontiers as the main objective of their analysis differs: production

functions look at average behaviour whilst production frontiers analyse best performers behaviour (Bonaccorsi & Daraio, 2004). Obviously, assessing the impact on the average performance is different than assessing the impact on the best performance. This distinction has been considered also recently in the theory of growth and in the managerial literature. From a methodological perspective, different approaches, both parametric and nonparametric (Badin, Daraio & Simar, 2012; Daraio & Simar, 2014) have been proposed.
On the other hand, classical methods of impact assessment (Bozeman & Melkers, 1993; Khandker et al., 2010) proved inadequate to the checklist of "sensitivity auditing" (Saltelli & Guimarães Pereira; Saltelli & Funtowicz, 2014).

Important role of data

The data dimension is characterized by a kind of "data paradox". On the one hand, we are in a "big data" world, with open data and open repositories that are exponentially increasing. On the other hand, in empirical applications «data constraints» are almost the same as those described in Griliches (1989, 1994).
We believe that a great improvement could come by the adoption of an Ontology-Based-Data-Management (OBDM) Approach (Calvanese et al. 2010; Lenzerini, 2011; Poggi et al., 2008) to integrate the heterogeneous sources of data on which the empirical analysis has to be carried out.

A framework for the analysis

A general framework to investigate and empirically assess the research activity and its impacts is derived integrating existing approaches according to three dimensions. The main building blocks of these dimensions are reported in Figure 1.

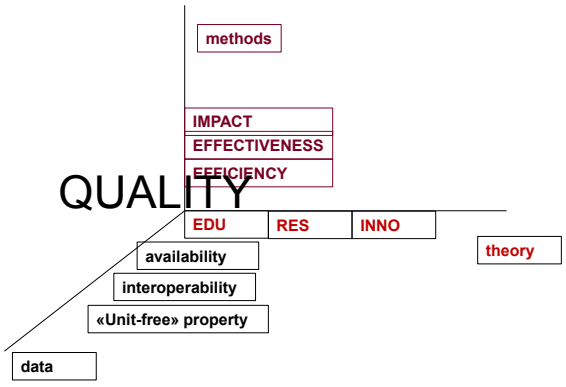

Figure 1. A framework for the analysis of research assessment and its impacts.

We propose "quality" as the overarching concept, which links together all the three dimensions. Quality should be declined along the three dimensions and by each building block. In theory, in education, a lot of progresses have been done. Much more work is needed for research and innovation. If we include quality indicators in the analysis we can move from efficiency to effectiveness. Moreover, it is the quality of education, research and innovation, which has an "impact" on the growth and development of the society. Finally, it is on the data dimension that the quality issues are of primary importance in all the three main building blocks proposed.
If we are not able to conceptualize and formalize in an unambiguous way the different meanings of «quality» for each building block proposed, we will not be able to make a real step forward in the empirical evaluation of the Efficiency, Effectiveness and Impact of Education, Research and Innovation. Third mission indicators (see Bornmann, 2013 for a survey) have a crucial role in this respect. It is indeed the role played by third mission indicators formally conceptualized as a measure of quality of higher education/research institutions, which can be used to investigate the Science-Society interplay.
For the conceptualization and formalization of the «quality» dimensions we suggest to adopt a very different approach based on: 1. Knowledge infrastructure (Edwards et al., 2013); 2. Convergence as «the coming together of insights and approaches from originally distinct fields», which «provides power to think beyond usual paradigms and to approach issues informed by many perspectives instead of few» (National Research Council, 2014).
We need to develop a knowledge infrastructure to model research and innovation and all the activities related to their (economical and societal) impacts in a systemic way. To advance towards an "open science" we have to build a common platform that has to be able to show us which data is relevant for assessing the model we selected for the analysis. In this way, the data could be analysed under different perspectives while sharing the same common conceptual characterization.

An introduction on data quality

Data quality has been addressed in different research areas, mainly including statistics, management and computer science. The statistics researchers were the first to investigate some of the problems related to data quality by proposing a mathematical theory for considering duplicates in statistical data sets, in the late 60s. The management research began at the beginning of the 80s; the focus was on how to control data manufacturing systems in order to detect and eliminate data quality problems. Only at the beginning of the 90s, computer science researchers began considering the data quality problem, specifically how to define measure and improve the quality of electronic data, stored in databases, data warehouses and legacy systems. Data quality has been defined as "fitness for use", with a specific emphasis on its subjective nature. Another definition for data quality is "the distance between the data views presented by an information system and the same data in the real world"; such a definition can be seen as an operational definition, although evaluating data quality on the basis of comparison with the real world is a very difficult task.

Data quality is well-recognized as a multidimensional concept including several distinct dimensions (Batini & Scannapieco, 2006) proposed in various contexts (Catarci & Scannapieco, 2002). A crucial dimension of data quality is data accuracy: it measures the closeness between a value v and a value v', considered as the correct representation of the real-life phenomenon that v is intended to represent. However, quality is more than simply data accuracy. Other significant dimensions play a role in the definition of the Data Quality concept, including completeness, consistency, and timeliness (i.e. degree of up-to-dateness), just to cite some significant ones.

Data Quality issues in data integration processes

In a data integration system, sources are typically characterized by various kinds of heterogeneities that can be generally classified into:

(i) Technological heterogeneities.
(ii) Schema-level heterogeneities.
(iii) Instance level heterogeneities.

Technological heterogeneities are due to the use of products by different providers, employed at various layers of an information and communication infrastructure.

Schema heterogeneities are principally caused by the use of (a) different data models, such as one source that adopts a relational data model and a different source that adopts a graph-based data model, and (b) different data representations, such as one source that stores addresses as one single field and another source that stores addresses with separate fields for street, civic number, and city. Schema level heterogeneities can be solved according to well-defined methods that harmonize data collected by the different sources with respect to a schema global to the whole data integration system. However, from a practical perspective, in order to make such harmonization possible it is also necessary to solve (iii) instance level heterogeneities, namely:

For overlapping data sources, same objects can be represented as different due to data quality errors. Hence, in order to resolve such conflicting representations, an object matching activity must be performed. Such activity should be as much automated as possible, especially in complex data integration systems (Zardetto, Scannapieco, Catarci, 2010).

For all sources, also those that are not overlapping, a quality control at instance-level is very useful in order to prevent the possible population of the data integration system with erroneous data. Depending on the specific types of data integration systems, such a quality control can be performed in different ways.

A Data Quality Approach to integrate HEIs microdata in a platform

For a platform supporting European Universities for Education, Research and Technology Studies, on the one hand, the lower level of disaggregation of data makes them more sensible and increases the chances of instance-level errors. On the other hand,

data collection is performed by integrating data already collected by statistical institutions by means of different statistical surveys or administrative data.

Hence, the quality control activity should have the following features:

1. It has to be applied on the overall collected data and cannot be applied to single processes producing data. Monitoring and control of processes producing data can be very useful to prevent quality problems, however, it cannot be applied to our case, due to the different nature of production processes and to the practical impossibility to revise such processes in a preventive fashion. This does not exclude of course the fact that feedbacks deriving from quality analysis could be used by organizations that produce data to revise their production processes.
2. A specific quality activity of outlier detection could be applied, by comparing data provided by "similar" sources on the same subject. Here, "similar" could mean, for instance, belonging to the same country and with analogous features such as the number of personnel. Data that are recognized as outlier by automated procedures should subsequently undergo a human analysis. This analysis can either explain the outlier on the basis of available context information, or it can recognize that the outlier is actually caused by quality problems. In this latter case, quality improvement actions must be engaged.

The following Table 1 illustrates the main sources of data which have been integrated to test the data quality approach proposed in the paper.

Figure 1 instead shows an example of outliers detection carried out through a systematic check against different distributions. The check has been done on the ratios given by number of publications divided by the number of academic staff, for all European universities in the sample.

Table 1. Main sources of data integrated

Introduction

The higher education system, in advanced countries, has reached the point of massification (i.e. enrolment rates exceeding 50% of the relevant age cohort), while the public budget has not grown correspondingly. Universities are put under pressure to use existing resources, namely staff and funding, in the most efficient way. At the same time there is an increased pressure from the research side: the expectations of society and policy makers on the contribution of research to societal problems have grown significantly, there are new entrants in scientific arena (particularly from Asia) and the competition for funding has increased sharply. This situation creates a classical issue in public policy: we have two valuable goals (serving better mass educational needs and producing good research) between which there is tension or trade-off.

Do universities benefit from having inputs (staff and funding) that can produce jointly teaching and research, or there are efficiency-enhancing specialization effects that suggest to keep these activities under separate institutions? What is the impact of the environmental context of the universities? We focus here on the complementarity between teaching and research, which is at the core of the Humboldtian model of university (Schimank & Winnes, 2000). Is the traditional Humboldtian model of university, in which teaching and research are produced jointly by the same academic staff able to foster the economic development of the area in which the university is located? What are the main contextual factors which affect the performance of the European Humboldtian universities?

Purpose of the analysis and method

The main objective of this paper is to investigate the determinants of the efficiency scores of European universities, whose production is characterized by teaching and research outputs.

In efficiency analysis, nonparametric estimators are particularly attractive because they do not rely on restrictive parametric assumptions on the process that generates the data.

We apply a nonparametric approach, DEA (Data Envelopment Analysis, Charnes et al., 1978), which allows for multi-input - multi-output analyses, followed by a bootstrap analysis to estimate bias corrected efficiency scores and to provide confidence intervals on the efficiency scores. Given that universities in Europe face heterogeneous conditions, in a second step, we applied a semiparametric bootstrap-based approach (Simar & Wilson, 2007) to assess the statistical significance of external contextual factors on their performance.

Data and variables

Our sample is composed by 753 HEIs (Higher Education Institutions) belonging to 22 different European countries.

In the following tables we present the data analysed, the inputs, the outputs and the external factors investigated in the paper.

Table1. Data.

Data Source	Description
SCIMAGO INSTITUTION RANKING	The SIR purpose is a characterization of institutions, based on three different ranges: research, innovation and web visibility. This source uses normalized indicators, in a scale from 0 to 100, to facilitate the comparison between the institutions. The SIR database provides some bibliometric indicators for each institution, like number of publications, high quality publications, normalized impact, international collaboration and specialization index.
ETER	The European Tertiary Education Register wants to build a complete register of higher education institutions. Its database gives various information, like number of students, professors, graduates, doctorates, total incomes and expenditures. This register is developed by the Directorate General for Education and Culture of the European Commission.
EUROSTAT database	The EUROSTAT database wants to be the leading provider of high quality statistics on Europe. It contains regional data at a very disaggregated level.

Table2. Selected inputs

Input	Formula
Teaching	$\frac{\#\text{ of academic staff}}{\#\text{ of students}} * 100$
Structural	$\frac{\#\text{ of administrative staff}}{\#\text{ of students} + \#\text{ of academic staff}}$
Research	$\frac{\#\text{ of graduates at ISCED 8}}{\#\text{ of undergraduates enrolled}}$

Table 3. Selected outputs.

Output	Formula
Teaching	$\frac{\#\text{ of graduates}}{\#\text{ of students enrolled}}$
Research	$\frac{\text{output (pub)} * \text{HQP(\% high quality pub)}}{100 * (\#\text{ of academic staff} + \#\text{of graduates at ISCED 8})}$
Third mission	Percentage of third party funding.

Table 4. Selected External factors.

External factor	Description
GDP	Gross domestic product at current market prices
PAT	Patent applications
HOSP	Hospital yes/no
ER	Employment rates- age group 20-64
GERD	Total intramural R&D expenditure (GERD) at NUTS 2 level
SIZE	Size
AGE	No. of years from foundation

Modelling strategy

We estimate several partial models, i.e. models of single output production (teaching model, research model, third mission model) as well as complete models (of joint production of teaching and research, including also the third mission dimension) to analyse how the evaluation of the impact of external factors affects the production of the considered universities.

A correlation analysis is carried out to analyse the degree of association of the obtained efficiency scores with the degree of internationalization of the considered universities to account for recent results that show that is the quality of the academic staff that plays an important role to facilitate and faster third stream activities as complement of teaching and research missions.

Preliminary results and next steps

Figure 1 reports some illustrative preliminary results of the two-stage analysis conducted on the dataset.

We are going to extend the analysis in the following directions:

1. Inclusion of other third mission indicators in the input-output characterization (Geuna & Rossi, 2015), to investigate how their inclusion affects the impact of the considered external factors.
2. Apply robust nonparametric approaches (Daraio & Simar, 2007) which do not rely on the separability condition assumed by the two stage approach applied in this paper, and are more robust to outliers and extremes in the dataset as well as more flexible directional distance models (Daraio & Simar, 2014; Daraio et al., 2015a,b).

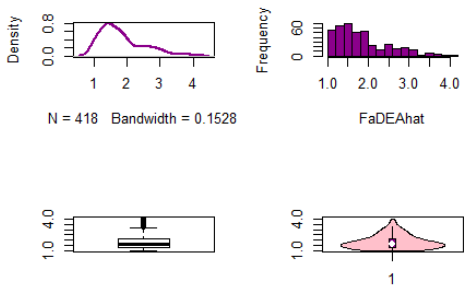

Figure1. Distribution of the European efficiency scores. Top left panel: nonparametric kernel density distribution, top right panel: histogram, bottom left panel: box plot and bottom right panel: violin plot.

The OBDM approach in a nutshell

The key idea of OBDM is to resort to a three-level architecture, constituted by the ontology, the sources, and the mapping between the two. The ontology is a conceptual, formal description of the domain of interest to a given organization (or, a community of users), expressed in terms of relevant concepts, attributes of concepts, relationships between concepts, and logical assertions characterizing the domain knowledge. The data sources are the repositories accessible by the organization where data concerning the domain are stored. In the general case, such repositories are numerous, heterogeneous, each one managed and maintained independently from the others. The mapping is a precise specification of the correspondence between the data contained in the data sources and the elements of the ontology.

The main purpose of an OBDM system is to allow information consumers to query the data using the elements in the ontology as predicates. In this sense, OBDM is a form of information integration, where the conceptual model of the application domain, formulated as an ontology expressed in a logic-based language, replaces the usual global schema. The integrated view that the system provides to information consumers is not merely a data structure accommodating the various data at the sources, but becomes a semantically rich description of the relevant concepts in the domain of interest, as well as the relationships between such concepts.

Sapientia: a Platform for Developing Science of Science's Policy Models

We consider the building of descriptive, interpretative, and policy models of our domain as a distinct step with respect to the building of the domain ontology. The ontology will intermediate the use of data in the modelling step, and should be rich enough to allow the analyst the freedom to define any model she considers useful to pursue her analytic goal.

Obviously, the actual availability of relevant data will constrain both the mapping of data sources on the ontology, and the actual computation of model variables and indicators of the conceptual model. However, the analyst should not refrain from proposing the models that she considers the best suited for her purposes, and to express, using the ontology, the quality requirements, the logical, and the functional specification for her ideal model variables and indicators. This approach has many merits, and in particular:

- it permits the use of a common and stable ontology as a platform for different models;
- it addresses the efforts to enrich data sources, and verify their quality;
- it makes transparent and traceable the process of approximation of variables and models when the available data are less than ideal;
- it makes use of every source at the best level of aggregation, usually the atomic one (see examples in the following).

In this framework, exploratory data analysis, and the building of synthetic indicators, are only an intermediate step of the modelling effort that aims to the interpretation of behaviours, the explanation of differences in performance, the identification of causal chains of phenomena. That leads to the development of a policy-design model, whose inputs are policy instruments, and whose outputs are performance indicators for research activities and economic welfare.

The learning and theory building process requires feedbacks that could also concern the ontology level: the addition of new concepts and data, through the specialization of general concepts or the enlargement of the ontology commitment, could reflect the intermediate achievements of the

learning process such as the necessity of improvement of the theories submitted to test.

More often, however, a well-conceived ontology will resist to the competency test implied by new model and theories, and the most serious constraint to model development will be the impossibility of a complete mapping between the ontology and the sources, i.e. the lack of data. This is a negative result only for the short-term. In the medium and long term, the dialogue within the community of researchers that use the ontology as a workbench will result in a joint effort towards other stakeholders in order to improve detail, quality, and scope of data collection. Moreover, the shared use of logically sound definition for indicators increase the ability of the analysts to compare their studies and to test old and new theories.

Consider as an example the important issue of the assessment of the effects of scale economies on the performance of a research institution and of its affiliates. The results can widely differ if you set the analysis at different levels of aggregation: all the public research and education institutions of single countries, single universities, faculties, let's say, of Science and Technology, departments of Computer Science, research groups, or individuals within these groups.

Moreover, at different aggregation levels, the possible moderating variables or causes of different performances can widely differ. Legislation and regulation, public funding, teaching fees and duties matter at national level. Geography, characteristics of the local economic and cultural system, effectiveness of research and recruiting strategy, budgeting, infrastructures matter at the university or department level. Intellectual ability of researchers, history and stability of the group, ability to recruit doctoral students, worldwide network of contacts matter at the research groups and individuals level.

Time is a crucial dimension of research modelling. We pursue a modelling approach based on processes, i.e. collections of activities performed by agents through time. To represent the knowledge production activities, at an atomic level, we consider both stock inputs such as the cumulated results of previous research activities (those available in relevant publications, and those embodied in the authors' competences and potential), the infrastructure assets, and flow inputs as the time devoted by the group of authors to current research projects. Similarly, we can analyze the output of teaching activities, considering the joint effect of resources such as the competence of teachers, the skills and the initial education of students, and educational infrastructures and resources. Thirdly, service activities of research and teaching institutions provide infrastructural and knowledge assets that act as resources in the assessment of the impact of those institutions on the innovation of the economic system. The perimeter of our domain should allow us to consider the different channels of transmission of that impact: mobility of researchers, career of alumni, applied research contracts, joint use of infrastructures, and so on. In this context, different theories and models of the system of knowledge production could be developed and tested.

Conclusions

To bridge the gaps existing in the literature, and to integrate existing bottom-up initiatives in a coherent theoretical-based platform, we suggest an OBDM approach.

We need a change in the overall approach to the assessment of science and technology: metrics and indicators can have negative effects on the scientific community because they encourage a reductionist philosophy; on the contrary, we propose using well-defined concepts and data to build interpretative models, in order to compare and discuss theories. That can be useful both to promote a pluralistic community of analysts, and to build consensus on less superficial evaluation procedures of researchers and institutions. Moreover, indicators are often produced in closed circles, collecting ad hoc databases, with no built-in interoperability, updating and scalability features. We have to move towards an environment in which data are publicly available, collected and maintained on stable platforms, where ontologies give confidence on the precise meaning of data to people that propose models and to those that evaluate them. These repositories of knowledge can evolve following the analytical needs of the research community and the policy institutions, instead of starting from scratch each time a new research project starts. We propose our *Sapientia* ontology as a starting point to be opened, shared with the community and further developed and integrated with existing bottom-up initiatives as well as with new theories and paradigms.

Abstract
Energy storage is an important topic as many countries are seeking to increase the amount of electricity generation from renewable sources. An open and accessible online database on energy storage technologies was created, incorporating a total of 18 energy storage technologies and 134 technology pages with a total of over 1,800 properties. In this database information on technical maturity, technology readiness level and forecasting is included for a number of technologies. However, since the data depends on various sources, it is far from complete and fairly unstructured. The chief challenge in managing unstructured data is understanding similarities between technologies. This in turn requires techniques for analyzing local structures in high dimensional data. This paper approaches the problem through the use and extension of t-stochastic neighborhood embedding (t-SNE). t-SNE embeds data that originally lies in a high dimensional space in a lower dimensional space, while preserving characteristic properties. In this paper, the authors extend the t-SNE technique with an expectation-maximization method to manage incompleteness in the data. Furthermore, the authors identify some technology frontiers and demonstrate and discuss design trade-offs and design voids in the progress of energy storage technologies.

Conference Topic
Mapping and visualization

Introduction
High dimensional datasets are difficult to visualize contrary to two or three dimensional data, which can be plotted comparatively easily to demonstrate the inherent structure of the data. To aid visualization of the structure of a dataset, a family of algorithms have been devised in the literature, which are collectively referred as dimensionality reduction algorithms, of which an extensive review can be found in (van der Maaten, Postma, & van den Herik, 2009).

Among these algorithms *t-stochastic neighborhood embedding* (t-SNE) is a novel machine learning technique that has burgeoning applications. t-SNE maps each data point in a given high-dimensional space to a low-dimensional space, typically to a two or three dimensional one, for visualization purposes. The algorithm does a non-linear mapping such that similar points in the high-dimensional space situated nearby each other in the low-dimensional space as well.

In its first stage, the algorithm constructs a probability distribution over pairs of high-dimensional points in such a way that similar points have a high probability of being picked. In the second stage, it constructs the same probabilities between these points in the low-dimensional space. Finally the algorithm minimizes the difference between these probabilities by minimizing Kullback-Leibler divergence between these two distributions (Van der Maaten & Hinton, 2008).

Inherently, the algorithm preserves the manifold that possibly exist in the high-dimensional data and represents this manifold in low-dimensional space. Indeed, this class of dimensionality reduction algorithms is called "manifold learning". In comparison to the more

conventional, linear dimensionality reduction techniques such as *principal component analysis* (PCA), which finds a linear mapping with an objective to find a subspace where the projection of each data point lies as close to the original point as possible, manifold learning algorithms preserve the distance between pairs of points. Because of this the manifolds are preserved as well, whereas with PCA, clusters that are far from each other in high-dimensional space might be merged in low dimensional space.

t-SNE also proves to be useful for technology analysts in monitoring target technologies. Technologies such as batteries and storage, which is the target technology in this article, have multiple characteristics that develop over time. The problem facing the analysts is that most modern data sources are unstructured in character. Unstructured data often indicates that the data is of mixed provenance and quality. Furthermore, readily available data is often a mix of actual performance results, and forecasts of potential future results. Even when performance data is available the data is rarely standardized, and therefore contains incomplete and uncertain data.

Table 1. List of technologies in the database.

Compressed Air Energy Storage (CAES)	Nickel–cadmium (NiCd) battery
Edison (NiFe) battery	Nickel-metal hydride (NiMh) battery
Flow batteries	Nickel–zinc (NiZn) battery
Flywheels	Pumped Hydro
Hydrogen storage	Saltwater (sodium-ion) batteries
Lead-acid battery	Sodium-sulfur (NaS) battery
Lithium–air (Li-air) battery	Supercapacitors
Lithium-ion (Li-ion) battery	Superconducting magnetic energy storage
Lithium–sulfur (Li-S) battery	Zinc-air battery

Table Table 1 shows typical sources used in appraising technological development. The data varies by provenance – it is provided through a mix of academic, commercial, government, non-profit and media organizations. Furthermore, the data itself pertains to technologies at different stages of development, and in different modes of deployment or development. An exemplary data source, discussed in the next section, compiles research and development data concerning storage and battery technologies.

Despite the mixed quality of the data sources, such data is useful and should be incorporated into quantitative analyses. In this paper we are primarily concerned with technometric approaches to modelling technology (Coccia, 2005). In particular we are concerned with utilizing such data to produce technological frontiers. Such frontiers are useful for anticipating the future rate of growth, and can be used for developing coordination mechanisms such as technology roadmaps (Phaal, Farrukh, & Probert, 2004).

Evidence and belief need not be mutually incompatible. Bayesian statistical techniques acknowledge that data is often collected in an open, rather than controlled, experimental framework (Gill, 2004). As a result the necessity for belief prevails in the collection of data. There are beliefs concerning the quality of data, the underlying system relationships, and the nature and number of underlying cases to be measured. What is significant then is that prior beliefs concerning the data are acknowledged, that these beliefs actually encompass the true state of the world, and that these beliefs are consistently updated in light of new data. These are requirements which are achievable given the appropriate collection, treatment, and handling of mixed data.

What is required therefore is a technique for handling complexly structured data, for judging cases and similarities, and for managing incomplete data. This paper approaches the problem through the use and extension of *t-stochastic neighborhood embedding* (t-SNE). The technique is used to develop a non-linear manifold of technological performance, and to use this manifold to manage incompleteness in the data. This builds on a long-established technique for handing missing data known as the expectation-maximization procedure (Dempster, Laird, & Rubin, 1977). In the next section, the paper details a database of storage and battery technologies. In the subsequent section, a method is proposed for dealing with this semi-structured data, and in specific, for dealing with uncertain and incomplete technological information.

Data Sources

This work builds upon data collected from Enipedia,[1] a website that collects, organizes and visualizes open data related to energy systems. One of the initiatives on the website has focused on gathering information related to energy storage technologies.

Energy storage is an important topic as many countries are seeking to increase the amount of electricity generation from renewable sources. An issue with renewable energy is that the amount of generation is often variable and can exceed or fall short of the amount that is demanded. If there is an excess of production, then not all of the electricity can be fed into the grid. If there is an undersupply, then power plants relying on fossil-fuels must often be relied on in order to help meet demand. To address this variability, large-scale energy storage could be used to store energy during periods of excess renewable electricity production, and then supply this energy during periods of increased demand.

A key problem is that large-scale energy storage does not currently exist, aside from pumped-storage hydroelectricity plants which can only be built in locations with suitable geography. The development of economically feasible large-scale energy storage technologies will be a major game changer in the energy sector as it can support a larger integration of renewables and decrease reliability on electricity generation from fossil sources.

The research indicated that a number of energy scenarios and simulations fail to include models on energy storage, and lack accurate data on technologies. Also, forecasting is often not included, while battery technologies and costs are rapidly evolving. By these needs, an accessible and open technology database was created, incorporating a total of 18 energy storage technologies and 134 facilities or technology pages with a total of over 1,800 properties. In this database,[2] information on technical maturity, technology readiness level and forecasting is included for a number of technologies.

An overview of sources of technology information on the potential and future demand for energy storage indicates that a number of technologies and solutions focus on applications with small time-scales, such as frequency and voltage control, load shifting, diurnal storage, output smoothing, mobility and reserve grid capacity. Far few technologies and facilities focus on providing seasonal and large-scale grid storage. For a number of these technologies, installations with a lower technology readiness level have been included to provide some numbers on feasibility.

Developing metrics on comparing these technologies was done through an iterative design scheme, incorporating metrics relevant to a range of applications. It was observed that a number of technologies cannot be described fully, as information is missing or the ranges in which information sources report the information are exceptionally wide. Also, the definitions found for some technologies, such as Li-ion, are weaker than those found for other

[1] http://enipedia.tudelft.nl

[2] http://enipedia.tudelft.nl/wiki/Electricity_Storage

technologies. Furthermore, metrics are often made available on a systems level, and information on other levels needs to be translated to this system level.

Table 2. Variable number, name and description

No.	*Variable Name*	*Description*
1	Case	Case number
2	Product	Product name
3	Technology	Technology type
4	Year	Reference year
5	Institutional Data	Indicator whether observation is institutional
6	Technology Readiness Level[3]	Technology maturity level
7	Investment per Unit Power	Investment unit power (EUR/KW)
8	Investment per Unit Energy	Investment cost per unit energy (EUR/KWh)
9	Efficiency	Energy efficiency
10	Cycles	Life span in cycle times
11	Energy Density	Energy density (WH/L)
12	Power Density	Power density (WH/Kg)
13	LCoE[4]	Levelized cost of energy

Method

The chief challenge in managing unstructured data is understanding similarities between technologies. This in turn requires techniques for analysing local structures in high dimensional data. The technique of choice for this is t-stochastic neighborhood embedding (van der Maaten & Hinton, 2008). Finding a manifold which represents the data is useful for developing lower dimensional representations of the data. Such a manifold is inherently non-linear, and by necessity it preserves the local structures in the data at the expense of finding any global structures which might be present. For this analysis we adopt an implementation of the algorithm created in Matlab (van der Maaten, 2007).

The t-SNE technique has previously been used in technometrics. Cunningham and Kwakkel (2014) investigate a case of electric vehicle and hybrid electric vehicle designs and technologies. The case benefitted from the use of a non-linear fitting technique since the designs considered differ substantially in fundaments. As a result different designs highlight fundamentally distinct kinds of engineering trade-offs. The case also demonstrated a potential convergence across multiple technologies. Other patterns of technological evolution on a manifold, in addition to convergence, are identified in the paper.

Other technometric approaches utilize a linear, or quasi-linear technological frontier. Many of these approaches also assume a constant rate of technological change as the frontier advances over time. These alternative approaches are useful for single technologies with well-understood morphologies. Such techniques are also suitable for technologies where there are suitable indicators of performance, outcome, or merit. The techniques are less useful for analyzing broader fields with a heterogeneous base of technology. In such fields different technological trade-offs may be at work, and the pace of technological change may be discontinuous or punctuated. Indeed, the technologies themselves each may be valued for different purposes and outcomes.

[3] http://en.wikipedia.org/wiki/Technology_readiness_level
[4] http://en.wikipedia.org/wiki/Cost_of_electricity_by_source

A desirable method must be suitable for use with diverse data types. Before applying t-SNE to the data set of Table 2, the data is first transformed and normalized. Transforming the data eases a search for locally similar data points. Furthermore, the normalization of the data helps address difficulties associated with variables being measured in different units, potentially highly discrepant in scale. The choice is made to take the logarithm of the data whenever the data is right skewed. Logistic transformation is used to create more normal-like distributions than the actual.

As previously noted, a major challenge in addressing such data sets is the presence of missing data. The principle technique for handling missing data in the statistical literature is known as the expectation-maximization procedure. This powerful technique has been extended to address the estimation of missing model parameters, as well as missing data, and later become a mainstay of machine learning techniques. Modern machine learning procedures are now availed of much faster algorithms than expectation-maximization procedures; nonetheless the technique has had a powerful effect on the field.

The expectation-maximization procedure consists of two steps. In the first, or expectation step, the missing data is replaced with an expected value. Initially the expected value can be set by the mean of the data, or even by replacing the missing data with random values. Then in the maximization step, a model of the data is selected and applied. After an initial modeling step, further estimates of expected values derived from the model can be derived. These expected values become new expected values for additional rounds of the modelling procedure. After repeated cycles of expectation and maximization the estimated values converge, and the full model of the data is derived. The technique has the benefit of replacing missing values with neutral values consistent with an assumed model of the data. The technique therefore makes the best use of available data that is possible, rather than excluding whole variables or cases because they are incomplete.

Unstructured data in this domain is not just incomplete, but also uncertain. This is expressed with reported ranges of expected performance data. In order to treat this data, an upper bound and a lower bound on the data is reported, using two distinct model variables. When the data is certain, the upper and lower bound of the variable is identical. In subsequent model runs a constraint is imposed on the expectation maximization procedure – the maximum estimated upper bound on missing data must be greater than the lower bound. When estimated variables do not satisfy this criteria they are either not updated, or both the upper and lower bounds are replaced with averages.

Every point on the manifold estimated by t-SNE is associated with a potential technological design. Thus the t-SNE model is generative – it reports the expected best fit to the data, and also anticipates new cases or designs which have not yet been reported. Nonetheless, technological constraints or other factors may mean that parts of the manifold are not populated with new designs. Interpolation using the manifold can proceed following two directions. A locally linear direction of change can be interpolated from the data given specific examples or cases. Or, a weighted average of surrounding points can be used given their relative proximity on the technological manifold.

Analysis

The following section details a complete procedure for analysis, as depicted in Figure 1Figure. The procedure begins with preprocessing the data. The raw data includes lower and upper bounds for various attributes. Thus, we made a choice to create two different features for each of such variables, e.g., both “Energy density lower bound” and “Energy density upper bound” features.

The next step identifies and masks out the missing data. The process is facilitated by the use of data structures (for instance in Python or Matlab) where the missing data is identified using

indicator values. A data matrix therefore contains two layers – the first layer stores the data itself, and the second layer contains a bit matrix for masking. The bit matrix indicates where the data is complete or non-missing, or incomplete and missing.

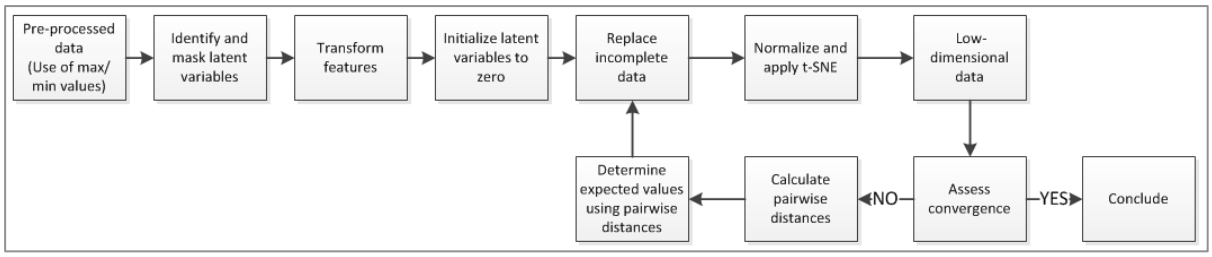

Figure 1. A Flow Chart of the Analysis Procedure.

Then the features are transformed and normalized to normal-like distributions. The following state initializes the missing variables to zero, which is in effect the mean of the normalized features. In subsequent iterations of the algorithm more refined estimates of the missing data are made. This brings us through the initialization and the first maximization step of the algorithm.

The data is complete, and can now be fitted using the t-SNE algorithm. The major output of the algorithm is a set of coordinates for all the cases – in this example there were 118 points. Intermediate outputs, such as data coordinates and scatter plots are produced.

Next, convergence of the algorithm is tested by comparing the current imputed high dimensional representation to the high dimensional representation of the previous iteration. Obviously this step is skipped for the first iteration.

If the algorithm has not converged, then pair-wise similarities between the points are evaluated as the next procedure. The purpose of this comparison is to determine the closest peers of any given technology. The basis for this comparison is the Euclidean distance between two points in the three-dimensional space as output from the t-SNE algorithm. The distance is then scaled according to the negative exponential of the squared distance between the two points. The total distance is then re-scaled to sum to 100% percent to create weightings for updating the originally missing variables in the data. The idea here is to calculate the new values for the missing data such that these values are closer to the related data points implied by the low dimensional data. Using pair-wise distances, a new expected set of values is established and finally the high dimensional representation is updated. The model converges when there is negligible differences between the consecutive imputed high dimensional representations.

Results and Visualization

This section discusses some results of the t-SNE analysis, visualizes and interprets some of the results, instead of all, due to space limitations, and displays the technologies according to their respective dates of introduction or their forecasted date of introduction. These colors suggest that the frontier of technological performance is gradually moving outward (to the upper right) over time. This is further illustrated in Figure 3.

Technological development, at least as measured by year of introduction is a somewhat noisy variable. Nonetheless, in Figure 3, we can qualitatively place three frontier lines. The first is dated 10 1985, the second to 2010, and the third to 2035. It seems plausible given the figure that the rate of technological change is higher among battery technologies than it is among storage technologies. This is demonstrated by the comparative “fanning out” of the battery technologies over time.

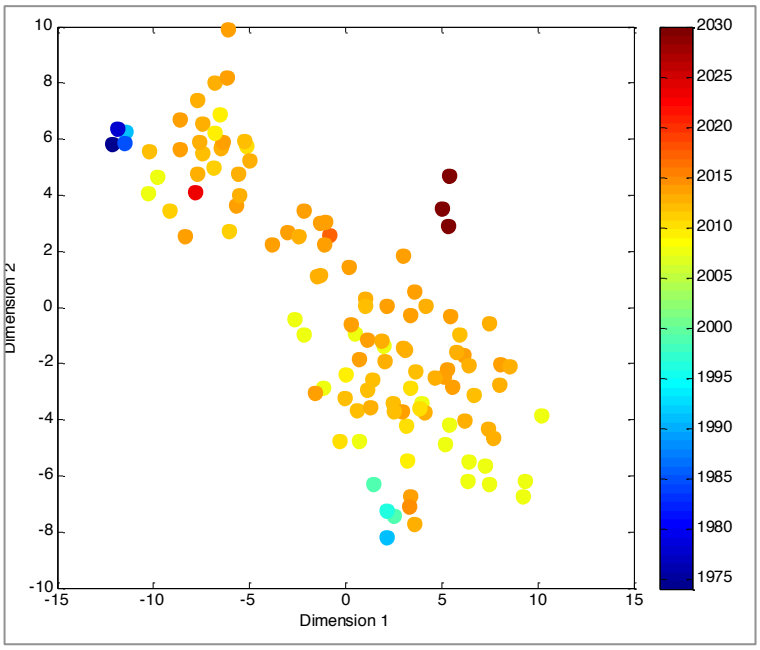

Figure 2. Technologies Positioned by t-SNE and Colored by Date of Introduction

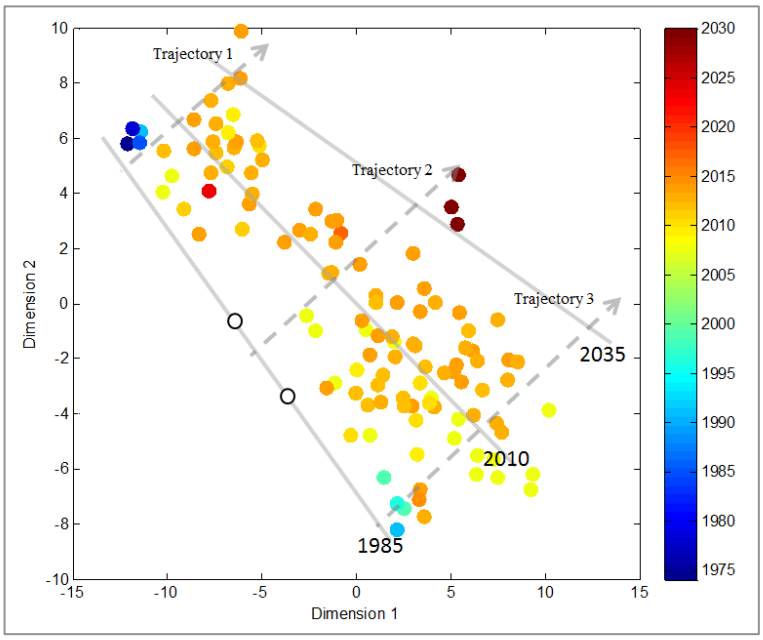

Figure 1. Technological Trajectories

In Figure 3 three technological trajectories are displayed. Changes in technological performance, based on benchmark technologies on or near the trajectory are calibrated. Then the three trajectories are compared with one another to determine whether there are common elements of change across the trajectories.

Figure 4 describes a potential trade-off in the design and selection of battery and storage technologies. In general the trade-off is between the respective cost and advantages of storage technologies versus batteries. Storage technologies are more robust, providing more cycles of operation at a lower levelized cost of energy. This comes at the cost of having a lower energy density, a lower technology readiness level, and a lower efficiency. In contrast battery technologies offer more energy density, are more readily available on the market, and operate

at a higher level of efficiency. In consequence, batteries are less robust, operating for fewer cycles, and requires a higher levelized cost of energy to be paid out.

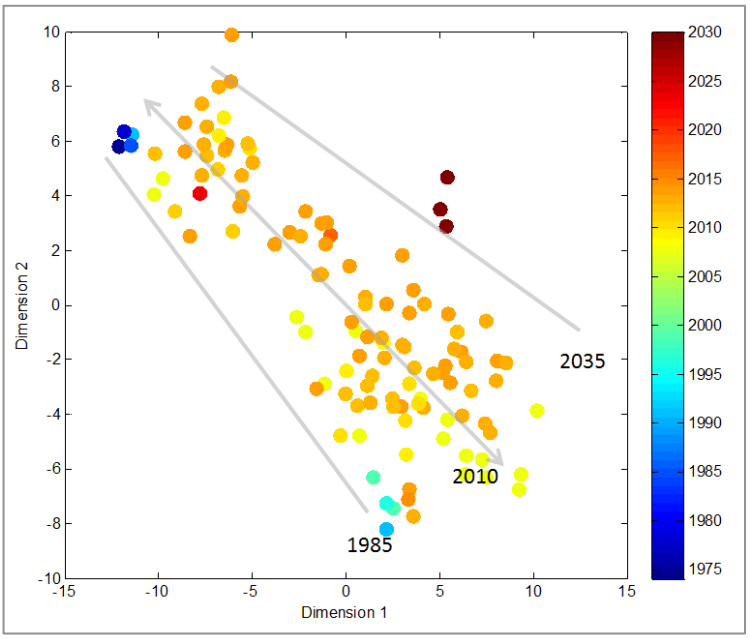

Figure 4. Design Trade-Offs.

There are three design voids on the manifold as shown in Figure 5. These are areas in the space of potential design which have not been explored. One space, design void 1, occurs along the 1985 technological frontier. The space is sparsely explored, although by 2010 a flywheel technology has emerged to occupy the space. The next two voids lie along the 2035 frontier. Because we are not yet on the 2035 frontier, these voids may be unanticipated breakthroughs. Design void 2 is in the space of high performing storage systems, and design void 3 is in the space of high performing batteries. One organization, EASE, anticipates a number of 2030 battery technologies on or beyond this frontier.

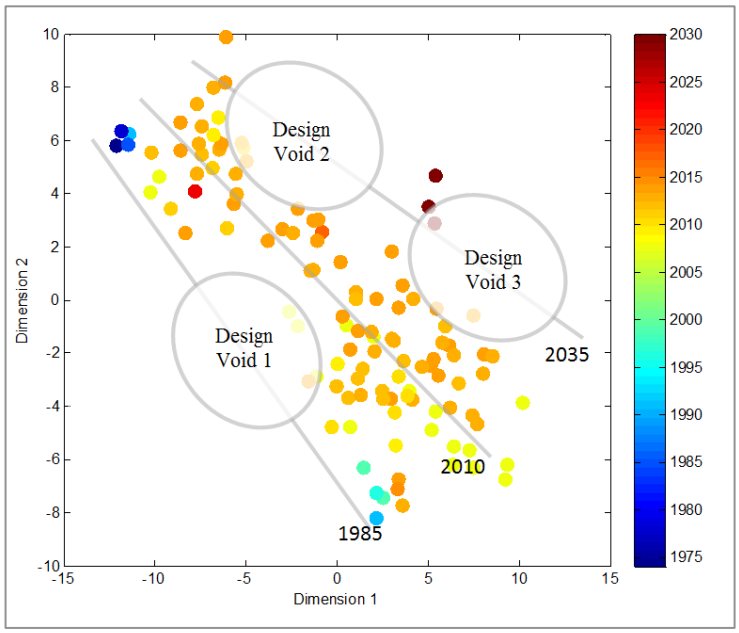

Figure 5. Design Voids.

Table 3 provides, by interpolation, the performance characteristics of the technologies in the three voids mentioned previously. The exemplary void 1 technology is most likely a battery. The year of introduction suggests that there have been too few lower technology exemplars, so that the performance here is likely highly overstated. There should likely be a lower power and energy densities, and a lower levelized cost of energy. The closest existing technology is the "Wemag AG Li-Mn storage plant."

The void 2 technology, likely a storage device, should afford dramatically reduced investment and investment per kilowatt hour over previous technologies. The cycle times should be up to an order of magnitude higher than the void 1 exempla. While the power density may not be affected much from its 1985 peer, the energy density is likely to be reduced. The levelized cost of energy may be half of the previous levels of the void 1 technology. The year of introduction is too early, suggesting still higher energy and power densities over those listed. The closest existing technology is an advanced compressed air energy storage device.

The exemplary void 3 technology is most likely a battery. It will require an order of magnitude less unit investment, although the investment in terms of euros per kilowatt may be up to one half of previous levels. Cycle times will be improved, and energy densities may be doubled or even tripled over previous technologies. Power densities will also be somewhat improved. The levelized cost of energy will be three or four times lower than the equivalent technologies from 1985. The technology as anticipated is closest to some of the forecasted lead-acid battery advances for the year 2030.

Conclusions

In this paper, a database of energy storage technologies with various corresponding attributes is examined. The authors described a method to manage incompleteness of the data. The described method synthesizes t-SNE technique, which is a novel dimensionality reduction technique, with long-established expectation-maximization technique. The completed database later used for building a technology frontier that shows the progress of technology in

time, discussing the design trade-offs in the technology and finally identifying some design voids in the progress of the technology.

The technique described in this paper can be complementary to wide variety of technometrics or evolutionary technology dynamics approaches which make use of high dimensional technology data.

The technique performs better especially in visualization than other dimensionality reduction applications such as feature selection or feature extraction for two reasons. Firstly, it uses expectation maximization to impute the missing variables, which manages the incomplete data in such a way that the imputed variables have minimal weighting in producing the low dimensional map. Hence, it has least effect on the derivation of the lower dimensional map. Secondly, the t-SNE technique itself is a more suitable approach compared to other dimensionality reduction algorithms such as incumbent Principal Component Analysis (PCA). PCA aims to keep variation in the data and does not care about the pairwise relationships between data points, whereas manifold learning techniques such as t-SNE performs better in keeping similarities.

As a follow up to this work, more applications of this techniques next to the technology trajectories and design voids, as showcased in this paper, are yet to be explored. The promise of this technique is its complementary position in various technometrics analysis, which is yet to be fulfilled.

Furthermore, a methodological study regarding the validation of the technique using controlled experiments on a complete data set is on the research agenda of the authors.

Bibliometric Characteristics of a "Paradigm Shift": the 2012 Nobel Prize in Medicine

Abstract
This research-in-progress paper reports bibliometric characteristics that illustrate and give credence to the claim of the Nobel Prize committee that its 2012 Nobel Prize in Physiology or Medicine was awarded for a "paradigm shift". An all-author co-citation analysis (ACA) of stem cells research 2004-2009 provides an interesting characterization of this paradigm shift, which was triggered by a mid-2006 publication by the younger of the two 2012 laureates. In particular, while ACAs of 2-year time slices for the period consistently indicate the presence of a single cohesive subfield in which the "paradigm shift" occurred, with some fluctuation in membership throughout the period, an ACA of the entire six year period shows instead a closely interlinked pair of subfields, which on closer inspection turn out to represent the pre- and post-paradigm shift states of the same subfield. This bibliometric characterization also correctly identifies the name of the researcher primarily responsible for the paradigm shift, namely, Shinya Yamanaka, as that of the dominant post-shift cited author in that subfield. The relative lack of dominant figures in the subfield in the pre-shift period also underlines the area's pre-paradigmatic state of multiple conflicting and relatively unsuccessful research directions attempting to address a fundamental crisis in that field at that point.

Conference Topics
Mapping and Visualization; Citation and Co-citation Analysis; Methods and Techniques

Introduction
The 2012 Nobel Prize in physiology or medicine was awarded to John B. Gurdon and Shinya Yamanaka for having triggered, the latter with a discovery first reported in his mid-2006 publication (Takahashi & Yamanaka, 2006), "a paradigm shift in our understanding of cellular differentiation" (Nobel.org, 2012).

In the present paper, we report bibliometric evidence and characteristics for this paradigm shift. Results from this study may contribute to research that combines relational and evaluative citation analysis methods to extend the research problems that are addressed by citation analysis.

Methodology
We examined the evolution of the stem cell research during 2004-2009 through an author co-citation analysis (ACA) of three 2-year time slices using the same dataset as in Zhao and Strotmann (2011), which reported results from a study of the full 6-year time period. We adapted methods from that study.

The data set was constructed by retrieving about 60,000 full PubMed records of stem cell research articles published during 2004-2009 with MeSH heading "stem cells", enriched by their cited references from Scopus records corresponding to these PubMed records (Strotmann & Zhao, 2009). Automatic author name disambiguation was performed on this dataset (Strotmann, Zhao, & Bubela, 2009).

For each of the three 2-year time slices, the 200 most highly cited authors were identified by fractional author citation counting, and their exclusive all-author co-citation counts were

calculated (Zhao & Strotmann, 2008). An exploratory factor analysis with oblique rotation was performed on each of these co-citation matrices (SPSS Direct OBLIMIN) with the number of factors to extract determined by Kaiser's rule of eigenvalue greater than one. Only factor loadings greater than 0.3 were retained in the factor analysis results in order to focus on the most important relationships.

The visualization used here is similar to that in Strotmann and Zhao (2012), improving on the one introduced in Zhao and Strotmann (2008). It visualizes directly the results of a factor analysis, with authors as square, and factors (research specialties) as circular nodes. An author node is colored according to the factor that it loads most highly on in the pattern matrix result of the factor analysis. Node sizes are proportional to citations received (author nodes) or to the sum of member author citations weighted by each author's loading (factor nodes). The visualization merges information on both the pattern and the structure matrix results of the obliquely rotated factor model, using the latter for automatic layouting (Kamada-Kawai algorithm in Pajek) and the former for gray-scale values of lines that link authors to the factors that they load on. Interpretation of the factor nodes (i.e., research specialties identified) proceeded exactly as in earlier papers, by manually examining highly co-cited papers of authors that load highly on a factor.

Results

Figures 1-3 show the intellectual structure of the stem cell research field for three consecutive 2-year periods.

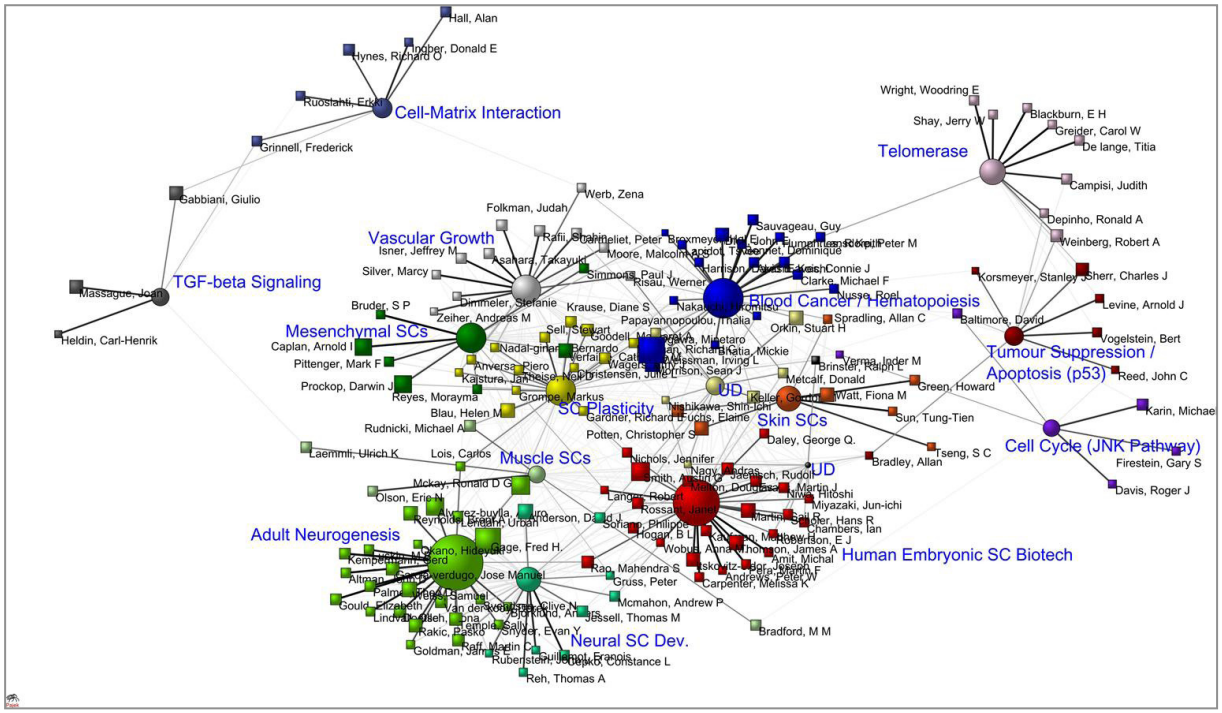

Figure 1. ACA of stem cell research 2004-05.

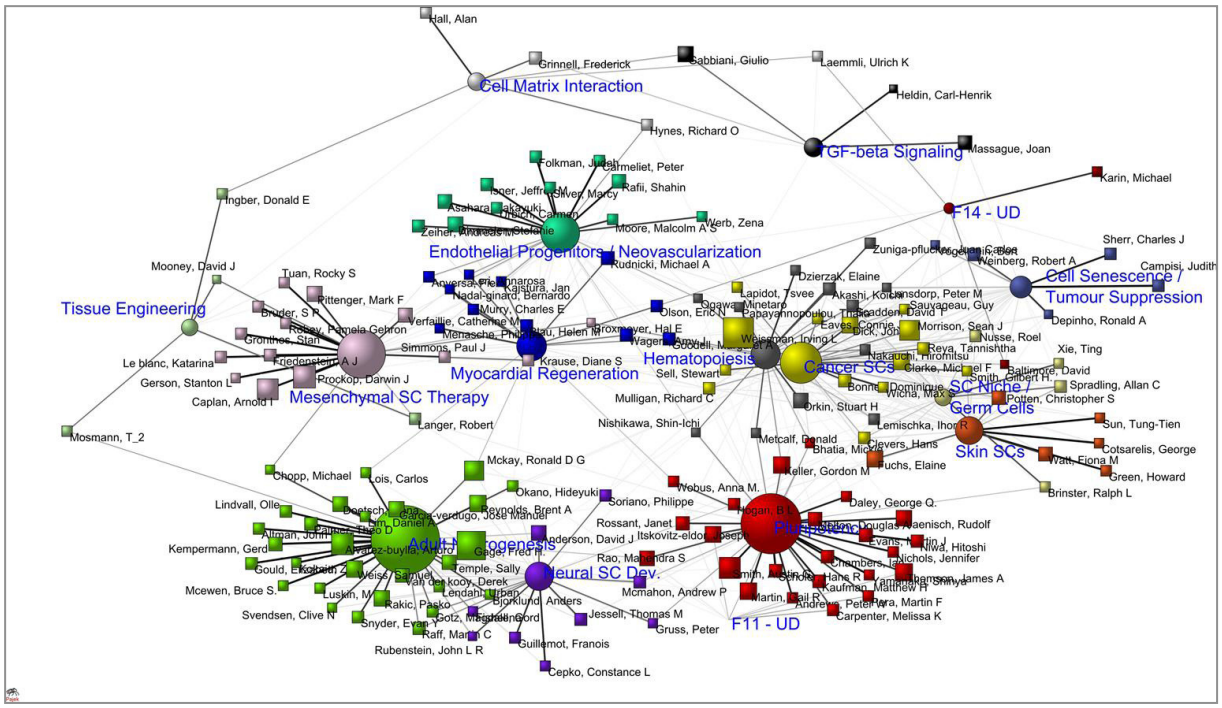

Figure 2. ACA of stem cell research 2006-2007.

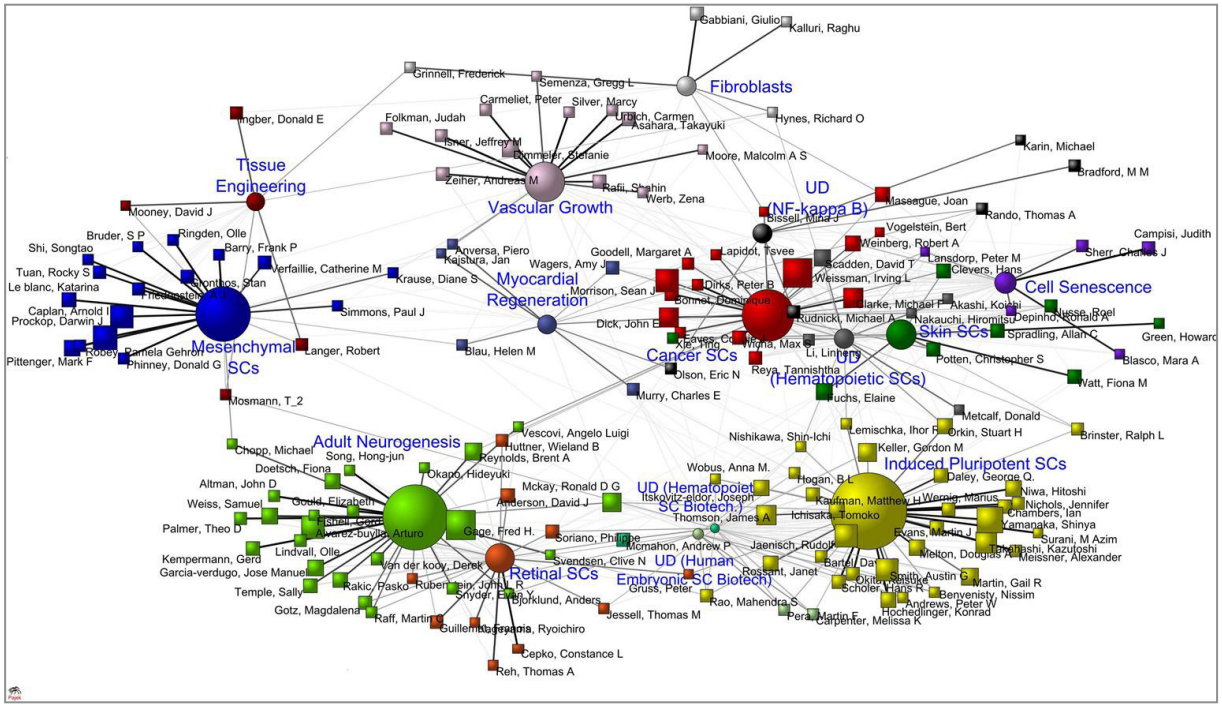

Figure 3. ACA of stem cell research 2008-2009.

While many interesting features of the international stem cell research field may be observed by examining these maps closely, we focus here on one particular major development in this field during the 2004-2009 time period as seen from changes over time. During the entire 2004-2009 time period, a subfield is shown prominently in the bottom right area of these maps as one of the two dominating specialties in stem cell research (the other being neural stem cells, bottom left). However, the entire focus appears to be shifting from (human) embryonic stem cell research in 2004-2005 (Fig. 1) through the study of pluripotency in

2006-2007 (Fig. 2) to the study of (human) induced pluripotent stem cells in 2008-2009 (Fig. 3). With this renewed focus on induced pluripotent stem cells, this subfield overtook the Neural stem cells specialty to become the most prominent specialty in the entire stem cell field in 2008-2009.

The transformation of this subfield is linked to the phenomenal rise of Shinya Yamanaka in these maps. Yamanaka was awarded the 2012 Nobel Prize in physiology or medicine for his discovery of induced pluripotent stem cells in mid-2006. He was not a highly influential researcher yet in 2004-05 as measured by citation impact (his name does not appear in Fig. 1); his name emerges in 2006-2007 (a small square in Fig. 2) and dominates this subfield by 2008-09 (the largest square in Fig. 3) with a citation impact reaching that of the two long-time most highly influential authors in the entire stem cell research field: Irving Weissman in the cancer stem cells specialty (red) and Fred Gage in the Neural stem cells area (green).

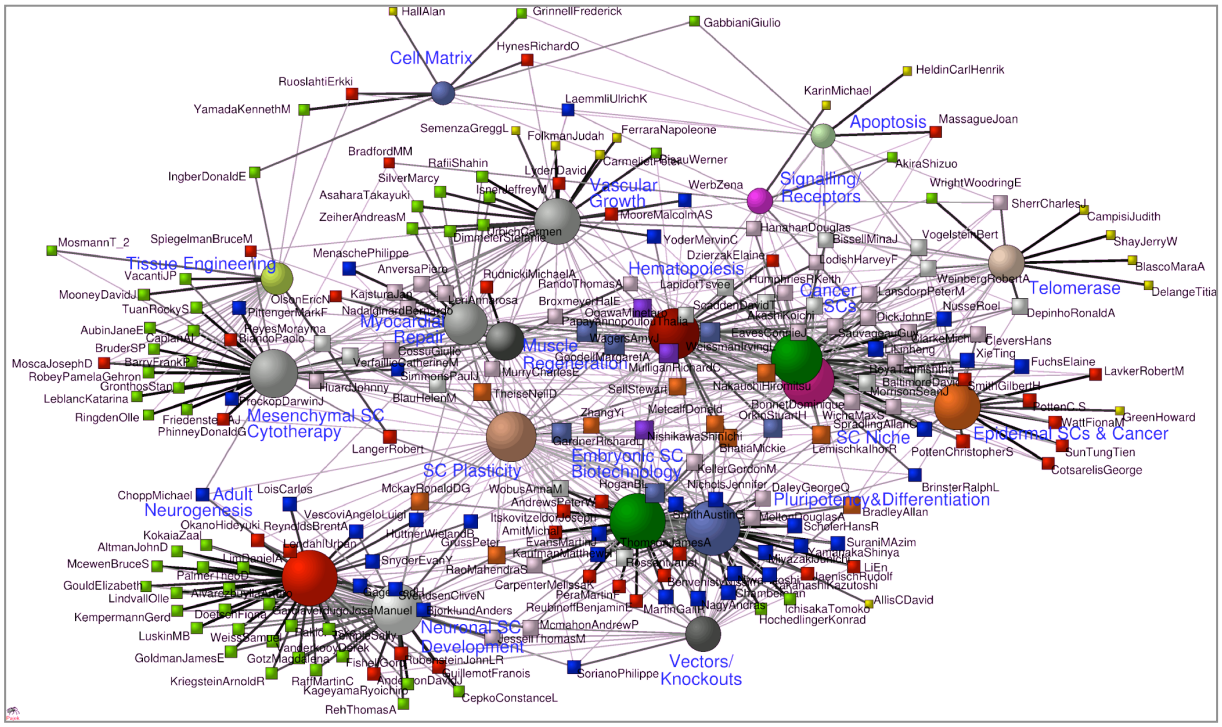

Figure 4. ACA of stem cell research 2004-2009.

By contrast, Figure 4, reproduced from (Zhao & Strotmann, 2011), which covered the entire 2004-2009 period in a single visualization, shows this subfield as consisting of two heavily interlinked research areas (bottom center), namely embryonic stem cell research (left, green) and (induced) pluripotent stem cell research (right, blue). This clarifies that what at first blush looks like it might have been a gradual change within this subfield when considering only Figures. 1-3 in fact constitutes a major in-place shift of research focus. Taken together with Figures 1-3, this confirms that the entire knowledge base for this subfield of stem cell research shifted from the former to the latter within just a couple of years of the publication of the key transformative paper – a true paradigm *shift* indeed. Most authors in this subfield co-loaded strongly on both these areas in the 6-year visualization, indicating a widespread realignment of researchers. A major paradigm shift becomes apparent.

Discussion

Kuhn's main criterion for a scientific revolution, or paradigm shift, is that something previously unthinkable becomes standard knowledge in a scientific field and a major crisis within the field is resolved as a result (Kuhn, 1970). In the case of stem cell research,

Yamanaka found that differentiated cells can be "reset" (induced) to undifferentiated (pluripotent) state, which essentially reverses the arrow of time in cell development biology, something previously unthinkable indeed.

It had been known in principle since Gurdon's 1960s paper (Yamanaka's co-laureate) that adult cells could be turned into even totipotent cells. For decades, stem cell research had been attempting to make this process feasible and controllable for therapeutic use, hoping someday to be able to regrow any type of damaged tissue (hence, the term regenerative medicine). The insurmountable research problem was a practical one: all methods for manipulating cells to this end produced stem cells that carried an unacceptably high risk of growing into malignant cancers rather than viable organs. Yamanaka's methods appear to have been the first (among uncountable failed attempts by others) to promise a fully viable resetting of cell development to the pluripotent or even totipotent state.

At the same time, Yamanaka's methods promised "safe", "natural", and abundant sources of pluripotent stem cells for research on early stages of cell development, which provided an immediate solution to a major social crisis that faced stem cell research in this subfield. This crisis came from the huge ethical and legal problems of obtaining and handling the embryonic stem cells that it required. By triggering a "natural" reset switch of much less problematic adult cells to the pluripotent state, as it were, the resulting stem cells not only side-stepped the ethically problematic use of embryos as a source, but did so without the kinds of major intervention such as genetic manipulation that had severely limited the usefulness of earlier versions of such cells for studying the "natural" biology of cell development.

As the Committee points out, Yamanaka's solution was also quite simple, so that human embryonic stem cell research was able to rapidly shift its entire focus to the study of induced pluripotent stem cells, in the remarkably short time of just a couple of years. Yamanaka's methods became standard knowledge very quickly – "textbooks were rewritten".

In the visualizations produced from an ACA of the type we performed here, this paradigm shift is characterized, somewhat paradoxically, by a stable visual appearance of the affected research subfield, accompanied by a shift in topic focus (factor labels). That a major topic shift took place can be confirmed through an analysis of a larger time slice spanning the triggering event, as we saw above. The initiator of the paradigm shift, Yamanaka, stands out as the author whose node shows explosive growth in citations received within the area as the shift occurs. The success of the paradigm shift is also seen from a rapid growth spurt of the shifting subfield relative to other subfields.

Interestingly, our visualization appears to also capture the "pre-paradigmatic" stage of this subfield, during which no single proposed solution managed to dominate the field (or subfield) that is undergoing a crisis (Kuhn, 1970). Unlike e.g. Gage in Neural stem cell biology or Weissman in bone marrow stem cell medicine research, whose citation impacts (indicated by relative node sizes) clearly dominated their respective subfields, no individual stood out in the embryonic stem cell research to that degree in Figure 1 (2004-2005). By 2008-2009, however, with the paradigm shift from embryonic to (induced) pluripotent stem cells as primary research tools completed, Yamanaka clearly plays that role in this area.

This ACA was actually performed, and Figures 1-4 were created, well before the 2012 Nobel Prize was announced (Strotmann & Zhao, 2011; Zhao & Strotmann, 2011). It appears that this paradigm shift could in principle have been identified and the 2012 Nobel Prize predicted through bibliometric studies of this kind (we did identify it as a "major development" of the field). Now that we have an idea what to look for, we could perhaps proactively look for patterns of this kind in bibliometric research in order to identify scientific breakthroughs and to make interesting predictions for major research awards. Research of this kind could enhance previous attempts to predict who among millions of scientists might qualify for the

honor of a Nobel Prize (Garfield & Malin, 1968) by combining relational and evaluative citation analysis methods to provide more convincing evidence.

Conclusions

This paper provides bibliometric evidence that the 2012 Nobel Prize in Physiology or Medicine was indeed awarded for a paradigm shift, through ACA of three consecutive 2-year time periods of stem cells research 2004-2009 compared to a single 6-year ACA for the same data. The success of this paradigm shift is seen on the ACA maps from the explosive growth in node size (citations received) of the researcher whose research initiated the shift, along with a complete shift of research focus in a subfield of stem cells research and a rapid growth spurt of this shifting subfield relative to other subfields. An ACA of the full period confirms that a major shift in the knowledge base of the subfield took place over this short time period; indeed, it shows signs of moving from a Kuhnian "pre-paradigmatic" to a "normal science" stage.

We hope that results from this study will contribute to research that combines relational and evaluative citation analysis methods to extend the research problems that are addressed by citation analysis.

Introduction[a]

Bibliometric mapping tools and other scientometrics analyses may be used to study the historical development of a research field. In our paper, we use automatic bibliometric mapping tools to visualize the history of analytical chemistry from the 1920s until the present, with special focus on the application of mass spectrometry (MS).

Data and methods

Co-word maps were based on noun phrases (nouns and preceding adjectives) parsed from titles and abstracts of all papers published between 1929 and 2012 by *Analytical Chemistry*, a key journal in the field of MS. Maps were constructed by determining the co-occurrence of noun phrases and visualized using VOSviewer software (Waltman & van Eck, 2010).

Results

Evolution of topics in analytical chemistry 1929-2012

Co-word maps were based on all texts published in *Analytical Chemistry* except for advertisements (1929-1995) or on all articles, letters and reviews published in *Analytical Chemistry* (1996-2012). Table 1 shows a summary of the different clusters in the co-word maps (due to space constraints, the maps themselves could not be included).

The maps show that inorganic chemistry has been an important topic within analytical chemistry for a long time; from 1929 until 1990 there were one or more clusters on inorganic chemistry. In the 1991-2000 period it was merged with the topics of electrochemistry and sensors. Much attention was given to (the development of) different apparatuses between 1929 and 198. A cluster on general and editorial issues can be found in almost every period. Topics that have developed over time include electrochemistry, chromatography and mass spectrometry. Electrochemistry shows up as its own cluster in the 1951-1960 period, but terms relating to the subject can also be found in the inorganic chemistry and metals cluster from 1941. This suggests the topic of electrochemistry has developed from inorganic chemistry and metals to form its own subfield. Chromatography is apparent in the maps from the 1951-1960 period onwards; mass spectrometry from the 1971-1980 period. The maps suggest the widespread use of mass spectrometry in analytical chemistry primarily developed through its coupling to chromatography; for the 1971-1980 period terms relating to mass spectrometry can be discerned in the maps, but the cluster is still dominated by chromatographic techniques and applications. However, from the 1981-1990 period, mass spectrometry broke off and formed its own subfield. Finally, from 2001 a cluster on separations and microfluidics emerged. This cluster also contains terms relating to theory and simulations (of such microfluidic systems).

Use of different techniques in analytical chemistry

Next, we analyzed the development and use of a number of techniques *within* analytical chemistry. As a proxy, we determined how many articles mentioned the technique in their titles during the 1929-2012 period. This shows that titration techniques reached their publication peak in the 1950s, gas chromatography in the 1960s, and liquid chromatography in the 1980s (Fig. 1). Of these techniques, only the latter was still mentioned in the titles of over 5% of papers published in the 2001-2012 period. On the other hand, microfluidics is an example of a technology not mentioned before 1990 that has really taken off in this 2001-2012 period. A technique not mentioned to a great extent in the titles of *Analytical Chemistry* papers is nuclear magnetic resonance (NMR). As the co-word maps already suggested, the mention of mass spectrometry increased throughout the entire period. Whereas in the 1929-1940 period none of the *Analytical Chemistry* papers mentioned mass spectrometry in their title, the percentage of papers that did increased to eighteen in the 2001-2012 period (Fig. 1). This indicates *Analytical Chemistry* has made a shift towards the publication of research using mass spectrometry instead of other techniques.

Introduction

Maps of science are an effective technique, especially for non-experts, to facilitate intuitive understanding of science activities, even though they could be cut both ways. Among such maps, science overlay maps have received adequate attention from scientometrics researchers (Perianes-Rodríguez et al., 2011; Grauwin & Jensen, 2011; Klaine et al., 2012; Leydesdorff, Rotlo, & Rafols, 2012; Boyack & Klavans, 2013; Gorjiara & Baldock, 2014). Actually they are an attractive approach "to visually locate bodies of research within the sciences, both at each moment of time and dynamically." (Rafols, Porter, & Leydesdorff, 2010)

To produce science overlay maps, (1) we draw a basemap, which contains positional information of nodes from bibliographical data, then (2) we overlay other information on the basemap by assigning the information (i.e., indicators like publications and citations) to the nodes with such factors as colors and/or size of circles representing the nodes.

To think more abstractly, an essence of science overlay maps is "sharing" of positional information of nodes by different science maps, which are similar in concept to thematic maps in geography. What makes such "sharing" possible is the stability of global maps (Rafols, Porter, & Leydesdorff, 2010). This perspective could broaden choices of expressions in science overlay maps to improve our understandings. For example, VOSviewer (Van Eck & Waltman 2010) provides five different views, i.e., label view, density view, scatter view, cluster view, and cluster density view, for a fixed set of positional information of nodes. By switching these views, we can understand phenomena behind the maps deeply and multidimensionally. Therefore, introducing a new way to project bibliographical information on given maps is expected to expand availability of science overlay maps, just as a new method to produce thematic maps does in geography.

From this perspective, the author first pays attention to density view provided by VOSviewer. By mapping journals in the fields of Business, Business-Finance, Economics, Management, and Operations Research & Management Science, Van Eck and Waltman (2010, p. 529) explain functionality of the density view as follows: "The density view immediately reveals the general structure of the map. Especially the economics and management areas turn out to be important. These areas are very dense, which indicates that overall the journals in these areas receive a lot of citations." As they pointed out, this view is helpful to outline the macro structures of maps and to show which areas in the maps are important. Basically, however, density view can be used only for representing quantitative indicators, because "the item density of a point in a map depends both on the number of neighboring items and on the weights of these items." (p. 533) If citations were used as weights of items, the density map might be seen to show "quality" of areas. Actually, citation densities are only a representation of quantities. That is particularly evident in assuming to represent quality (impact) indicators like proportion of top 10% publications in the density view.

Judging from many scientometrics studies rely on density or heat maps (e.g., Pinto, Pulgarin, & Escalona, 2014), it would be reasonable to assume that graphical representations like the density view to represent quality indicators on science maps is very helpful to outline the structures of bibliographical data and to show which areas in maps of science are efficient, superior, or highly shared. Then, this paper introduces "kriging" to scientometrics for representing quality indicators.

Data

The author uses a data platform that consists of datasets from SCI Expanded, PubMed, and USPTO patent databases. By adopting matching methods developed in Shirabe (2014), records in PubMed are linked to those in SCI expanded, and non-patent references in the face sheets of US utility patents are also matched to records in SCI Expanded. As a result, three databases can be analyzed in an integrated fashion by using this platform.

This platform contains the product set (number of items is 8.5 millions) of SCI expanded (articles, reviews, letters, notes, and articles & proceedings papers; their database years are between 1992 and 2011) and PubMed (their publication years are between 1991 and 2012) as well as science citations of US utility patents registered between 1991 and 2012.

Method

First "macro and micro" basemaps are constructed by co-occurrence analysis of MeSH terms (Leydesdorff & Opthof 2013), where VOSviewer is used for mapping and clustering. For making the macro map, all the items of the product set are included in the analysis, and only third layer descriptors are treated as subjects of co-occurrence analysis. For that, lower layers' MeSH terms are replaced by their higher taxon. For making the micro map, only items containing mesenchymal stromal cells, mesenchymal stromal cell transplantation, totipotent stem cells, multipotent stem cell, induced pluripotent stem cells, pluripotent stem cells, and embryonic stem cells as their MeSH terms are included in analysis. Top 150 MeSH terms (except highly shared terms) are used in co-keyword analysis. Thus, this micro map is a map of pluripotent stem cell research.

Secondly, sets of data overlaying on the basemaps are produced. For that, positional data (i.e., two-dimensional position coordinate) of nodes produced by VOSviewer are transmitted to SAGA (Böhner, McCloy, & Strobl, 2006). Then, overlaying data for density maps (by Gaussian kernel function) or those for isograms (by kriging) are calculated from bibliographic indicators and overlaid on the basemaps.

Results

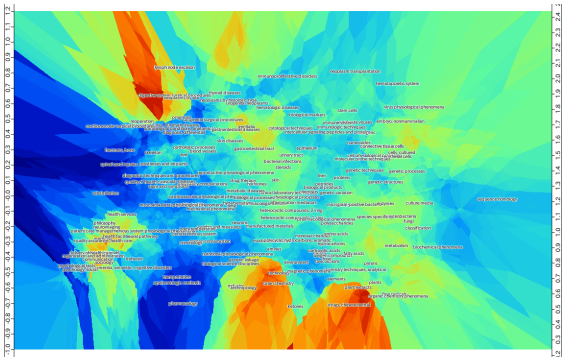

Figure 1. Japanese Share of Life-Science Papers cited by US Patents Registered between 2001-11.

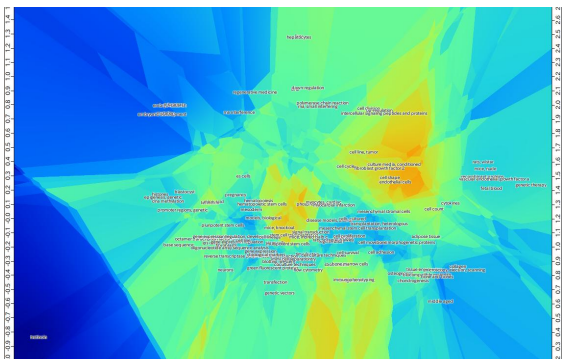

Figure 2. Japan's Relative Frequencies of Top 10% Cited Papers in Stem Cell Research.

The above figures show examples of overlay maps to represent quality indicators. They make it easier to understand the quality of Japanese research outputs intuitively and multidimensionally either at macro or micro level.

Acknowledgments

This research is partly supported by JST/RISTEX research funding program "Science of Science, Technology and Innovation Policy".

The *Technology Roots spectrum*: a New Visualization Tool for Identifying the Roots of a Technology

Eduardo Perez-Molina[1]

[1]*eperezmolina@icloud.com*
CTB, Universidad Politecnica de Madrid (Spain)

Introduction

The purpose of this work is to present a new tool for identifying the technological foundations, or roots, of a specific technology in the whole range of existing technologies. The idea is to go back to the date before a specific technology existed as such—its origin date—and to evaluate the influence of every existing technology in relation with it. Our tool is based on the role played by prior art patent citations as a historical footprint. The documents cited in the prior art search reports by patent examiners against patent applications in a particular —new—technology link the new emerging techniques to the conventional existing ones. The nature of this particular set of references, namely *who* produced the citations—the patent examiner in place of the author—and *why* they are cited—the evaluation of the novelty and non-obviousness—, is unique within the body of bibliographic references (Meyer, 2000), and explicitly points to temporal and conceptual proximity. These two factors seem fundamental to the study of history and technology.
The *Technology Roots spectrum* (*TR spectrum*) is a tool for visualizing the components at the origin of the specific technology under study, showing their relative weight as bars in a graph containing the whole range—the spectrum—of technologies. It uses the computer to exploit the network formed by prior-art citations in patent publications and the classification codes assigned to them. This tool can be used to study the history of technology and, as a technology indicator of technological origins, can also be used for defining technology metrics.

Data Collection Methodology

The data collection methodology is shown in Figure 1. First, we select the whole collection of patents published in a specific technology using classification codes. For example, if this technology is graphical user interfaces (GUI), we must use the IPC code G06F3/048, literally "Interaction techniques based on graphical user interfaces" (IPC codes and titles can be consulted at http://www.wipo.int/). In this way we get the specific "technology" collection. From this set we extract all the citations from its search reports building the "citations" collection. Then, we keep the patents filed before the specific technology has emerged, in this case 1975 (Reimer, 2005) and we obtain the "Roots" collection.

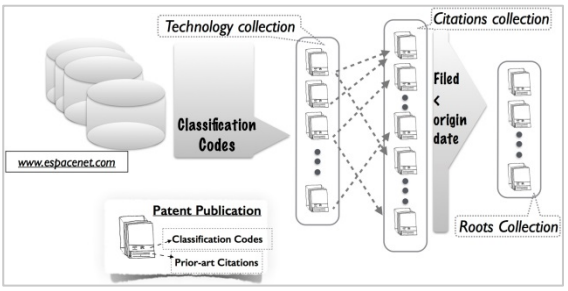

Figure 1. Data collection path

The *TR spectrum*

The set of selected patents—the "Roots" collection—is formed by patent publications disclosing technology methods, concepts, devices or systems intertwined with different aspects of the specific technology under study and filed (and therefore developed) before this technology existed —the origin's date. Analysing in turn the codes assigned to them provide us with indications of the technological foundations of the technology under study. This is why we use the expression: *Technology Roots*. Furthermore, every patent publication in the "Roots" collection is classified with a code representing a technology chosen between all possible existing technologies, this is why we use the term: *spectrum*.
The *TR spectrum* is built by aggregating the classification codes allocated to each document within the "roots" collection, and ordering this dataset in a sequence in accordance with the IPC scheme at a certain level of granularity—*section, class, sub-class, group or sub-group*—(WIPO, 2014). Changing the level of granularity we zoom out or zoom in on the techniques to have different conceptual resolutions and in consequence we can identify more technical details or we can have global views of technical fields. Figure 2 (top graph) shows the *TR spectrum* for computer graphics (CG) at the IPC *class* level. This spectrum was built using the IPC codes G06T11 (2D image generation), G06T13 (Animation), G06T15 (Image rendering), G06T17 (3D image modelling for computer graphics) and G06T19 (Manipulation of 3D models) for the "technology" collection, and the origin date was set at 1960 (Perez-Molina, 2014).
Following our methodology the "technology" collection contained 32,034 documents. Then, all

the patent publications cited in their search reports made a "citations" collection with 83,719 documents. Finally, the "roots" collection is formed by 344 patents.

A tool for studying the history of technology

The direct analysis of the main components of the spectrum provides us with an indication about the technological foundations of a specific technology. Looking, for example, at the computer graphics *TR spectrum* at IPC-*class* level (see Figure 2 top graph), it is straightforward to note that the foundations of CG are mainly in computers, electrical devices and electronics, and photography (the right-hand side of the spectrum), and to a lesser extent in medicine (left) and mechanics (left-center). The main components are G06 (computation), G01 (measuring), G09 (Education, cryptography, displays and seals), H04 (electric communications) and G03 (photography and cinematography).

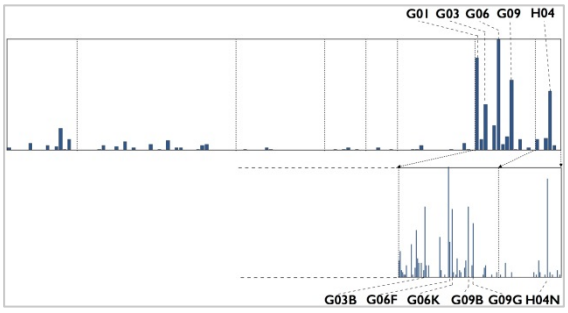

Figure 2. C.G. *TR spectrum* at IPC-*class* level (top) and partial view of the CG *TR spectrum* at IPC-*subclass* level (bottom)

At finer granularity, in other words, aggregating the dataset at the level of *sub-classes*, we have more precision in these technologies already identified. Then, it is clear from the partial view of the TR-spectrum at IPC *sub-class* level (see Figure 2 bottom graph) the importance of digital processing (G06F), television (H04N), photography (G03B), pattern recognition (G06K), educational appliances (G09B) and display control circuits (G09G). If, for instance, we are interested to know which specific technology is behind educational appliances, we zoom in on this spectral component, discovering that the most populated group is simulators (G09B9), and zooming in again we find in particular flight simulators (G09B9/08).

A tool for technology metrics

The *TR spectrum* contains information about the technological influences at the origin of a specific technology. It forms a sort of technology affiliation fingerprint of its origins, thereby it can be used as a technology identifier in technology metrics.

We have used it to get an indication of the relative distances between technologies. The different spectral bin values of the *TR spectrum* are considered as coordinates in a *technology-roots* space, thereby every particular *TR spectrum* is a point in this space. Then, applying *multi-dimensional scaling* (Wickelmaier, 2000) we have reduced the dimensionality for visualizing the relative positions of technologies. Figure 3 shows the results for four technologies—computer graphics (CG), graphical user interface (GUI), computerized tomography (CT) and Airbags—using Euclidean distance.

At present we are experimenting with other distance metrics more suitable for classification spaces.

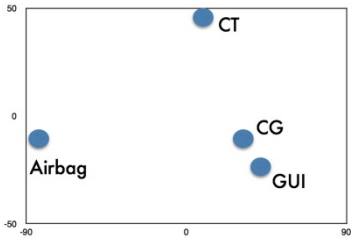

Figure 3. Relative position of CG, GUI, CT and Airbags after applying *multidimensional scaling* to its respective TR spectrums

Conclusions

We have introduced a new visualization tool—the *TR spectrum*—for identifying the technological foundations of a specific technology. We also have briefly disclosed the application of this tool for studying the history of technology and its use as a technology indicator.

Introduction

An analysis of the interrelationships between elements within dynamic structure typically involves perturbation methods based on the minimum energy. In result, the researchers use minimum distance-based algorithms and therefore the shortest path between the various components of the system. However, the history of science development shows that collaboration between the researchers in different disciplines becomes effective and fruitful when scientific explorations do not follow the "shortest possible" roads.
In current work authors present a novel approach, how to analyse and evaluate the possible collaborations ways in a small team of researchers (number of nodes is less than 100) participating in the project network KnowEscape COST Action.[1]

Data, metrics and assumption

Analysed dataset consists of 83 records characterized each member of COST network. Input data organized in 83x83 matrix, describe two years collaboration within such activities as: mobility, events organization, publishing (also for former years) and project management. The dataset was gathered using KnowEscape website (knowescape.org), ResearchGate and Mendeley services.
To describe the mutual relationships between members the graph based on Mycielski concept was constructed (Larsen, Propp & Ullman, 1995). The authors identified graphically four attractors of maximum energy. The clique represents each researcher's pair, and arbitrarily large chromatic number means any combination of disciplines. Presented visualisation (Fig. 1) was generated by using the Poincare section (PS) of the 3D space which is defined by all ties between team's members (Tamassia, 2000).
The main problem concerns identification subgroups categories with regard to scientific activity. The matrix was generated using selected nodes and links through Poincare projection (Clifford, Azuaje, & McSharry, 2006).

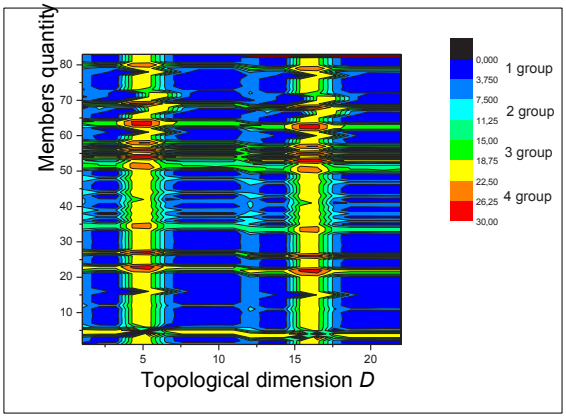

Figure 1. An iterated visualization of discrete distance routes.

Obtained iterated visualization of discrete distance routes is shown on Figure 1. As a final result we observe four clear clusters. All participants were divided on four groups by describing appropriate roles in social network: leaders, connectors, performers and outliers.
This approach was tested using algorithms adopted from medical data analysis for time series (Swierkocka-Miastkowska & Osinski, 2007, Mazur, Osinski, Swierkocka, 2009).
The authors evaluate also the dynamics of total activity by using fractal dimension (FD) of each PS image. FD is the measure of nonclassical geometry shapes and can be used as a pattern's complexity parameter (Osinska 2012).
Fractal dimension was obtained by Higuchi algorithm, so the resulting maps help to discover possible opportunities for further development of cooperation between the scientists.

Visual results

All members' activities represented by matrixes are summarized and full collaboration is weighted by appropriate real numbers. Popular application *Gephi* allows finding collaboration groups and revealing the scientists with basic roles: leader,

[1] This research is sponsored by National Science Center (NCN) under grant 2013/11/B/HS2/03048/ Information Visualization methods in digital knowledge structure and dynamics study.

subgroup leader, connector, outsider and so on. By using force directed layout (*force atlas 2*) the authors have obtained clarify configuration presented on Figure 2. As expected, the central point is occupied by the real team's leader. The closer node to central one represents the scientist who is more active in collaboration with the team's leader.

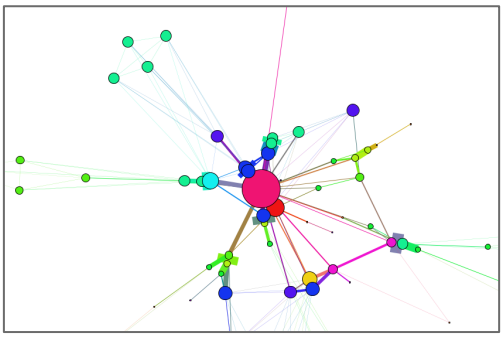

Figure 2. The graph of full activity of team's members.

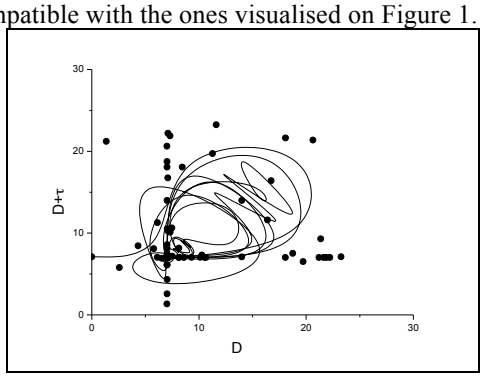
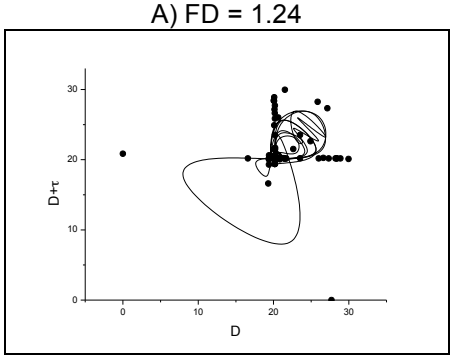
Network visualisation exposes also some subgroups where intrinsic collaboration (mainly in publishing) is significant. The scientists within these groups share a common feature: geographic localisation. They work in the same country.

Simple quantitative proportional correlations between identified groups on a graph are compatible with the ones visualised on Figure 1.



A) FD = 1.24



B) FD =1.39

Figure 3. Two variations of collaboration between scientists with different social roles: A) Leader-performer; B) performer-performer.

Next step, calculation of fractal dimension, was accomplished for combinations of representatives of different groups, for example: leader-performer, subleader-leader, connector-performer and so on.

Two variations of collaboration with appropriate FD are shown on Figure 3. Fractal dimension is always lower for every pairs composed from the leader or subleader compared to the performers and connectors.

Conclusions

The authors propose new parameters for the prediction of a stable way of scientific collaboration. First is the shape of Poincare section (Return Map Poincare). For inhomogeneous academic groups where there is no self-consistency (like in this work), the level of nonlinearity can also reflect collaboration potential. It is proportional to the quantity of curves on Figure 3. The second indicator – FD shows the possibility to cooperate as well as its dynamics.

Higher fractal dimension in the case of performers can be explained by larger dynamics of predictive collaboration. This indicates the pattern is more complex. It means the pair covers significant collaboration potential.

Visualisation can help discover possible opportunities for further development of scientific cooperation. Therefore, we can observe common career landscapes of the various members and groups.

Monitoring of Technological Development - Detection of Events in Technology Landscapes through Scientometric Network Analysis

Geraldine Joanny[1], Adam Agocs[2], Sotiri Fragkiskos[2], Nikolaos Kasfikis[2], Jean-Marie Le Goff [2] and Olivier Eulaerts[1]

[1] *geraldine.joanny@ec.europa.eu*
Joint Research Centre, European Commission, Brussels (Belgium)

[2] CERN, Geneva, (Switzerland)

Introduction

Monitoring technological development is an important challenge for research organisations and regulators. For decision-makers, the detection of early signals of technology maturation is key to designing proper standards and regulations. Anticipating the arrival of new technologies also allows policy-makers to develop and implement fit-for-purpose research or industrial policies. Scientometric analysis (in this case using both publications and patents) is a powerful tool to monitor technological fields and can be used to detect events in the lifecycle of a technology (Rotolo et al., 2014).

Objectives

- to analyse different cases (historical) of technological change by monitoring the evolution of patterns of collaboration between research organisations, the apparition of new keywords and/or subject categories in articles as well as changes in quantitative data such as patent or publication counts;
- to investigate whether network analysis can be used for the detection of events related to technological change;
- to identify potential indicators of technological maturation useful in the context of early warning to regulators.

Methods

Results relating to 4 technologies are presented here. Publications for each technology were retrieved from the Web of Science Core Collection database and patents from Thomson Innovation. To select the technologies, a semantic search was used in the abstract, title and author keywords of the publications.

Different network landscapes were then created using the retrieved patents and publications: sociograms showing how organisations collaborate together (through co-publishing and co-patenting); keywordgrams based on co-occurrence of author keywords in articles; and subject-category-grams based on subject categories given by Thomson Reuters. These three types of network landscapes were created and analysed for each technology.

Results

Shale Gas and horizontal drilling

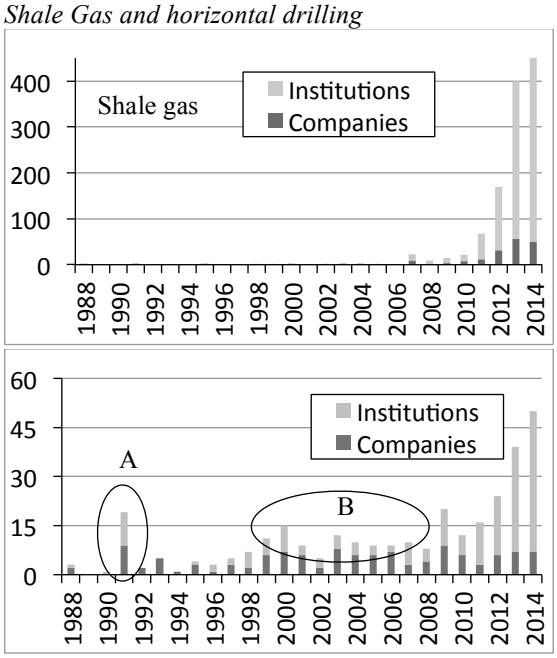

Figure 1. Number of patents and publications for horizontal drilling and shale gas from 1988.

Figure 1 shows that the number of patents and publications mentioning "shale gas" in the abstract, title or keywords started to increase noticeably in 2007 and boomed from 2011 onwards. By contrast, articles mentioning horizontal drilling, one of the key enabling technologies for "shale gas" appeared earlier (A) and rose from the year 2000 onwards (B). In addition, comparison with press content analysis shows that the rise in articles mentioning "shale gas" correlates with an increase of occurrences of press articles about shale gas (data not shown), which leads to think that this rise does not correspond to a technological trend. This shows that for the prediction of technological change the subjacent technologies - not the broad concepts - are more meaningful for the early detection of technological change.

The 2nd graph of Figure 1 shows the need to build composite indicators to avoid false positive signals. The peak of publication activity in 1991 is indeed not correlated to increased activity in other

indicators such as volume of patents or variation of number of players, for example (data not shown).

3D-printing - Detection of new uses of a technology
The number of patents and publications on fused-deposition modeling (a key enabling technology of 3D-printing) is growing steadily from 1995 to nowadays (data not shown). The subject categories of the journals in which the selected publications were published are manifold and evolve in time. As shown in Figure 2, from 1998 to 2014 a few clusters of new subject categories appear. In 1998 the articles relating to fused deposition modeling were belonging to engineering, material science and automation, which are categories describing the core of this technology. Categories describing applications of 3D-printing appear as of 2001, i. e., earlier than the entry of the first 3D printer on the market (2009).

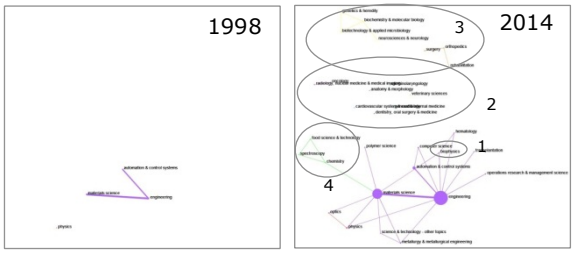

Figure 2. Subject categories for publications on fused-deposition modeling in 1998 and 2014. The circles show appearance of new non-core subject categories. 1. Biophysics (2001), 2. Radiology (2004), dentistry (2005), oncology (2006) 3. Genetics, Biochemistry (2007), Neurosciences (2008) 4. Food science and chemistry (2011).

CRT - Detecting substituting technology
The study of the author keywords for publications related to cathode ray tube (CRT) allowed to observe the emergence of the replacing technology, Liquid Crystal Display, in the CRT space. Figure 3 shows various synonyms of LCD in the keywordgram for CRT. The LCD nodes are quite big, showing their relative importance. The keyword LCD or its synonyms appear in 35 out of 649 publications or 5% of the publications.

Silicon wafer for microelectronic and for solar cell
Two application lifecycles can be observed for silicon wafers by analysing the number of related publications and patents (data not shown). These two lifecycles culminate respectively around the years 2000 and 2010. Analysing the keywordgram for the selected publications we see the keyword "silicon solar cells" appearing in 1999, and being increasingly used until 2011. Figure 4 shows its co-occurrence with other keywords in 2014. The emergence of this keyword reflects the apparition of a new use of silicon wafers for solar applications.

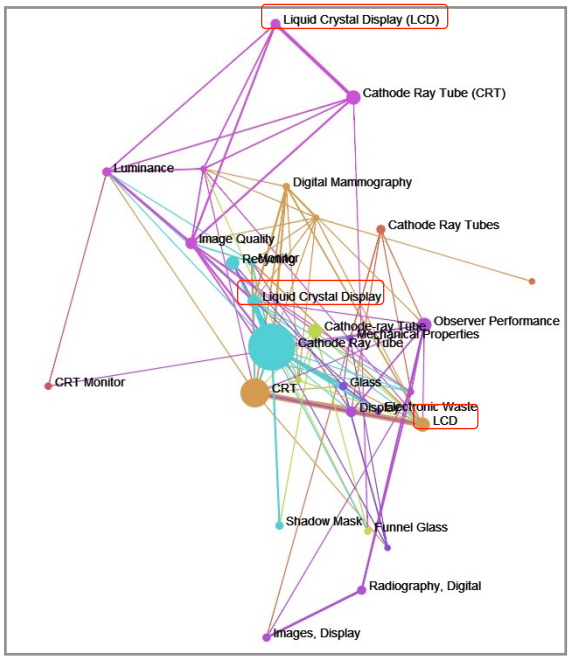

Figure 3. Author keywords view for Cathode Ray Tubes in 2014.

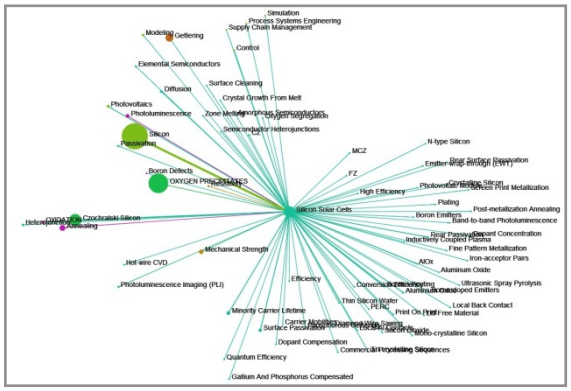

Figure 4. Centric view of keyword "Silicon Solar Cells" and its co-occurrence with other author keywords in the publications space relating to Silicon wafers.

Conclusions

Our study suggests that network analysis can be used for the detection of events relating to technological change.
We have identified several types of indicators that could be combined in order to design an early warning system to alert decision-makers of changes in technology landscapes.

Introduction

Autoimmune diseases (AD), referred to as abnormal immune responses of body against self-antigen, are caused by the loss of immunologic self-tolerance resulting in damage to the cells, tissues and organs. The National Institute of Health (NIH) lists more than 80 autoimmune diseases that affect varied organs of the body including rheumatoid arthritis, multiple sclerosis, systemic lupus erythematosus and so on.

Significant advances of AD have been made in the understanding of clinical and pathological mechanisms involved but, to date, a few elements have been identified as being responsible for the autoimmune process. With a better understanding of the causes and treatments of AD, many potential novel therapies have recently been developed and evaluated, focusing on cellular or molecular targets.

Although there have been several research activities carried out with scientometric tools to evaluate scientific output for individual autoimmune diseases such as rheumatoid arthritis, Crohn's and Behchet's disease (Shahram et al., 2013), there was no scientometric studies on the entire autoimmune disease to date. Density-equalizing algorithms, scientometric methods and large scale data analysis were applied to evaluate quality and quantity of scientific researches in rheumatoid arthritis (Schöffel et al., 2010). Various scientometric analysis including literature-related discovery (LRD), text-mining was more broadly performed to produce knowledge discovery such as gene expression and proteomic studies. Data mining and bioinformatics approaches for autoimmune biomarker discovery studies were also attempted (Kostoff, 2014).

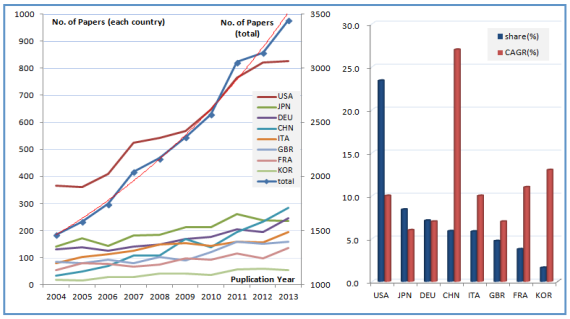
The purpose of this study is to analyze the status and trends of treatments for AD using scientometric methods, and intend to give researchers and policy-makers valuable information in the field of AD.

Data and Methods

Publications associated with the treatment of AD were retrieved from Elsevier's SCOPUS database. The query to collect data for scientometric analysis was as follows: "TS=(autoimmun*) AND TS=(therap* OR treatment*)" Total 23,587 articles published during recent 10 years (2004-2013) were collected and analyzed. Microsoft Excel, KITAS, NetMiner and VOSviewer software were combined to analyze bibliometric data. KITAS software from KISTI (Korea Institute of Science and Technology Information) was used for data extracting and cleaning. NetMiner and VOSviewer software were also used for clustering and mapping.

Results and Discussion

Figure 1 shows R&D trends over time in major countries, and the share and CAGR (compound annual growth rate) of each country based on scientific papers regarding treatments of AD. Over the last 10 years, there has been a significant growth in performance of papers with CAGR 10% in this field. Although the US quantitatively represents the largest share (23.4%), China shows the most rapid CAGR 26.6% followed by Korea (13.2%). Especially in the field of AD, Japan and Germany show a strong tendency compared with other general aspects of pharmaceuticals.



(a) (b)

Figure 1. The changes of number of papers (a) and the share and CAGR by major countries (b).

2-mode network in Figure 2 shows the co-occurrence between main countries and keywords extracted from papers, which can help identifying; which country related to; which kind of autoimmune diseases or therapeutics or treatment technologies. Circle nodes represent countries and the size of each node indicates the number of publications. The degree of relationships is

indicated by the thickness of the link and the distance between two nodes.

Keywords are divided into 2 groups, different types of AD at the bottom of Figure 2 and its technical terms at the top. In terms of the disease, high prevalence of AD including rheumatoid arthritis, multiple sclerosis, type I diabetes have shown a high correlation with US. Japan is estimated to be active in the field of autoimmune pancreatitis, autoimmune hepatitis, and Germany seems active in multiple sclerosis and type I diabetes. In particular, autoimmune thyroiditis shows a high correlation with Japan, Germany and Italy rather than US. As shown in the top of Figure 2, US is very active across all areas of the field. Advanced immunotherapies with cell-based technologies using dendritic cell, regulatory T cell (T-reg) are particularly revealed to be active in Japan and Germany as in the US.

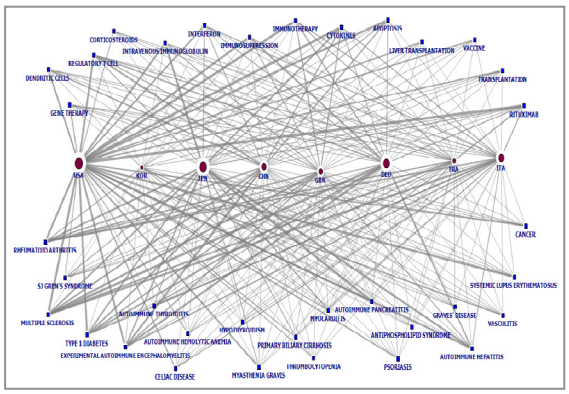


Figure 2. 2-mode network of the major countries and keywords related to autoimmune diseases.

Figure 3 provides the knowledge mapping for AD treatment drawn by co-word analysis, which shows the hot topic field or an increasing R&D productivity trend for AD treatment. To find out changes in R&D trends for treatment of AD, the dataset was divided in two time periods: 2004 to 2006 and 2011 to 2013. Several changes are found in the map of the past 3 years (2004-2006) compared with the last 3 years (2011-2013).

Figure 3 shows an experimental study using experimental autoimmune encephalomyelitis (EAE) animal model of multiple sclerosis has been disappeared in the last map (2011-2013). As time passed, clinical studies on many diseases considered to be autoimmune have been conducted with various organs and systems including endocrine, hepatobiliary, vascular systems. In addition, cell-based immune therapies with regulatory T cell (T-reg) or Th17 cells gradually have emerged in the last map (2011-2013). Immunomodulatory effects of mesenchymal stem cell (MSC) are also shown in the second figure of Figure 3. This might imply that a targeted immune therapy had been developed and successfully utilized in treating AD patients.

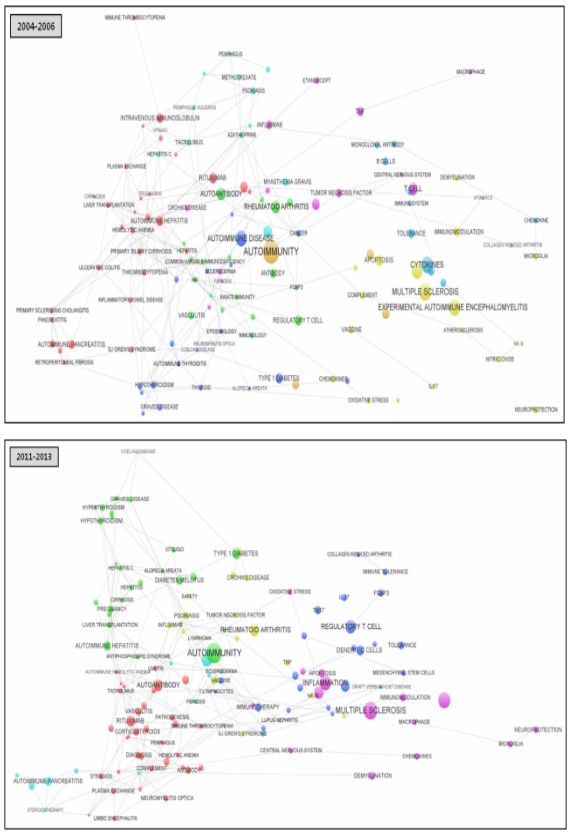

Figure 3. Co-word knowledge mapping product for the treatment of autoimmune disease.

In this study, we investigated present R&D status and trend for the treatment of AD using scientometric analysis methods. The trend in advanced R&D for the treatment of AD was identified through knowledge mapping techniques such as co-word analysis of articles and visualization technology. The results show that each country has progressive development of AD therapeutics with any other aspect. Additionally, the approach to identify the molecular and cellular mechanisms of AD underlying the immune tolerance has been increased.

Introduction

Convergence refers to the creation of new technologies (or industries, markets) through the combination of two or more technologies (or industries, markets), which is promoted by technical changes, innovations, and technology diffusion, and plays a key role in changing gradual innovations to destructive innovations. Furthermore, convergence is a key factor in accelerating changes in the growth curve of technologies and the life cycle of products (Pennings & Puranam, 2001). This study was conducted to analyze convergence trends in secondary batteries and find their implications. For this purpose, useful papers and patent data for analysis were selected, collected, and processed to calculate the convergence index. This attempt is expected to provide the foundation for predicting convergence by identifying major causes that accelerate convergence. To effectively measure convergence status in this study, the diversity index suggested by Yegros Yegros et al. (2003) was used. The diversity index, which is used to measure interdisciplinary studies, considers three aspects: variety, balance, and disparity. An interdisciplinary study means the integration of different disciplines, thereby creating new academic disciplines. In this study, the convergence index was derived by the integration of different technologies into one technology.

Method of Analysis

For this purpose, the diversity index suggested by Yegros Yegros et al. (2013) was used for analysis, and IPC International Patent Classification) was used for the analysis of patents. IPC codes are assigned to individual patents and multiple codes can be specified depending on the case. In this study, IPC codes were used to analyze the convergence phenomena in secondary batteries (Stirling, 1998, Purvis et al., 2000, Stirling, 2007). The equation for each variable is given below.

$$\text{Variety} = n$$

$$\text{Balance} = -\frac{1}{\ln(n)}\sum_i p_i \ln p_i \quad (1)$$

$$\text{Disparity} = \frac{1}{n(n-1)}\sum_{ij} d_{ij} \quad (2)$$

(d_{ij} = 1-cosine coefficient)

In this equations, n means that number of IPC codes and p_i means that ratio of i IPC code.
In this study, U.S. patents about secondary batteries that had been opened or registered between January 1, 1998 and December 31, 2011 were analyzed with the IPC code for secondary batteries H010-010 using the USPTO database. In this study, we use patent data until 2011 because patent data is valid until 2011.

Table 1. Search formula for secondary batteries

Data	Search formula	Number of patents
USPTO	IPC=H01M-010*, PY=19880101~20111231	8,181

Result and Discussion

The measurement of variety through the number of IPC subclasses about patents in secondary batteries by year showed that the variety value was increasing sharply over time. In particular, the variety value greatly increased after 2009 when the number of applicants in medium- and large-sized secondary batteries increased rapidly, indicating that the variety value of secondary batteries increased with the active research related to medium- and large-sized secondary batteries. The measurement of balance by year showed that the balance value decreased between 1988 and 2000, and steadily increased again after 2003. This suggests that with the beginning of the development of the medium- to large-sized secondary batteries, research and development of various technologies have been carried out to develop the required technologies. The measurement of disparity values by year showed that the disparity value has been decreasing over time. This suggests the decreasing distance between technologies and the progress of convergence.

Figure 1. (left) Trend of variety by year; (middle) Trend of balance by year; (right) Trend of disparity by year.

In particular, the distance between technologies has become very low after 2001. As analyzed above, with the emergence of medium- to large-sized secondary batteries, convergence with other technology fields such as eco-friendly cars and solar cells has been going on.

Figures 2 and 3 show the network structure of IP codes for secondary batteries by period (1988-2000, 2001-2011). The node size indicates the number of IPCs and the length of link indicates the distance between different IPCs. The network structure of IPC codes shows that IPCs have gathered together since 2001, indicating that the relationships among different technologies have been strengthened and the distances shortened since 2001. Furthermore, IPCs related to new application fields for medium- and large-sized secondary batteries such as solar cells and wind power energy have appeared, and the distance between them and the representative IPC for secondary batteries has become closer since 2001. In other words, with the research and development of medium- and large-sized secondary batteries since 2001, the convergence in secondary batteries has become conspicuous.

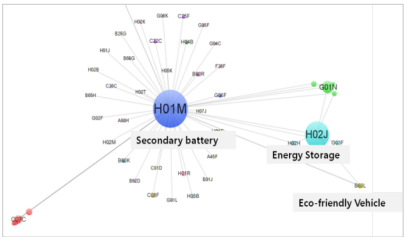

Figure 2. IPC network structure (1988-2000)

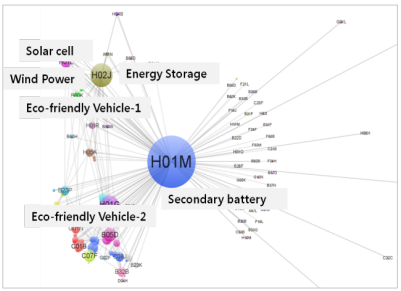

Figure 3. IPC network structure (2001-2011)

Conclusion

In this study, we analysis of convergence trend using patent data of secondary battery. As a result, it can be summarized as follows: First, as passing by year, convergence of secondary battery has increased, especially, in terms of variety and balance. This means that as increasing convergence, various field has merged and increased similarity between fields. Second, as the comparing result of IPC mapping between 1998-2000 and 2001-2011, convergence in secondary batteries is greatly increasing around the medium- and large-sized secondary batteries with the progress of convergence with eco-friendly vehicles, wind power energy, and solar energy and the decreasing distance between technologies. Predicting the convergence trends in secondary batteries has great implications to countries and companies in that they allow us to predict future industries and search for new markets and strategic partners. Furthermore, considering that existing studies used patents in a limited way due to limitations of patent analysis and limited use of time-series patent data so far, the analysis in this study was useful.

Introduction

The Intellectual Property & Science division of Thomson Reuters curates millions of records a year covering scholarly literature (Web of Science®), patents and intellectual property (Derwent World Patent Index®) and life sciences discovery (Cortellis®). These millions of records could be connected through billions of potential relationships, such as that represented by a citing relationship between literature and patents, or by different documents that pertain to similar topics. By building these relationships using machine learning techniques we hope to unite information from different data sources to enable extraction of knowledge such that the whole is greater than the sum of the parts, with minimal human effort required.

However, connecting these documents in a meaningful way is challenging from both a technological perspective as well as a usability perspective. As shown in Figure 1, studying citation patterns among approximately 250,000 articles from the Web of Science, or 1/200 of the full data set, generates a citation graph that, while rich with information, is extremely difficult to use to understand knowledge flows.

This challenge is the focus of our presentation. For this research project, we have created a graph of the topics represented in a subset of the scholarly literature and granted patents, in order to explore ways to constrain the visualization of this topic graph to emphasize usability. While many additional research areas remain, our initial findings suggest that such constraint enables users to easily explore the knowledge graph in way that maximizes understanding while minimizing user effort.

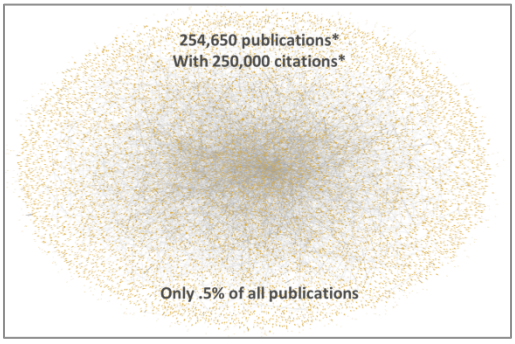

Figure 1. Ball and stick diagram of the citing relationships among a select set of publications from Web of Science®.

Generation of the Topic Graph

We chose to use topic modelling based on the latent dirichlet allocation (LDA) algorithm (Blei, Ng & Jordan, 2003) to generate connections between documents that reflect the shared knowledge among scholarly articles and granted patents. From Web of Science, we selected 27 million publications published since 1990 that had abstracts in English. Our past experience with LDA topic modelling led us to take a hierarchical approach to clustering the documents based on topics. We created a tree of over 1 million topics for the corpus, parceling out the topics into manageable chunks (20 at a glance) which were a better fit for human perception. We also created our own algorithm for applying these topics to patents, demonstrating a flexible, unsupervised technique for combining two distinct content sets. We found that the hierarchy we produced generally exhibited 4 to 5 levels of depth to the terminal nodes or documents.

Understanding the Knowledge Graph

We created the Epiphany tool to more effectively navigate the corpus of scholarly articles, using both browse and search interactions. As shown in Figure 2, the tool supports drill-down (e.g. 2.6 million articles assigned to an algorithm-focused topic; left side green), as well as search, (e.g. 8 topics strongly related to "genetic programming"; right side orange). This allows users to interact with topics and the relevant documents to understand the underlying data.

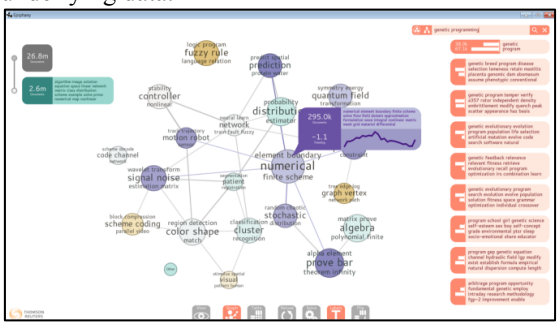

Figure 2. Screenshot of Epiphany tool showing topic clusters matching "genetic programming" search criteria.

Drilling down into the topic details is show in Figure 3. At the top in purple are statistics on the topic itself including the number of documents closely associated with the topic, the most frequent terms and the Trending metric score for the topic.

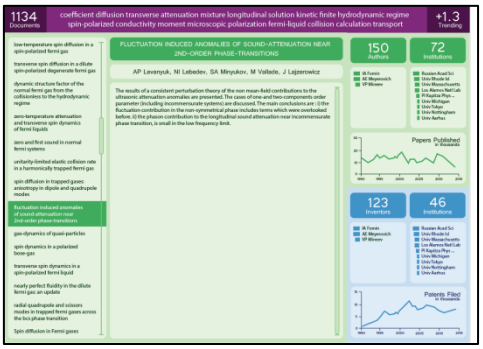

Figure 3. Screenshot of Epiphany tool Topic Details screen.

The right side of the panel contains two statistics sections, one in green for scientific papers and one in blue for patents. The header for each of the sections includes counts of the unique number of authors (or inventors) and unique number of institutions (or assignees) responsible for creation of the documents associated with the topic. Below these counts are a breakdown of the most commonly mentioned authors (inventors) and institutions (assignees). Finally, the bottom part of the statistics section is a graph of the proportion of documents assigned to this topic out of all documents published for each year.

Project Outcomes

The purpose of this research project is to test the application of scalable machine learning techniques to generate a knowledge graph that is accessible to the analyst. Now that we have developed the Epiphany tool, we have begun using it to gather feedback on this approach from a cross section of potential users. We expect to present that feedback at the ISSI2015 conference specifically to answer the question of whether a topic graph of millions of records of scholarly literature and granted patents can indeed be represented in hierarchical structure with a maximum of 20 topics at each level.

Acknowledgments

We acknowledge the support of the Intellectual Property & Science staff and the Data Center Operations staff for improvements made to this research project.

A Sciento-Text Framework for Fine-grained Characterization of the Leading World Institutions in Computer Science Research

Ashraf Uddin[1], Sumit Kumar Banshal[2], Khushboo Singhal[3] and Vivek Kumar Singh[4]

Introduction

This paper describes our experimental framework for a text analysis based fine-grained characterization of leading world institutions in Computer Science (CS) research. Though the present paper uses CS research output data from Web of Science, it can be extended and applied to any discipline and data source. The existing well-known ranking systems, such as ARWU[1],Times Higher Education World University rankings[2], QS World University Rankings[3], SIR[4], Leiden Ranking[5] and Webometrics[6], only present an overall (or for a whole discipline) rank of institutions. These rankings may not be helpful if one is interested in knowing centers of excellence in research in a particular area (say Artificial Intelligence or Software Engineering in CS). Such fine-grained characterization could be very useful for different purposes. Prospective students looking to work in a particular specialized area may look at the fine-grained characterization and select institutions accordingly. Academicians or industry professionals looking for collaboration in a particular area can use the information for selecting potential institutions for collaboration. Similarly, funding agencies and policy making bodies in a country may identify institutions strong in different specialized areas of research. The other advantage of this kind of sciento-text characterization is that it is completely automated, verifiable and does not use any perceptual scores for ranking (such as reputation survey and perceptual scores of QS). Our system thus proposes a framework that uses scientometric data to produce a fine-grained research strength characterization of institutions and to rank them in order of their research excellence in a particular area.

Data Collection

We have demonstrated the working and suitability of our approach for CS domain. We obtained research output data for CS domain for the period 1999 to 2013 indexed in Web of Science (WoS). The data has been collected through an institution-wise search and we collected data for top 100 most productive institutions. A total of 261,154 records were obtained. This data constitutes about 34% of the total worldwide CS domain research output (784,920 records in total) for the period 1999-2013.

Sciento-Text Based Analytical Framework

Since our main objective is to produce a fine-grained characterization and consequential rankings, we had to first assign every research output to one or more particular research specialization. We identified a total of 11 major thematic areas (specializations) in CS domain research output. The 11-classes are based on perusal of data, some recent work (Gupta et al., 2011; Uddin et al., 2015) and recent research trends in the discipline. We processed each record in the data, extracted its 'title', 'author keywords' and 'abstract' fields and obtained the text contents of these fields. For classifying a record (research paper) to belong to one or more of the 11 thematic areas (specializations), a simple Naïve Bayes (NB) text classifier is used. The names of the 11 classes are embedded in table 1. For obtaining training data for the NB classifier, we used a keyword-match strategy for a part of the data. First of all, we created a term-profile for each thematic area (through a manual annotation by three independent annotators). Then, each record is checked for occurrence of any term from the term-profile of the 11 thematic classes, in its 'author keyword', 'title' and 'abstract' fields, in a sequential manner. Those records which get an exact match of keywords with one or more of the 11 thematic classes are assigned that class label. The assigned records then serve as training set for NB classifier, which is then used to classify the remaining unclassified records. In this manner, we classify each record to belong to one or more of the 11 thematic classes. After assigning thematic class to each record, we partitioned the data into 11 groups. Now, we have research output data for each of the major thematic areas (specializations) from the 100 most productive institutions of the world. This information is now used to first produce a plot of the research output landscape of the 100 most productive institutions and then to identify top ranking institutions in all the thematic areas. For ranking we use a simple average of scientometric indicator values for these

institutions, namely TP (Total Papers), TC (Total Citations), ACPP (Average Citations Per Paper), and HiCP (Highly Cited Papers). The absolute scores are first normalized to 0-100 range and then a simple arithmetic average is computed. One such similar ranking work (without thematic areas) is presented in a past literature (Ma et al., 2008).

Results and Conclusion

Our framework produces a detailed characterization of research output along the major research themes by the 100 most productive institutions of the world. The Figure 1 presents a plot of TP and TC values along the 11 research themes for the whole set of 100 institutions. Top ranking institutions identified in all 11 thematic research areas for the given period are listed in table 1. It can be seen that many of the institutions are almost available in each list but with different rank positions. Thus the presented results verify the importance of ranking institutions in different thematic areas rather than doing it for a broader research field. The paper thus presents an interesting framework for fine-grained characterization of leading world institutions and to identify the top ranking institutions in different thematic areas of CS domain. The work is extendable to other disciplines and data sources. The work may benefit more if we would have incorporated the number of researchers and graduate students for better insightful result but unfortunately obtaining those data for each institution is cumbersome and time consuming. See http://www.viveksingh.in/publications/issi2015/appendix.pdf for the full names of institutions.

Influence of *Human Behaviour and the Principle of Least Effort* on library and information science research

Yu-Wei Chang

yuweichang2013@ntu.edu.tw
National Taiwan University, Department of Library and Information Science, No. 1, Roosevelt Rd., Taipei (Taiwan)

Introduction

The principle of least effort (PLE), a concept advanced by the American linguist George Kingsley Zipf, indicates that people complete tasks by choosing the way of least effort among various options (Zipf, 1949). To prove that the PLE is an indication of human nature, Zipf analyzed numerous empirical data collected from various human activities and used mathematical formulae to explain his findings. Zipf explained the PLE in detail in his classic 1949 entitled *Human Behaviour and the Principle of Least Effort: An Introduction to Human Ecology* (HBPLE).

The PLE represents a common human behavior; it may thus be expected that the HBPLE has become visible in various fields and applied to various human activities. HBPLE was also compared with similar theories and was reconceptualized in the field of library and information science (LIS) (Austin, 2001; Gratch, 1990). The LIS publications on PLE have indicated that the concept of the PLE is connected to various topics (Bronstein, 2008; Chrzastowski, 1995, 1999; Kim, 1982; Wang, 2001).

This paper presents partial results of a research project for exploring the interdisciplinary influences of HBPLE. The focuses is this paper are on which concepts and citation functions of HBPLE were cited by authors of LIS articles that were published between 1949 and 2013. We analyzed citation frequency trends and the research topics of citing articles to identify emerging trends in the influence of HBPLE on LIS research and to determine which topics in LIS research have involved applying the concepts in HBPLE. In addition, citation context analysis was used to identify the cited concepts and the citation functions of HBPLE; thus, whether the PLE was the most frequently cited concept in HBPLE and the reasons HBPLE was cited were identified. The results may contribute to the understanding how a classic book on linguistics has influenced LIS research.

Methodology

The bibliographic records of LIS articles citing HBPLE published between 1949 and 2013 were searched and collected from the database Web of Science. The LIS journal candidates had to be included in the subject category of "Information Science and Library Science" in the 2012 Journal Citation Reports and the subject category of "Library and Information Science" in the database provided by Ulrichsweb.com. The publication language of articles had to be English and only research articles were collected. Regarding the search strategy used for collecting the citing articles, search terms were combined in two designated fields: the cited author field and publication year of the cited work.

A citing article could have two or more citation contexts referring to HBPLE. Each in-text citation was defined as an independent citation context. Of the 274 citing articles, three were excluded from the dataset because of citation errors existed between the in-text references and reference lists (two articles), or because full-text articles could not be obtained (one article). Finally, we analyzed 260 citing articles including 310 citation contexts. The records of cited concepts were analyzed and divided into several categories. The classification scheme of citation functions was developed based on a temporary classification scheme devised after reviewing previous studies and was modified during the analysis process. The main topic of each citing article was also coded.

Results

Topics of citing articles

Table 1 shows that HBPLE is more associated with bibliometrics and information retrieval research than are other research topics.

Table 1. Distribution of citing article topics.

Topics	No. of articles	Percentage
Bibliometrics	121	46.5
Information retrieval	64	24.6
Information behavior	24	9.2
Information system	12	4.6
Information service	7	2.7
Collection development	7	2.7
Information science	7	2.7
Knowledge organization	7	2.7
Management	5	1.9
Scholarly communication	3	1.2
Resource allocation	2	0.8
Information literary	1	0.4
Total	260	100.0

Cited concepts and citation functions

Table 2 shows the distribution of 17 cited concepts in 11 citation functions. The most frequently cited concept was "Zipf's law" and was mainly used for comparison with other bibliometric laws, whereas the second-most cited concept, the "PLE," was mainly used as evidence.

Among 201 citation contexts referring to the concept of "Zipf's law," 52.2% used the term "Zipf's law," 28.4% used other terms, such as "Zipfian distribution," "power law," "hypobolic distribution," and "rank-size law," and 19.4% contained a statement to describe or imply the concept of "Zipf's law." Although Zipf's law is a well-known informetrics law, not all authors have used the formal term "Zipf's law" to refer to the law emphasizing the relationship between word rank and word frequency.

Although the concept of the PLE, which is derived from Zipf's law, is the focus of HBPLE, the number of citation contexts referring to the PLE was lower than that referring to "Zipf's law." This result ran counter to our assumption that the number of citation contexts referring to the concept of the PLE would be highest. This implies that citing behavior is complicated and that various motivations for citing publications also affect the visibility of cited publications.

Table 2. Distribution of cited concepts according to citation functions.

Cited concepts	Citation functions											
	E	C	RS	H	R	D	E	F	Exp	T	M	Total
Zipf's law	29	38	30	27	21	22	17	7	4	5	1	201
Principle of least effort	15	13	8	6	11	7	1	4	8	3		76
HBPLE	2		2	2	2		1					9
Word distribution	3	1	1				1					6
Human behavior			2									2
Information cycle	2											2
Publication productivity			1	1								2
Rank				1								1
Sample size							1		1		1	3
Information nonuse			1									1
Language analysis	1											1
Lotka's law						1						1
Richer effect										1		1
R.Y. Chao	1											1
Signal information theory								1				1
Social physics								1				1
Optimization problem								1				1
Total	53	52	45	37	34	30	21	14	13	9	2	310

Note: (1)E: Evidence. (2)C: Comparison. (3)RS: Related studies. (4)H: History. (5) R: Relationship (6)D: Definitions. (7)E: Examples. (8)F: Further reading. (9)Exp: Explanations. (10)T: Terms. (11) M: Methods.

The 17 cited concepts were examined by year. Figure 1 shows large fluctuations for the two concepts of "Zipf's law" and the PLE; opposing trends appear. A "falling after rising" trend was observed in the concept of "Zipf's law" whereas a "rising after falling" trend was evident for the concept of the PLE. These opposing trends have resulted in a decreased difference in the annual percentage between the top two cited concepts. Although a close relationship exists between the PLE and Zipf's law, they exert an evidently different influence.

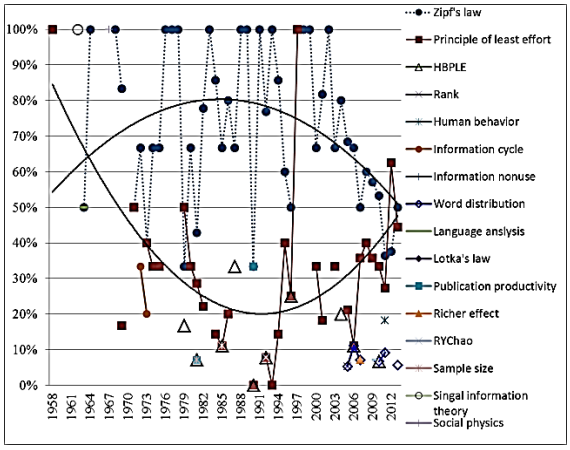

Figure 1. Changes in the percentage of cited concepts by year.

Document type assignment accuracy in citation index data sources

Paul Donner

Introduction

The observed citation counts of publications can be divided by the average of a reference set of similar publications in order to get a relative impact measure. It is customary to define the reference set by publication date, scientific discipline and document type. Different document types (DT) have very different citation distributions, leading to very different results in calculations of indicators when separating reference sets by DT and disregarding this kind of normalization (Sirtes, 2012). Thus, when computing relative impact, the correctness of the assignment of document types to publications is crucial. The correctness of DT assignment in citation indexes has been called into question by studies of van Leeuwen et al. (2007), drawing attention to the treatment of letters and 'research letters' from medical journals as the same type in Web of Science and by Harzing (2003), illustrating how WoS is using some highly questionable assignment criteria. In this contribution DT assignments in WoS (Thomson Reuters, 2013) and Scopus (Elsevier, 2014) by their respective staff are compared to those of the publishers.

Methods and data

For this study data licenced from Thomson Reuters Web of Science and Elsevier Scopus and loaded into SQL databases was used. The databases are part of the infrastructure of the German Competence Centre for Bibliometrics project. Random samples of document identifiers were drawn from the WoS records, stratified by DT as assigned in WoS, restricted to items published in journals. Subsamples of the document types 'article', 'review' and 'letter', as well as of records not assigned to any of those three types (here called 'other') were taken. This follows the convention of distinguishing between 'citable items' and others. They were linked to the Scopus records detailing the same documents using DOIs. It follows that only documents with a DOI are used. In the resulting sample table, only the WoS and Scopus document identifiers and the DOI are saved in a row. The rows were randomized.

To each sample record, bibliographic description data comprised of article title, first author family name and initials, publication year, journal name, volume and issue were queried from the WoS data and saved along with record IDs into a separate table. Student assistants were tasked to search for the article abstract web pages online using the bibliographic information to query Google Scholar and web search. On the individual article web page of the journal, they were instructed to find the officially assigned document type, if specified, and code it as article, letter, review, other or not found. If no type was stated but it was clearly deducible from the abstract or title, this was also accepted.

A sample of 528 publications was analyzed so far, on which the following provisional results are based. For a further 90 publications, no certain DT assignment was possible. Found (true) DT and Scopus/WoS DT were tabulated and classified as true/false positive/negative. From those counts precision and recall were computed for each DT and combined precision and recall as weighted by DT occurrence frequency in the databases. The effect of false DT assignment on publication normalized citation score is measured in percent deviation.

Results

The results depicted in Fig. 1 show that in both citation indexes the accuracy of correct DT assignment is quite poor. WoS gives the correct DT in about 72%, Scopus in about 80% of cases (as weighted by shares of DT in the databases). On average WoS finds about 81% of publications of a given DT while Scopus will return about 73%. Error bars for the DT specific results are 95% posterior probability Bayesian credible intervals for the binomial proportion, using a flat beta prior with both shape parameters set to 1.

These findings necessarily have an adverse effect on the mean field/DT/year specific expected citation rates used as reference standards in obtaining normalized publication level citation scores. To give an idea of the magnitude of this effect, the normalized article citation score (3-year citation window) for publications that were assigned an incorrect DT in WoS was calculated following Waltman et al. (2011).

The differences between incorrect and correct score in percent of the correct score are plotted as a histogram in Fig. 2. Publications with zero citations are not used (N_0=34), since no difference could manifest.

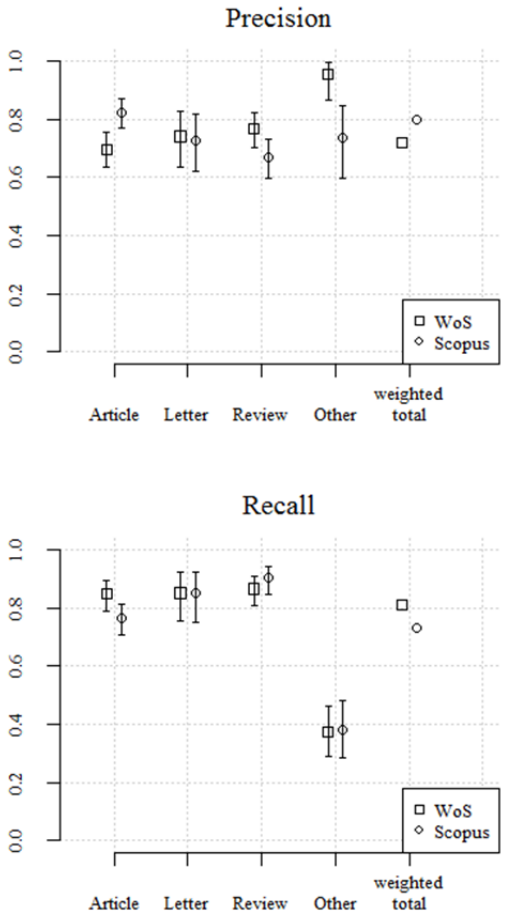

Figure 1. Precision and recall per document type in WoS and Scopus (N=528).

Conclusion

Document type assignment is unreliable in both Web of Science and Scopus and will cause large errors in publications' normalized citation scores and consequently derived indicators such as field-normalized mean citation rate.

Introduction

Citation Indices are very useful tools that were firstly used to help finding articles easily and then, used to provide information about research output. They can be used as indicator to measure research performance, provide information about trends in research and compare and rank the research output of countries, institutes and authors. It is well known that English is the universal language for science and technology and that have resulted in having many citation indices like Web of Science (Formerly ISI) and SCOPUS. It has been reported in the literature that such Indices overlook and hide publications in other languages (van Leeuwen et al., 2001) and that -with other reasons- have resulted in having indices for other languages like Chinese, Portuguese and Korean. Arabic publications is one of the least represented in the scientific community despite its been spoken by more than 200 million which makes it the fifth spoken language in the world (Gordon Jr., 2005). This work investigates the possibility of making a Citation Index for Arabic literature and addresses the challenges associated with that. This is supported by initial implementation of web based Arabic Citation Index (ACI).

Challenges

This section discusses challenges associated with non-English citation indices with special focus on the one dealing with Arabic literature. In order to have citation index for any language, it is very important to make it integrate with other English-based indices. Non-English citation indices should be able to read citations from other indices in order to see how any article or language is impacting the scientific community. This raises some issues of how to make cross languages referencing; if an article written in Chinese has cited other article in Korean, how the Chinese/Korean indices will identify this citation. This problem is not easy to be solved unless if there is a well established standardization for citations which allows identifying any article in any language. Such identifier should be unique across the globe and can be used in every citation. Luckily, Digital Object Identifier (DOI) can be used to serve this purpose while the adoption of using DOI in referencing is not yet being very popular as citation styles are still not considering that as part of the cited article. Having DOI as a compulsory in each citation style makes it easier for articles to be identified, then cited and discovered in citation indices across languages.

Unfortunately, there is no enough information about the scientific contribution written in Arabic. One of the most accurate information we found is the number of periodicals that have ISSN. According to a report by ISSN foundation, in 2012 there were 4489 new periodical record in Arabic which makes it the 26th most registered language in the world. The ISSN records do not represent only scientific journals but it registers any types of periodical. Also, there is a report by Thomson Reuters about the contribution of Arab countries recorded in their databases. The report shows that the number of scientific documents produced in those countries is around 13,574 in 2008 (Adams et al., 2011) where most of the written articles are in English. In fact, there are many journals written in Arabic that are not well recognized in the internet and digital libraries. We have noticed that Arabic scientific journals are still focusing on publishing printed format with no much focus on the electronic version.

In reality, there are some digital libraries that aggregate articles of major Arabic journals and provide electronic versions of such articles. However, having seen some of the main digital libraries and aggregators in Arabic, we still believe such aggregators have some issues as they provide the articles as scanned documents that cannot be indexed automatically. Also, such digital libraries do not have the full bibliographic information like title, abstract, authors, year of publishing, publisher name, volume, ISSN and list of references. Having bibliographic information is vital for building any citation index as they are the raw data to draw the relationship between article and scientific work in term of citations. If bibliographic information is not available for any reason, the PDF electronic version of the article could be used to extract the bibliographic information. Extracting such information from any electronic file can be done with some challenges if the article is saved as text rather than picture. The process becomes very

sophisticated if article is saved as picture where scanning should be done properly. Then Arabic text recognition algorithm should be used to recognize text used when current algorithms in Arabic are not reliable and accuracy rate is low.

Additional challenge in working with Arabic literature is the lack of standardization of the structure and the location of different section in articles. Any software that scan or parse the paper will make some assumptions of the location of the title, authors and abstract. Google scholar software that extract bibliographic information from files directly without having bibliographic information assumes that first line is the title which is written in large font. It has been stated in a study of Arabic journals that "instructions to authors" are generative and are not precise enough (Alkholaifi, 2001). That results in having different interpretations of instructions specially in using referencing style. Variations in formatting could happen at different places of the article, including authors' names, authors' salutation (Dr, professor), availability of abstract and list of references. List of references can be written in mixture of two languages at the same time (Arabic and English) which makes extraction harder. The extraction program should be able to work with different languages at the same time and be able to differentiate between different citing styles.

Extracted Information from article could include errors that can be stored in the index. The program should be aware of such errors and correct them before storing. Detecting errors is not an easy task as it should understand the context of the information. Names sometimes could be recognized as error or misspelled words as some names could have different variations or do not have a direct meaning especially if the name is not Arabic. After the information about any specific word is stored in the index, a query can be done to find a specific article or articles in certain subject. For this reason, search query should be able to consider all possible errors that user might have done when entering the keywords beside the stemming and lemmatization process that happens at indexing phase. In fact, there are several Arabic spelling correction techniques (Manning et al., 2006; Attia et al., 2012; Larkey et al., 2002; Rytting et al., 2011; Shaalan et al., 2012). Using such techniques will be of great important in implementing any Arabic based citation index. These techniques in Arabic are similar to other languages with few differences include the morphological analysis and context understanding of the language where Arabic language is complex in comparison to English.

The proposed system

The overall architecture of the system is shown in Figure 1 where it shows the five main components: Crawler, Parser, Matcher, Database and User Interface. This architecture is inspired by the typical design of search engines as they share similar concepts. One major difference between the two systems is that citation indices use citations as way to rank and measure the impact of an article whereas search engines normally uses the links and other metrics as a way to rank sites and documents.

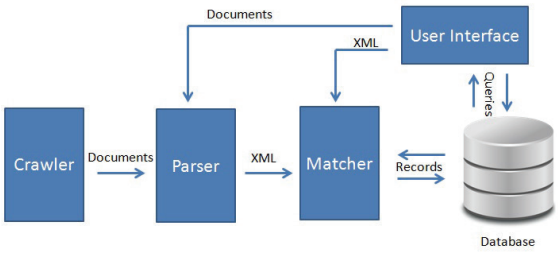

Figure 1. The proposed Architecture of ACI.
